From Figure8 and Figure 9(b), it can be seen that: (1) When reduced wind speed is less than3.77, torsional angular displacement of rectangular section is very small and is decreasing with the increase of time. This illustrates that the total damping of model is positive. (2) When reduced wind speed reaches to 4.0, torsional angular displacement of rectangular section is increasing dramatically with increase of time. What is different from streamlined section is that vibration amplitude of rectangular section keeps a constant value at last. When reduced wind speed continues to increase, the amplitude increases to a greater constant value. This illustrates that the flutter critical wind speed of rectangular section is around 4.0. The rectangular section shows obvious soft flutter characteristic. (3) When flutter occurs, the torsional vibration frequency is 6.52Hz. This frequency is very close to nature torsional vibration frequency. This suggests that flutter style for rectangular section is single-degree torsional flutter.

In Table 2, direct numerical simulation result and wind tunnel test result were compared. It can be seen that direct simulation results are in good agreement with wind tunnel test results. This shows that the direct simulation method used in present paper is correct.

Table2. Compare of wind tunnel test result and direct simulation result

section type	flutter stability	wind tunnel test	direct simulation
rectangular section	non dimensional flutter critical wind speed	4.00	3.77~4.00
	flutter frequency (Hz)	6.63	6.52
streamlined section	non dimensional flutter critical wind speed	10.67	11.51~11.74
	flutter frequency (Hz)	3.99	3.10

5 CONCLUSION

In present paper, a direct simulation method for flutter stability of bridge deck was developed based on CFD software Fluent. Flutter stability of two representative sections, rectangular section and streamlined section, was simulated by using this method. The validity of the simulation method was verified by comparison of simulation result and wind tunnel test result. In further study, the flutter stability of bridge deck with more complex geometry, such as Π-shaped section, separate twin box section and so on, will be calculated using this simulation method.

ABSTRACT: This paper presents Computational Fluid Dynamics simulations of two existing bridges which exhibited vortex-induced vertical vibrations: Alconétar upper steel arch bridge (2006, Cáceres, Spain, 220 m main span) and the Volgograd Bridge (2009, Volgograd, Russia, 155 m main span). The Vortex Particle Method is used for the analysis.

KEYWORDS: Aerodynamics, Vortex shedding, Vibration, CFD, Bridge, Volgograd, Alconétar

1 INTRODUCTION

Vortex shedding from bridge cross sections can lead to significant aerodynamic excitation of the structure. This is a limited amplitude phenomenon, which however can be critical to the serviceability of the bridge or lead to fatigue damage. For structures sensitive to vortex shedding an adequately realistic assessment of the problem is required.

Traditional wind tunnel testing of all alternatives is often dismissed in early design stages unless in the case of large-scale or other high-profile bridge projects. Various analytical models exist for assessing vortex-induced vibrations (VIV), however these are of limited use for complex bridge deck geometries. Numerical simulations of the fluid flow provide a further method for modelling the physical problem. Such methods are gaining popularity in the field of civil engineering because of their growing reliability provided by the implementation of new computational methods and the availability of more powerful computational resources.

2 GENERAL APPROACH TO THE AERODYNAMIC PROBLEM

2.1 *Vortex shedding phenomenon*

Dynamic actions due to wind flow are usually associated with long span bridges such as suspension and cable stayed bridges. The design optimization has resulted in a reduction of the cross section depth to decrease its weight and static wind loads. However, this also brings increased flexibility and the likelihood of dynamic effects at lower wind speeds if the geometry of the cross section is not adequate. In particular, a characteristic of the aerodynamic problems in the range of low wind speeds is that of the vortex induced vibrations (VIV). When the wind impinges on a body with sharp edges, a shear layer separation is produced resulting in vortical structures, which are displaced downstream, as the air is a viscous fluid. These vortical structures induce differences in pressure between the upper and lower body surface, which result in aerodynamic forces. If the frequency of generation is near the natural frequency of the structure, a phenomenon of resonance or coupling between the two frequencies occurs, initiating a process whose vibrational amplitudes, although limited, can have serious consequences by affecting serviceability conditions, or even be the main cause of its long-term decline and decrease their service life.

$$St = \frac{fs\,D}{U} \tag{1}$$

where St=Strouhal number; f_s=vortex shedding frequency; D=cross-sectional dimension perpendicular to the wind direction.

The Strouhal number relates the vortex shedding frequency with the incident wind speed, and depends mainly on the geometry of the section and the Reynolds number. In bridge aerodynamics, the latter parameter is usually always greater than 10^5, so the Strouhal number is not strongly conditioned by the Reynolds number. Furthermore, the shear layer is controlled by the sharp edges of the section, and not by the fluid flow regime [1].

The VIVs are associated with a single mode of vibration, so this is a decoupled phenomenon. It can result in vertical movement or rotations, depending on which natural frequency is being excited. The cases included in this study correspond to vertical vibrations, because bridges with high torsional stiffness have higher torsional natural frequencies, thus implying wind speeds well above the normal values. Nevertheless, there are cases, like the Bay Bridge in Tokyo, that have suffered vibrations associated with vortex shedding and whose primary mode of torsion was close to vertical modes [2].

The primary goal is the identification of the critical wind speed which gives rise to resonance phenomena between the vortices generated and the natural frequency of the bridge. Once the Strouhal number associated with a given geometry and the vortex shedding frequency matches the natural frequency, the critical velocity is estimated by the following expression:

$$fs \approx fn \quad \Rightarrow \quad v_{crit} = \frac{fs\ D}{St} \tag{2}$$

where fs=vortex shedding frequency; fn=natural vibration frequency of the bridge; v_{crit}=critical wind speed; D=cross-sectional dimension perpendicular to the wind direction; St=Strouhal number.

The study of fluid-structure interaction tends to classify the VIV phenomenon as an instability induced by the fluid (Instability Induced Excitation, IIE) [1], where the influence of movement of the structure in the steady state over the aerodynamic forces responsible for this movement is irrelevant, partly because these vibrations are of limited amplitude. At the time when the vibrations exceed a certain maximum amplitude (usually given as limit cross-sectional transversal dimension), the process of generation and shed of vortex along the wake becomes unstable causing the excitatory action to disappear. The same happens if the wind speed generates a shedding frequency outside the interval of resonance of the bridge natural frequency (f_n), which traditionally is considered limited between the values of $0.8f_n$ and $1.2f_n$.

The resonance phenomena which gives rise to VIV can be avoided by furthering the vortex shedding frequency from to the considered natural frequency. This last parameter is determined by its mass and mechanical stiffness, in turn conditioned by resistant and constructive criteria, so it seems more logical to act on the cross section. The key is to design an efficient geometry so that the resonant phenomenon can only occur with high wind speeds that fall outside the range of average wind speeds of where the bridge stands. The VIV only takes place when the wind regime is more or less regular and average speed remains substantially constant for a given time, usually greater than 20-30 minutes.

To simplify the analysis, the majority of the models consider that the aerodynamic forces act over the static section, and the parameters that identify the phenomenon, e.g. Strouhal number and force coefficients, are obtained from wind tunnel static testing. Simple or regular geometries values (circle, square, rectangle, U-sections) are reflected in various standards and publications, such as the Eurocode (EN 1991 1-4), the British Design Manual for Roads & Bridges (BS 49/01) and the Canadian Highway Bridge Design Code (CAN/CSA-S6-06) . Different expressions to obtain the maximum vibration amplitude of the oscillations associated with VIV are also includ-

ed. Nevertheless, the parameters for sections of irregular or complex geometry are not included, and their estimation from static tests turns more complicated because several vortex shedding frequencies converge and it is not possible to distinguish which one is the main one.

This fact is also evident in sections whose aspect ratio (B/D) is greater than 2.0, since the evolution pattern of the wake does not obey the classical Von Karman vortex street (KV). Vortical structures generated in leading edge are not able to pass over the entire width of the section without causing its reattachment on its surface, resulting in a release pattern known as impinging leading edge vortex (ILEV) [1,3]. It has been found that the regularity of vortical structures shedding in the ILEV pattern are more affected by the movement of the section configuration than in the KV pattern. The static consideration of the aerodynamic forces is less accurate, although it remains valid. Nevertheless, the critical speed should be determined by other tests rather than static tests. The phenomenon of vortex induced vibrations is still regarded as an induced instability excitation (IIE), according to the classification criteria offered by Rockwell and Naudascher [1], but the change in the shedding pattern as a result of the oscillations of the section in its interaction with the wind in the range of resonant frequencies, identified as movement-induced excitation (MIE) [1] can not be ignored.

For regular sections, the Strouhal number is very similar to the reduced frequency corresponding to the moving section. However, in the cases of asymmetric, twin tandem, multibox and other complex sections, this does not hold true. Consequently, it is more accurate to use the reduced frequency parameter, f_{red}, to refer to the relationship between the vortex shedding frequency and incident wind speed on any type of wind tunnel test, being the Strouhal number equal to the value of reduced frequency referred only to static wind tunnel tests.

$$f_{s,red} = \frac{fs\,D}{U} \qquad Static\ tests \Rightarrow f_{red} \equiv St \tag{3}$$

In order to avoid this drawback, forced wind tunnel tests can be addressed, assigning a frequency oscillation similar to their natural frequency and moderate amplitude of vibration. A value between 0.1D and 0.2D (D, cross-sectional transversal dimension) is often used because the maximum amplitudes of oscillation of the phenomena of VIV on bridges studied stand close to these values.

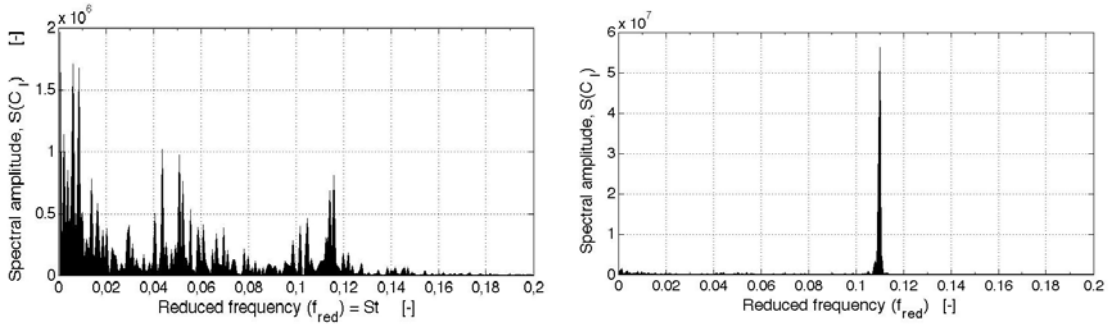

Figure 1. Spectral amplitudes of lift coefficient for a static numerical simulation (left) and a dynamic (right).

It is also possible to achieve dynamic wind tunnel tests, assigning the model the corresponding mechanical properties of stiffness and mass, thus representing the real bridge for its scale, by the progressive increase in wind speed up to the point of resonance and critical speed, where the models vibrate regularly. Following increasing wind speed, the resonance disappears and the models cease to experience these vibrations.

2.2 *Numerical simulations*

In this study several simulations of flow past bodies have been performed using a technique based on the Vortex-In-Cell (VIC) method. This is a hybrid particle-mesh algorithm that uses a discretization of the vorticity field and particles through a Lagrangian scheme for solving the Navier-Stokes equations describing fluid motion, while allowing high-resolving simulations resolution with a reasonable computational cost. To model the diffusion term in the Navier-Stokes expression, the random walk method is applied, which has been very successful in some fields of engineering, such as bridge aerodynamics. A comprehensive description of the simulation method can be found in [4] and in previous publications referenced in the mentioned document.

The use of numerical simulation methods are useful to achieve optimal geometric design of the cross section in those bridges that may be subjected to aerodynamic problems during its construction and service. It replaces or reduces aerodynamic tests necessary to verify the performance of several alternatives, thereby reducing cost and time, making it possible to extend its application to minor bridges that would not initially be tested. Although aerodynamic testing is essential for bridges with special features, the results can be compared with numerical simulations that can be carried out simultaneously.

This paper presents a computational analysis of the phenomenon of VIV in real bridges that have experienced an episode of vibrations of this type, and a comparison of critical speed values of wind and amplitudes of oscillation recorded.

3 THE VOLGOGRAD BRIDGE

3.1 *Outline of the vibration episode*

On May 20th, 2010, the new bridge over the Volga River in the city of Volgograd was closed to traffic because it was swinging dangerously due to the wind regime existing in the area. According to meteorological data, average speeds between 11.6 m/s and 15.6 m/s were recorded with a direction deviated 7 degrees from the normal direction to the longitudinal axis of the bridge. This suggested that it could be an episode of vertical vortex induced vibrations; there are other conditions surrounding the phenomenon that lead to the same hypothesis:

- Relatively low average wind speeds and constant regime with little turbulence, caused by the orography. The great width of the Volga River helps direct the wind along the smooth surface provided by the water.
- The oscillation frequency coincides with the fundamental frequency of vertical vibration of the bridge, indicating that there was a phenomenon of resonance or coupling between these frequencies associated to the vortex shedding.
- The amplitudes of vibration were limited (not exceeding one meter) according to the observations made by people who witnessed the phenomenon. The image recordings made during the development of the phenomenon were used to estimate the vibration amplitudes more accurately, reaching around 65-70 cm.

Initially, there was speculation on the fact that the vibrations could be caused by a moderate earthquake, alone or in coalition with the wind, although this hypothesis was discarded because an earthquake would not correspond to the development of the vibrations. The board swung slowly and regularly for about four hours, while the oscillations due to earthquakes are more irregular (incorporating various frequencies) and generally only last for so long.

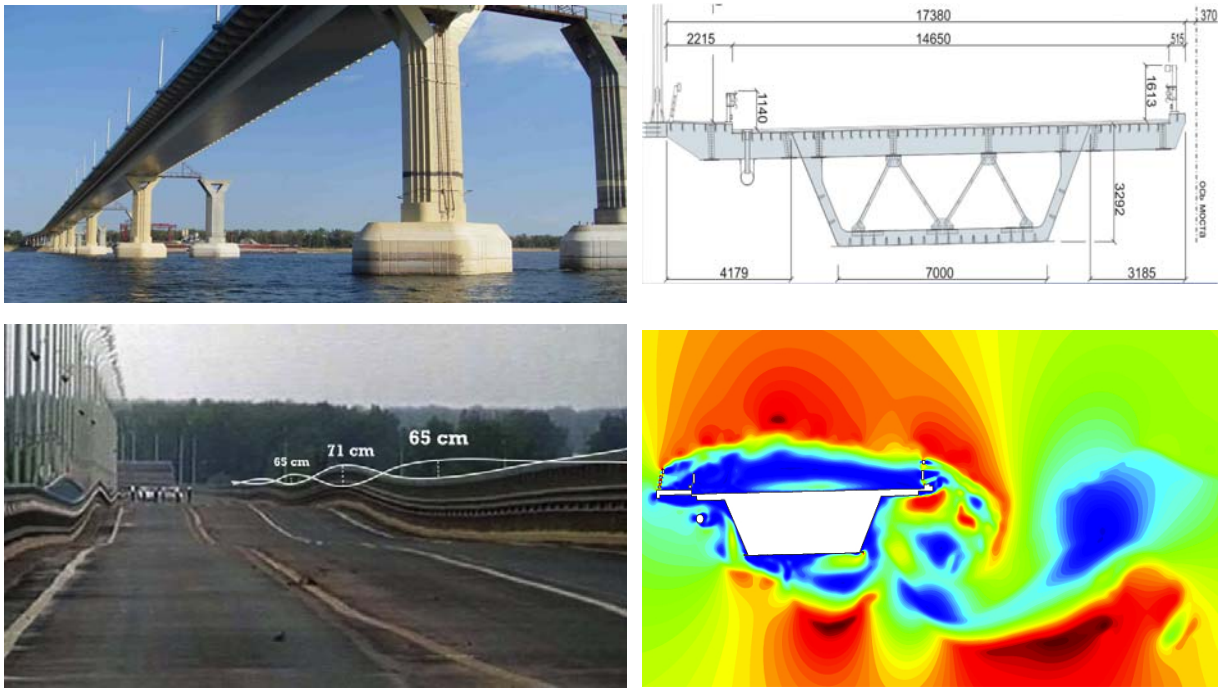

Figure 2. Volgograd Bridge. Top, left: General view. Top, right: cross-section dimensions of bridge deck. Bottom, left: video snapshot showing the vortex-induced oscillations episode (20th, May, 2010). Bottom, right: Velocity field visualization frame, obtained from the numerical simulation carried out.

A special commission was created to examine the state of the structure to check for damage that could keep the bridge from safely reopening. The bridge was reopened to pedestrians and passenger vehicle traffic five days later. However, traffic from heavy vehicles was not allowed until August 25th, 2010, once the bridge was examined in detail and no external or internal damage in the structure was found. After phenomenon experienced by the bridge, a monitoring system along the bridge to control its possible movements, and a weather station for the continued observance of the weather conditions in the area were implemented. An intervention plan was also designed so that emergency departments could act quickly if the phenomenon recurred. At the same time, wind tunnel tests on sectional models were carried out in Central Aero-Hydrodynamics Institute (TsAGI), near Moscow, to study the problem in detail. In recent years, a number of cable-stayed and girder bridges over rivers with wide channels that run through vast plains have been built in Russia. The aerodynamic problems observed on the bridge of Volgograd have focused attention on the remaining bridges of similar properties that may be subjected to the same problems. On March 2011, the bridge over the Volga River near Kineshma became the sixteenth bridge tested at the TsAGI wind tunnels.

3.2 *Numerical simulations*

The bridge, inaugurated in October 2009, is the only structure to cross over the Volga in the region, in addition to the existing dam on the Volga Hydroelectric Power Station, near the city. It has a total length of 7110 m, including the flyovers. The middle section overpasses the Volga and is composed of seven spans of 155 m length each. The cross section is a steel box of 10.02 m wide, with an upper and lower width of 7.00 m; 7.44 m if the overall width, which forms the base, is taken into account. The deck has two flies over the box on both sides of 4.179 m and

3.185 m, so that the total bridge width is 17.38 m. It has two traffic lanes separated by a barrier free median, and a strip for pedestrian traffic. There are two guardrails at each along each side of the bridge and an additional one to separate the vehicle traffic from pedestrians. The deck has an inclination of 1.1 degrees counter-clockwise about its longitudinal axis, so that its horizontal dimension parallels the wind direction at 17.25 m.

Figure 3. Flow visualization through vortex streaks and effective dimensions of cross-section with bars

Figure 3 shows the interaction of the fluid stream with the section through the vortex streaks generated by the simulation code. During the interaction process, three points of particular importance can be identified: (1) the detachment of the shear layer, which reattaches again on the lower surface, resulting in the pattern known as ILEV; (2) the actual detachment of the fluid shear layer. On the upper surface, the interaction between the fluid and the structure is similar, generating a release ILEV type pattern that is maintained along the entire width; (3) the final take-off of the fluid stream at the top of the section and its junction with the bottom which will cause a series of vortex structures of certain regularity throughout the wake downstream. It somehow determines the cyclic variations of pressure on the two surfaces of the section and therefore the aerodynamic forces acting on it.

The Strouhal number defines the frequency of generation of said vortical structures, and hence the frequency of variation of the aerodynamic forces responsible for the vibrations. The fluid-structure interaction mechanism in sections of complex geometry can be likened to what occurs in a rectangular section of dimensions B* x D*. To do this, these parameters must first be identified. B* represents the distance between the point of origin of the interaction of the surface of shorter length (1), which will condition the process and the final release point of the shear layer (2), that will subsequently converge with the other part of the fluid flow after passing the obstacle represented by the cross section. D* is the dimension perpendicular to the flow direction, causing the separation of the fluid flow. Figure 4 represents the Strouhal number against the B/D for rectangular sections, according to results of several investigators collected by Deniz & Staubli [3]. Results obtained by numerical simulation (Vortex Particle Method, VPM) of static tests have been added. The two different lines obtained for relations B/D between 2.0 and 5.0 confirm the coexistence of two patterns of evolution: the pure ILEV type, which identifies the lowest values, and another pattern closer to the KV type, where the shear layer reattachment on the surface of the body occurs alternately, resulting in higher values of the Strouhal number. When the section vibrates, the latter is favoured.

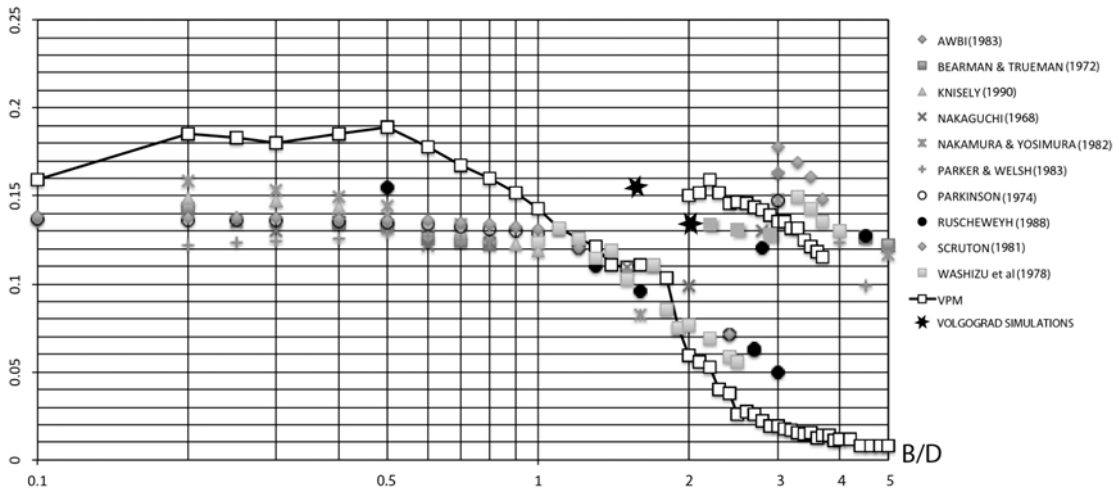

Figure 4. Strouhal number as a function of the side ratio, B/D, after [2] with present results added

Furthermore, higher Strouhal numbers correspond to lower wind speeds, and therefore have greater probability of occurrence. For B/D ratios exceeding 2.0, the lower Strouhal numbers are less than 0.06, which would require an average wind speeds too high for the associated release pattern to be given in most of the bridge sections. The Reynolds number corresponding to the numerical simulations is of $2.24 \cdot 10^6$. Although its influence on the Strouhal number is not as significant in bluff bodies, there can be some slight variation.

To analyse the VIV episode suffered by the Volgograd Bridge, two types of two-dimensional numerical simulations have been performed, using the cross section of the bridge with barriers and without them. The contours of both have been identified, which represent the surface exposed to the air stream and define a simple degree of freedom model where the only motion possible is vertical displacement. The natural frequency of the structure associated with the first vertical vibration mode is 0.42 Hz, and the mode shape is defined as a sinusoidal function, with the maximum in the centre span. The damping ratio relative to critical used is ζ=0.003, a typical value for steel bridges. The corresponding sectional mass is 2,500 kg/m, its effective width B* is 17.25 m. The effective vertical dimension D* is 3.61 m for the section without barriers, and 4.82 m for the section with barriers, being the B*/D* ratio of 2.06 and 1.54. Strouhal numbers obtained from static tests are 0.133 and 0.155, respectively. Both are represented in figure 4 and keep some consistency with the other values showed.

Figure 5 shows the evolution of the root mean square values (RMS) of the vibration amplitude as a function of the reduced wind speed of the two cases studied. To achieve a better comparison between them, the vertical dimension D of 3.61m in both cases has been considered, so that the Strouhal number of the barrier section is 0.116 instead of 0.155. The VIV takes place in the section with barriers in the low wind speed range of 6.60 and 9.60, corresponding to a wind speed of 10.0 m/s and 14.50 m/s. The critical speed is estimated around 13.0 m/s, the point where the structure reaches its maximum semi-amplitude vibration. This speed is included in the range of average speeds measured in the area between 11.6 m/s and 15.6m/s. The RMS value is estimated at 0.32 m, while the maximum value registered in the simulation is of 0.53 m. The temporal evolution of lift coefficient for this case is shown in figure 5. To determine the RMS value, the temporal force register has been filtered using a frequency range between and $1.1f_s$ $0.9f_s$, being f_s vortex shedding frequency calculated through the Fourier transform. Its value is RMS,Cl=0.55.

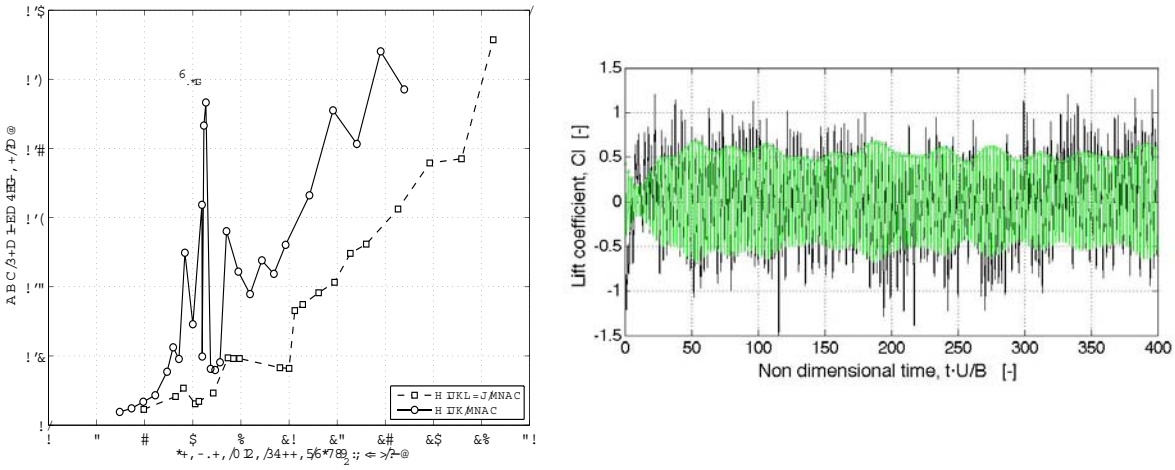

Figure 5. RMS semi-amplitude corresponding to the cases modeled (left), and lift coefficient history of the section with bars (right)

These figures are an accurate estimation of the values recorded during the vibration episode in May 2010, oscillations with a maximum amplitude of 0.71 m (0.36 m semi-amplitude), were reached. From 14.50 m/s, the amplitudes of vibration progressively increases as the wind speed increases, thus indicating the starting of another aerodynamic effect such as galloping, which leads to the dynamic instability of the structure if a certain speed is exceeded.

In the case of simulation of the section without barriers, the presence of VIV phenomenon is not detected as in the previous case, but a tendency to suffer obvious galloping effects as speed increases it is also checked. An interval in the curve where there is a sharper increase in the amplitude of vibration (between the values of reduced wind speed of 6.85 and 10.0) can be identified as a possible VIV effect.

A summary of previous results is shown in Table 1.

Table 1. Summary of results: Volgograd

2D model	B	D	B*	D*	B*/D*	St (D*)	vcrit	MAX (y)	RMS(y)	RMS(Cl)	Cd
	m	m	m	m	-	-	-	m	m	-	-
without bars	17.25	3.61	7.44	3.61	2.06	0.133	11.3	0.26	0.097	0.11	1.13
with bars	17.25	4.83	7.44	4.83	1.54	0.116	12.9	0.53	0.32	0.55	1.46

where B=section width; D=section depth; B*=section effective width; D=section effective depth; St=Strouhal number (static sectional simulation); vcrit=critical wind speed; MAX (y)=maximum semi-amplitude of oscillation; RMS(y)=root mean square referred to the semi-amplitude of oscillation; RMS(Cl)=root mean square of lift coefficient, $Cl=Fl/(1/2\rho U^2 D)$, with Fl=lift force; U=wind speed, ρ=air density, and D=3.61m for both cases; $Cd=Fd/(1/2\rho U^2 B)$, drag coefficient, with Fd=drag force.

The code employed also allows a numerical simulation based on a multimodal quasi-3D scheme. It is possible to discretize the total length of the bridge through slices of a given length and assign geometric and mechanical characteristics associated with each mode (frequency, mass, damping and mode shape). The fluid-structure interaction is developed in each slice independently of the others, i.e., there is no aerodynamic interference between the different slices. However, the movements of each slice depend on each other because there is a

structural connection between them, and this in turn influences the process of interaction with the fluid flow. This additional tool allows for a more detailed study of the interaction problem, and is especially useful when the bridge has variable sections along its longitudinal axis, as its geometry greatly influences the generation and development of the vortices during interaction. The correlation between oscillations of each of the sections will be smaller if the coupling phenomenon occurs at different rates in each of them, and therefore the vibration amplitudes will in principle be lower.

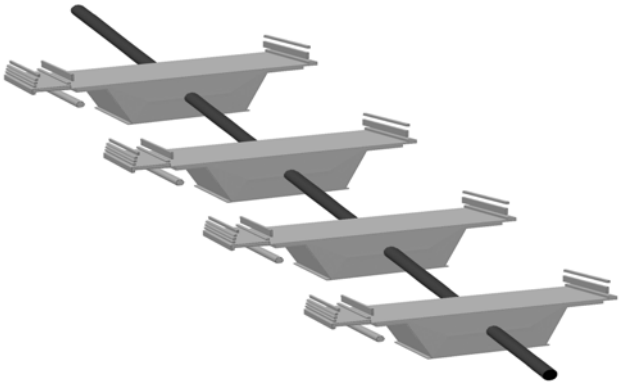

Figure 6. Draft of the quasi-3D scheme of the Volgograd Bridge composed by several slices

The Volgograd Bridge has a constant section and the slices considered in the quasi-3D scheme are closely correlated, because the lock-in occurs at the same speed throughout them. In this case only the simulation of the section with barriers has been carried out. The total length of the central span of 155 metres is discretized into 16 slices, 9 m each except those located at the boundaries, which are of 10 m. The maximum semi-amplitude vibration is 0.41 m, and the RMS value is 0.30 m, results close to the two-dimensional case; RMS value of lift coefficient is 0.54.

4 ALCONÉTAR BRIDGE

4.1 *Outline of the vibration episode*

The oscillations of Alconétar Bridge due to vortex shedding took place on January 2006 during the bridge erection, once the arch was completed. Two rectangular variable depth boxes in tandem arrangement braced by X-trusses formed each of the two arches. The maximum amplitude reached was 80 cm on the vertical axis and seriously threatened the structural stability of the arch [5,6]. The braces managed to resist the wind action. The box depth corresponding to the maximum amplitude value is D=2.41 m, the box width is B=1.2m and the total width is W=7.74 m, giving a side ratio of W/D = 3.21. Measured wind speeds during the Alconétar Bridge vibration episode did not exceed 30 km/h, so the corresponding reduced frequency was close to 0.21, typical from a H-shaped section with the same side ratio. [3]. The modal mass is 1,133 kg/m and the damping ratio of critical, 0.0048.

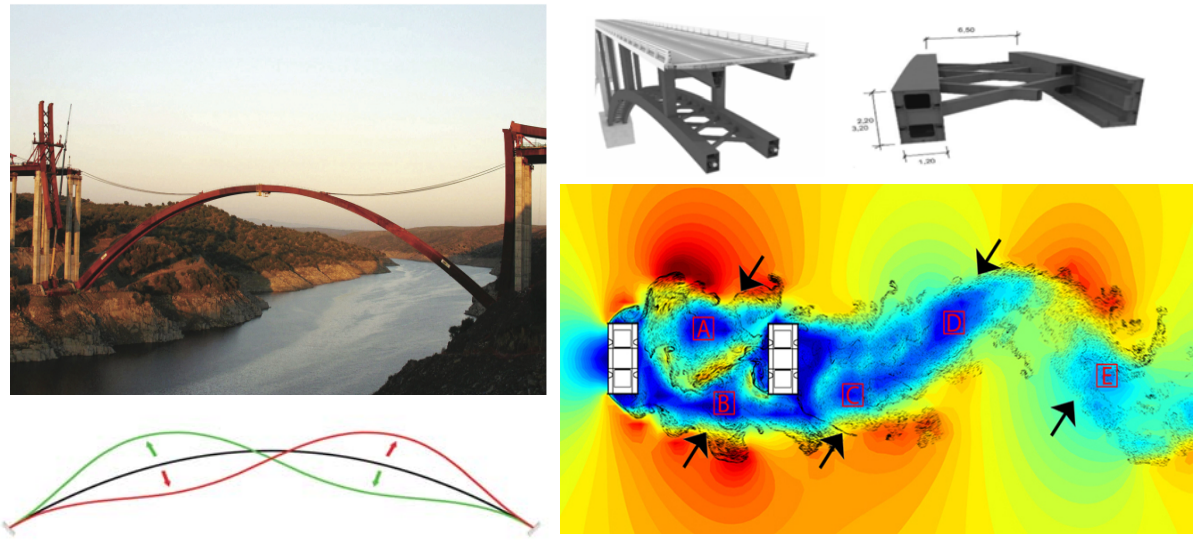

Figure 7. Alconétar Bridge. Top, left: the bridge under erection. Bottom, left: mode shape of the first vertical vibration mode of the single arch. Top, right: 3D bridge scheme, with main dimensions. Bottom, right: velocity field visualization from the simulation.

4.2 *Numerical simulations*

Two cross-section variants are studied for Alconétar Bridge: the twin steel box section with two little rectangles in the middle that represents the braces, and the cross-section without the influence of these elements. To identify the lock-in effects and thus the vortex-shedding phenomenon, a certain range of wind speeds are employed in the numerical simulation process. The Alconétar Bridge does not have a conventional H-section because the X-trusses connecting the twin boxes do not occupy the whole space between them. It can be thought that the vortex shedding mechanism obeys a tandem configuration, as previously seen, having a spacing ratio of (W-2B)/D = 2.21.

The main results are collected in Table 2.

Table 2. Summary of results: Alconétar

2D model	B	D	B*	D*	B*/D*	St (D*)	vcrit	MAX (y)	RMS(y)	RMS(Cl)	Cd
	m	m	m	m	-	-	-	m	m	-	-
without braces	7.74	2.41	1.20	2.41	0.5	0.140	11.81	0.43	0.29	1.4- 1.3	2.4-0.3
with braces	7.74	2.41	1.20	2.41	0.5	0.140	11.81	0.34	0.18	0.85-1.1	1.8-0.2

where B=section width; D=section depth; B*=section effective width (one box); D=section effective depth (one box); St=Strouhal number (static sectional simulation); vcrit=critical wind speed; MAX (y)=maximum semi-amplitude of oscillation; RMS(y)=root mean square referred to the semi-amplitude of oscillation; RMS(Cl)=root mean square of lift coefficient, $Cl=Fl/(1/2\rho U^2 D^*)$, with Fl=lift force; U=wind speed, ρ=air density, and D=2.41m; $Cd=Fd/(1/2\rho U^2 B^*)$, drag coefficient, with Fd=drag force. The dual values of RMS(Cl) and Cd correspond to the upstream section and the downstream section, respectively.

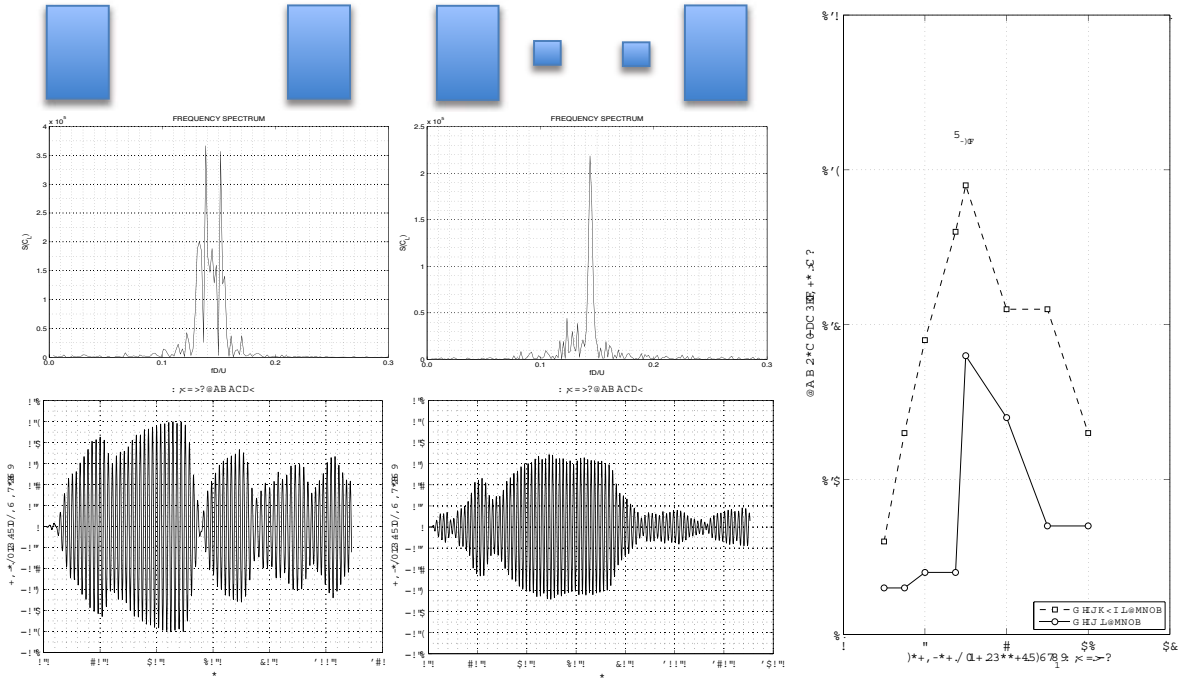

Figure 8. Comparison of frequency spectrum and vertical displacements of the two cross-section variants (with and without braces) (left); semi-amplitudes corresponding to these numerical simulations (right)

According to the results of the simulations the reduced frequency is 0.14 for both sections (without and with braces), and hence the estimated critical wind speed is:

$$!!!\ "\ !\quad !"\ !\quad !\ !!\ "\ !!\ "\ !!!!!\overset{!}{\Rightarrow}\ !!!!!\ !"\#\$\ !\ \frac{!\ "\ !!}{!\ !\ "\#}\ !\ \frac{!\ !!\ "\ !!\ !!\ "}{!\ !!\ "}\ !\quad !\ "\ !!\ !\quad !\ !\quad !\quad !\ "\ !!\ !\ "\quad !\ ! \tag{3}$$

Figure 7 c) shows the simulation of vortex shedding process in a rectangular prism with a side ratio B/D = 0.5, and its interaction with another twin section situated downstream. The vortex pattern for both sections corresponds to the KV. For a specific spacing ratio between 2.5D and 3.0D, vortices shed from upstream prism coalesce with those being formed downstream, thus leading to a resonance phenomenon. However, some arguments suggest that the vortex shedding pattern is closer to the H-section rather than the tandem configuration:

- The braces partially occupy the gap between the two boxes, interceding in the vortices convection process and thus hindering the coalescence phenomenon. In addition to that, the varying depth of the boxes results in different shedding frequencies, which are not excited by the same wind speed.
- The critical wind speed below 30 km/h, as measured during the excitation episode, does not correspond to the critical wind speed estimated for the tandem configuration.
- Wind tunnel sectional tests were carried out resulting in a measured Strouhal number of 0.15, closer to that of the tandem configuration. However, it is necessary to point out that three-dimensional effects must be taken into account: the fact that the wind speed is not homogeneous along its axis, the varying depth (D = 3.2 m in abutments and D=2.2 m in the central point) and the bracing configuration can greatly influence the resonance phenomenon.

The more homogeneous the bridge is, the more representative the sectional wind tunnel tests are. The specifications mentioned previously cause the vortex shedding mechanism to have a significant three-dimensional component, which must be taken into account. As a consequence, a full-bridge wind tunnel test should be conducted to consider all of these properties and experimentally corroborate the above results arisen.

5 COUNTERMEASURES

5.1 *Volgograd Bridge*

Wind tunnel sectional model tests conducted confirmed that the oscillations suffered by the Volgograd Bridge were due to a problem of aerodynamic resonance, and it was decided to place three sets of dynamic dampers in its three main spans. Technical work began in mid-summer 2011 and was completed in October. The total cost was about 112 million roubles (3.8 billion US dollars), accounting for 4.5% of total budget of the bridge (2,500 million roubles, 84 million US dollars). The traffic was not interrupted during the assembly process.

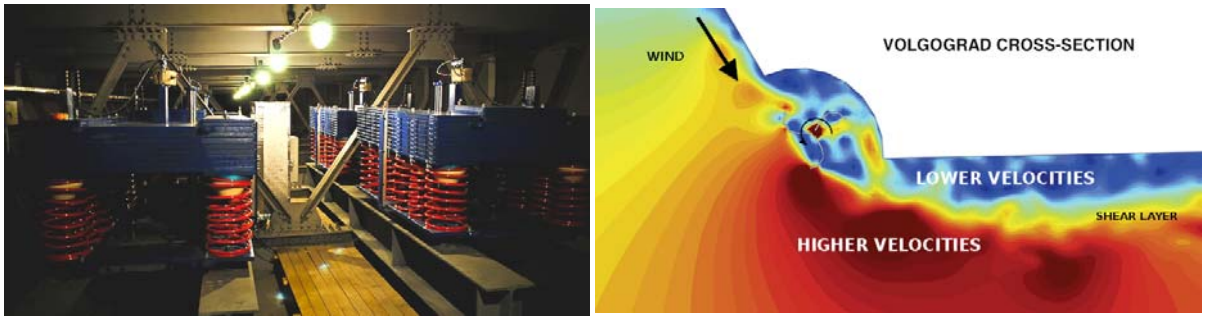

Figure 9. Damping system assembled inside Volgograd Bridge (left). Improvement of bridge behavior against VIV effects by adding a Savonius type turbine on the lower corner of the cross-section (right)

No major vibrations since the dampers were added have been detected. A similar solution was adopted in Niterói Bridge in 2004 to end the nagging vibrations that were given from time to time. [7] Volgograd Bridge has thus become the first continuous deck bridge in Russia to adopt this solution. The damper system becomes an expensive alternative to reduce these effects and avoid the lock-in phenomenon with other natural frequencies that could be excited. An adequate aerodynamic study of the section prior to its erection could have raised the choice of a more efficient geometry against the effects of VIV. Figure 9 shows an example of an alternative section tested using the simulation code in which a small Savonius type turbine is added to the lower corner of the box section.

This configuration would modify the vortex-shedding pattern allowing the maximum amplitude to decrease to a half of the amplitude associated to the standard section (0.20 m). Moreover, this solution would have permitted the small-scale energy generation that could contribute to the bridge illumination and other small necessities related to its maintenance. It is also planned to build a second bridge deck next to the current in the future, so its influence over the aerodynamic actions have also been studied using the simulation code. As shown in Figure 10, the location of a second section reduces the amplitude of vibration of the initial section.

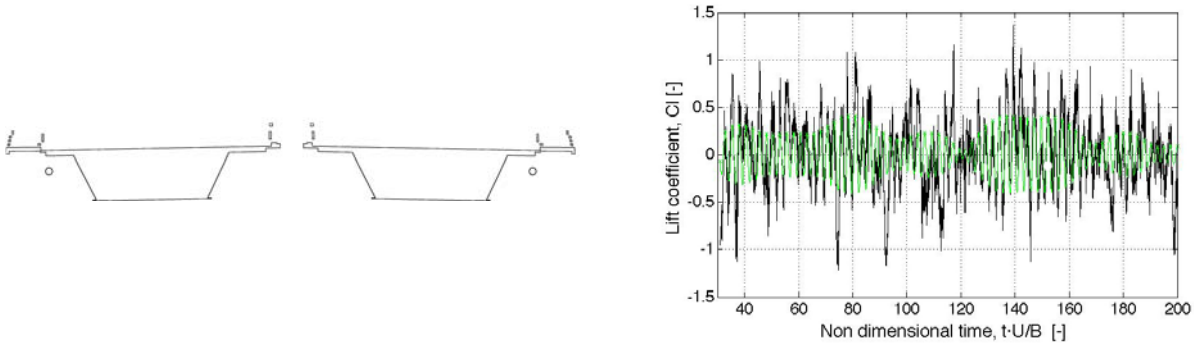

Figure 10. Double deck configuration of Volgograd Bridge (left) and lift its lift coefficient evolution (right)

For a critical wind speed of 13m/s, the RMS amplitude is 0.14 m while it was 0.32 m for the standard section. The lift coefficient is 0.24, not considering the contribution of the lift forces of the right section (downstream).

5.2 *Alconétar Bridge*

A number of deflectors were welded along the section arch in order to modify its geometry and, consequently, avoid the lock-in phenomenon. After placing the two upper decks above the arches, its global stiffness, mass and geometry were modified so that the Bridge is safe from suffering any VIV problem.

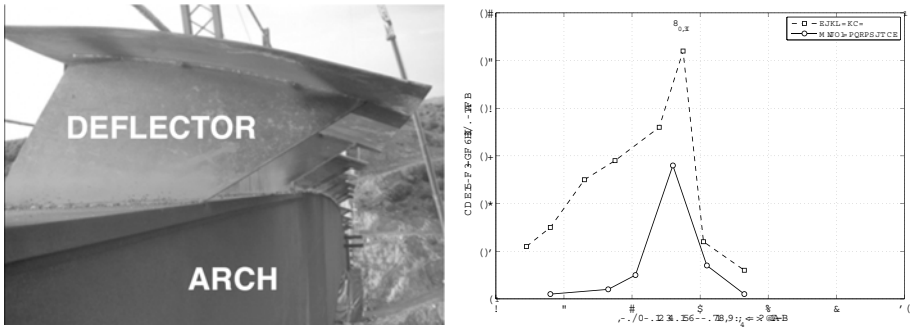

Figure 11. Deflectors added to Alconétar Arch Bridge (left) and maximum semi-amplitude value as a function of the reduced wind speed for the standard cross-section and with deflectors (right)

6 CONCLUSIONS

The vibrations suffered by some bridges have been controlled by the addition of tuned mass dampers. Examples include the steel girder bridges of Rio Niterói (1980, Niterói, Brazil, 300 m main span) [7] and the Trans-Tokyo Bay Bridge (1997, Tokyo Bay, Japan, 240 m main span) [2]

On the contrary, computational methods are aimed to identify the potential problem in early design stages, and thus avoid subsequent interventions (e.g. installation of damper devices) which have major economic implications, unless strictly necessary for other reasons.

The maximum amplitude has been successfully reduced for both cases. As for the Volgograd Bridge, it has been seen that the presence of a twin girder deck next to the existing one would lead to a notable reduction in the maximum vibration amplitude. This additional deck is planned to be constructed in the future.

The influence of the braces geometry together with the twin box cross-section of Alconétar Bridge is not very clear. It is important to analyse the influence of the solidity ratio of the horizontal strip that braces the two sections in tandem arrangement, since this parameter determines the force coefficient and therefore the amplitude of oscillation of the VIV phenomena. Therefore, a deeper study should be conducted.

ABSTRACT: The present paper discusses the characteristics of unsteady aerodynamic forces on long-span vaulted roofs, based on a wind tunnel experiment and a CFD simulation. A forced vibration test is carried out in the wind tunnel to investigate the effects of wind speed, vibration amplitude, reduced frequency and rise/span ratio of the roof on the unsteady aerodynamic forces. Furthermore, the influence of the unsteady aerodynamic forces on the dynamic response of practical long-span vaulted roofs is investigated using the results obtained from the wind tunnel experiments. The CFD simulation is used effectively to evaluate the unsteady aerodynamic forces on the vibrating roof in a wider reduced frequency range.

KEYWORDS: Unsteady aerodynamic force, Long-span curved roof, Wind tunnel experiment, Dynamic response, Computational Fluid Dynamics (CFD)

1 INTRODUCTION

Many long-span structures with curved roofs, such as stadiums, auditoriums, airports and railway stations, have been constructed in recent years, because they can provide a large space with no intermediate columns. Being light and flexible, such roofs are vulnerable to dynamic wind actions. Furthermore, the wind-structure interaction may affect the response significantly. The interaction is represented by the unsteady aerodynamic forces, or the motion-induced forces, which may increase or decrease the response of the structure. Many researches have been made of the unsteady aerodynamic forces on long-span bridges and tall buildings (e.g. Taniike et al. [1]). The results indicate that unstable vibration may be induced by the negative aerodynamic damping in some cases. By comparison, the number of researches on long-span roofs is quite limited. Daw and Davenport [2] carried out a forced vibration test on a semi-circular roof to investigate the dependence of unsteady aerodynamic forces on the turbulence intensity, wind speed, vibration amplitude and geometric details of the roof. Ohkuma et al. [3] investigated the mechanism of aeroelastic instability for long-span flat roofs using a forced vibration test in a wind tunnel. They discussed the effects of unsteady aerodynamic forces on the wind-induced responses, based on the wind tunnel experiment as well as on the dynamic response analysis. At present, however, the characteristics of unsteady aerodynamic forces on long-span curved roofs are not understood well. So, it is necessary to investigate this problem further for developing more reasonable methods of response analysis for these roofs.

The objective of the present study is to describe the characteristics of unsteady aerodynamic forces acting on a vaulted roof vibrating in the first anti-symmetric mode. A forced-vibration test is carried out in a turbulent boundary layer. The effects of wind speed, vibration amplitude and frequency on the characteristics of unsteady aerodynamic forces are investigated. However, the range of these parameters involved in the wind tunnel experiments is limited. Therefore, a CFD simulation is carried out to investigate the problem in more detail. In the simulation, the parameters are varied over a wider range.

2 UNSTEADY AERODYNAMIC FORCE

The displacement of structure in the *j*-th mode may be represented by the following equation,

$$z_j(s,t) = \phi_j(s)\, x_j(t) \tag{1}$$

where φ_j and x_j are the mode shape and generalized displacement of the *j*-th mode, respectively; and *s* represents the circumferential coordinate taken along the roof.

Applying a modal analysis to the equation of motion for the roof, we obtain the following equation of motion for the *j*-th generalized displacement:

$$\ddot{x}_j(t) + 2\zeta_j \omega_j \dot{x}_j(t) + \omega_j^2 x_j(t) = F_j(t) / M_j \tag{2}$$

$$F_j(t) = F_{Wj}(t) + F_{Aj}(x_j, \dot{x}_j, \ddot{x}_j, \ldots) \tag{3}$$

where M_j = generalized mass; ω_j = natural circular frequency; ζ_j = critical damping ratio; and F_j = generalized force. F_{Wj} represents the fluctuating wind force due to the oncoming flow and wake instability, while F_{Aj} the unsteady aerodynamic force due to the wind-structure interaction.

In the case of the forced-vibration test, a steady vibration in the first anti-symmetric mode represented by a sine curve is applied to the roof. The unsteady aerodynamic force F_{Aj} (here $j = 1$) may be obtained from Eq. (4) by using the Fourier series at the frequency f_m of the forced vibration:

$$F_{Aj}(t) = F_{Rj} \cos 2\pi f_m t - F_{Ij} \sin 2\pi f_m t \tag{4}$$

$$F_{R_j} = \frac{1}{T}\int_{-T}^{T} F_j(t) \cos 2\pi f_m t\, dt \tag{5}$$

$$F_{I_j} = \frac{1}{T}\int_{-T}^{T} F_j(t) \sin 2\pi f_m t\, dt \tag{6}$$

where F_{Rj} and F_{Ij} are the in-phase and out-of-phase components of the unsteady aerodynamic force, respectively.

The effect of unsteady aerodynamic force may be represented by the aerodynamic stiffness and damping coefficients a_{kj} and a_{cj}, which are given by the following equations [4]:

$$a_{Kj} = \frac{1}{q_H A_s (x_0 / L)} \frac{2}{T} \int_0^T F_j(t) \cos 2\pi f_m t\, dt \tag{7}$$

$$a_{Cj} = \frac{1}{q_H A_s (x_0 / L)} \frac{2}{T} \int_0^T F_j(t) \sin 2\pi f_m t\, dt \tag{8}$$

where q_H = velocity pressure at the mean roof height H; A_s = roof area; x_0 = vibration amplitude; L = span of the roof; f^* = reduced frequency defined by $f_m H / U_H$, with U_H being the mean wind speed at the mean roof height H.

The generalized force F_j may be described in terms of the external and internal pressures p_e and p_i, as shown in Eq. (9):

$$F_j(t) = \int_0^{R_s} \left[p_{e_j}(s,t) - p_{i_j}(s,t) \right] \phi_j(s)\, ds \tag{9}$$

where R_s = total length of the vaulted roof. Internal pressure p_i is ignored in the present study, because the first anti-symmetric mode under consideration causes no change of internal volume.

3 WIND TUNNEL EXPERIMENT

3.1 *Experimental apparatus and procedures*

The experiments were carried out in an Eiffel-type wind tunnel with a working section 6.5m in length and 1.0m×1.4m in cross-section. A turbulent boundary layer with a power-law exponent of α=0.23 was generated on the wind tunnel floor by using a set of turbulence-generating spires installed at the entrance of the working section, and a number of roughness blocks distributed on the floor. The profiles of the mean wind speed and turbulence intensity are shown in Fig. 1. The reference wind speed was measured at a height of Z_G = 500mm. The longitudinal velocity spectrum, not shown here to save space, was found to be generally consistent with the so-called Karman type spectrum.

The wind tunnel model was a vaulted roof made of 0.8mm thick polyester film, as shown in Figs. 2 and 3. A pair of end plates was used to make the flow two-dimensional. Two models with rise/span ratios of 0.15 and 0.20 were tested. Each model had 12 pressure taps of 1mm diameter distributed along the roof's centerline. The pressure taps were connected to pressure transducers in parallel via 80cm lengths of flexible vinyl tubing. The tubing effects were numerically compensated by using the gain and phase-shift characteristics of the pressure measuring system used in the experiment. The signals from the pressure transducers were sampled simultaneously at a rate of 500Hz for a period of approximately 60s. Table 1 summarizes the range of experimental parameters involved in the experiment.

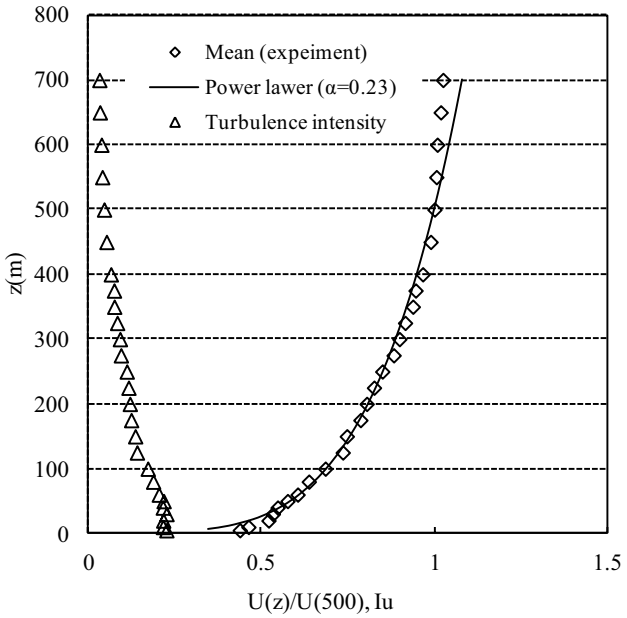

Fig.1 Profiles of the mean wind speed and turbulent intensity

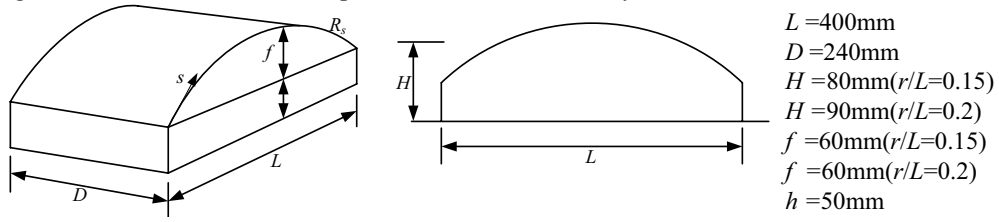

Fig.2 Geometry of the experimental model

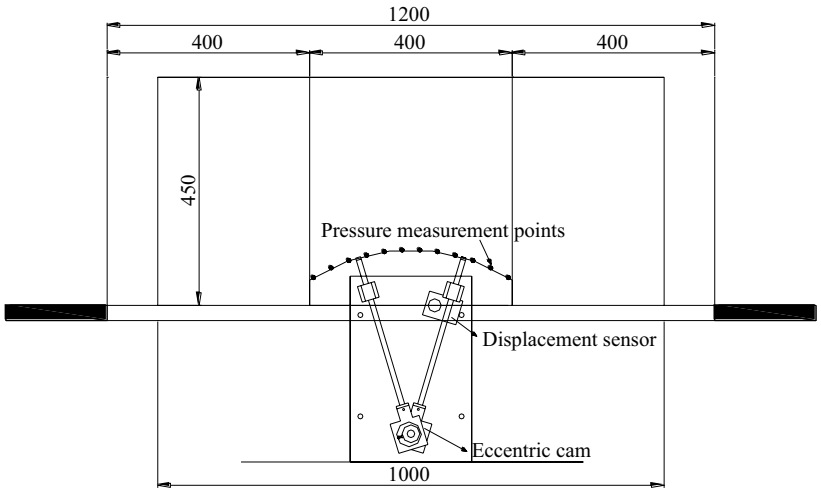

Fig.3 Experimental setup of the forced vibration test

Table 1 Parameters of experiment

Rise/span ratio r/L	0.15, 0.20
Wind speed U_H (m/s)	5.0, 7.0, 10.0
Amplitude of the forced vibration x_0 (mm)	1.0, 2.5, 4.0
Forced vibration frequency f_m (Hz)	5 to 25 at an increment of 1 Hz

3.2 *Results and Discussion*

Fig.4 shows the variation of the aerodynamic stiffness coefficient a_k with the reduced frequency f^* for various wind speeds (Fig. 4(a)) and vibration amplitudes (Fig. 4(b)); the rise/span ratio is 0.15. The value of a_k generally increases with an increase in f^*. As the reduced frequency decreases, the value of a_k approaches the quasi-steady value (dashed line in the figure). Similar results were observed for r/L=0.20. Within the limits of the present experiment, the value of a_k is generally positive, which may reduce the total stiffness of the structural system resulting in a lower natural frequency.

Plotted on Fig.5 are the variations of aerodynamic damping coefficient a_c with the reduced frequency f^* for various wind speeds and vibration amplitudes; the rise/span ratio is again 0.15. The values of a_c are generally negative except for small f^*values, which may result in an increase in the total damping of structural system. The magnitude of a_c increases as the f^* value increases. Similar results were observed for r/L=0.20. It can be seen that the effects of wind speed and vibration amplitude on the aerodynamic stiffness and damping coefficients are not so significant and the values of a_k and a_c are mainly dependent on f^*.

4 PREDICTION OF DYNAMIC RESPONSE

This section outlines a method for predicting the dynamic response of a full-scale vaulted roof to turbulent winds, in which the effects of the unsteady aerodynamic forces are taken into account. As an example, we consider a long-span membrane structure with the same shape as that used in the wind tunnel experiment. In general, the natural frequency of membrane structure with a span of approximately 100m is in a range from 0.5Hz to 1.5Hz and the mass from 2 kg/m^2 to 15 kg/m^2. The dynamic responses of such structures in a turbulent wind are evaluated by using the averaged

curves of aerodynamic stiffness and damping coefficients obtained from the wind tunnel experiments.

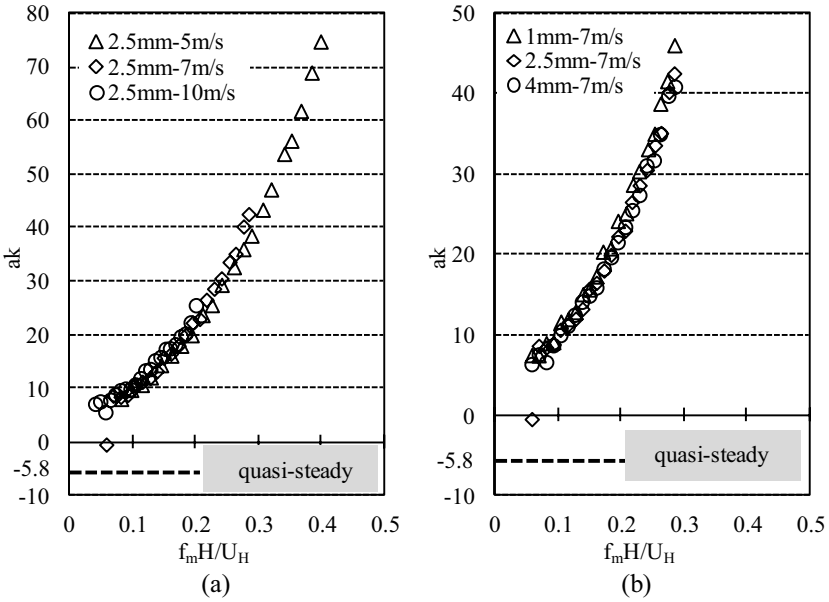

Fig.4 Aerodynamic stiffness coefficient versus f^* (r/L=0.15)

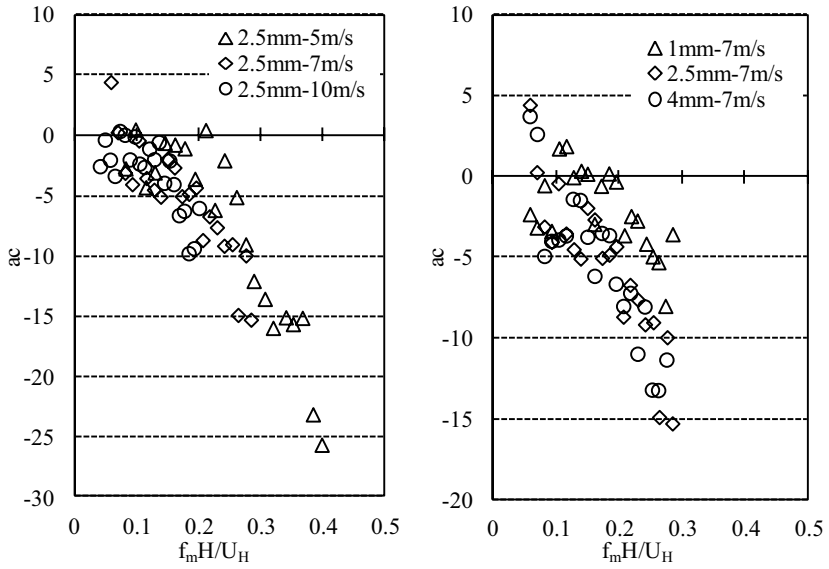

Fig.5 Aerodynamic damping coefficient versus f^* (r/L=0.15)

Aerodynamic stiffness (K_{aj}) and aerodynamic damping ratio (ζ_{aj}) are given by Eqs. (10) and (11). The mechanical admittance including the aerodynamic stiffness and damping is defined by Eq. (12), in which we assume that the structural damping ratio is ζ_s =1% and the natural frequency of the first anti-symmetric mode is f_s=0.5Hz. Only the first vibration mode (j=1) is considered, because the roof response to turbulent wind forces is thought to be dominated by this mode [6].

$$\zeta_{a_j}(f) = -\frac{1}{16\pi^2}\frac{\rho_a}{\rho_{s_j}}\left(\frac{U_H}{f_{s_j}H}\right)^2\frac{H}{L}a_{c_j}(f) \tag{10}$$

$$\frac{K_{a_j}(f)}{K_{s_j}} = -\frac{1}{8\pi^2}\frac{\rho_a}{\rho_{s_j}}\left(\frac{U_H}{f_{s_j}H}\right)^2\frac{H}{L}a_{k_j}(f) \tag{11}$$

$$\left|\chi_j(f)\right|^2 = \frac{1}{\left[1-\left(\frac{f}{f_{s_j}}\right)^2+\frac{K_{a_j}(f)}{K_{s_j}}\right]^2+4\left(\xi_{s_j}+\xi_{a_j}(f)\right)^2\left(\frac{f}{f_{s_j}}\right)^2} \tag{12}$$

Fig.6 illustrates the mechanical admittance functions plotted against frequency f for various wind speeds, where the structural mass is assumed M_s=4kg/m^2. As the wind speed increases, the resonant frequency decreases and the peak value of the mechanical admittance function at the resonant frequency increases. The decrease in the resonant frequency is due to the positive aerodynamic stiffness coefficient.

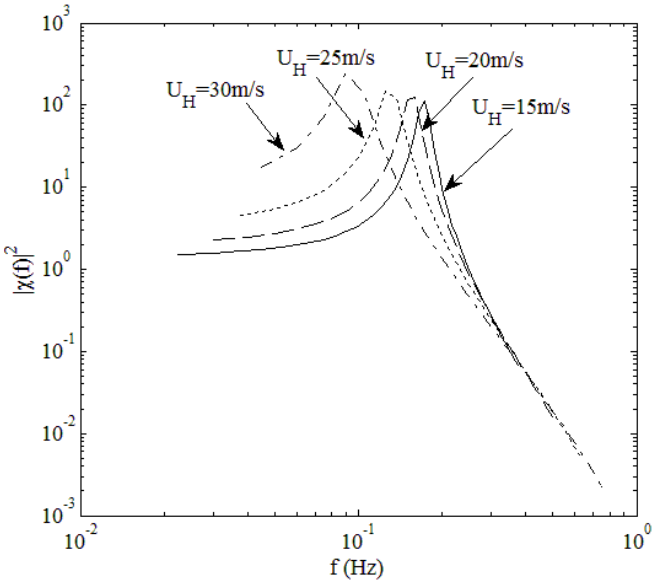

Fig.6 Variation of mechanical admittance function with wind speed

The variation of mechanical admittance function with the roof's mass is illustrated in Fig.7, in which we assume that U_H=20m/s. The resonant frequency increases and the resonant peak value of the mechanical admittance function decreases as roof's mass increases. This feature implies that the increase in mass is quite effective for reducing the aerodynamic excitation of the roof. In other words, the effect of unsteady aerodynamic forces on the response of the roof becomes less significant for heavier roofs.

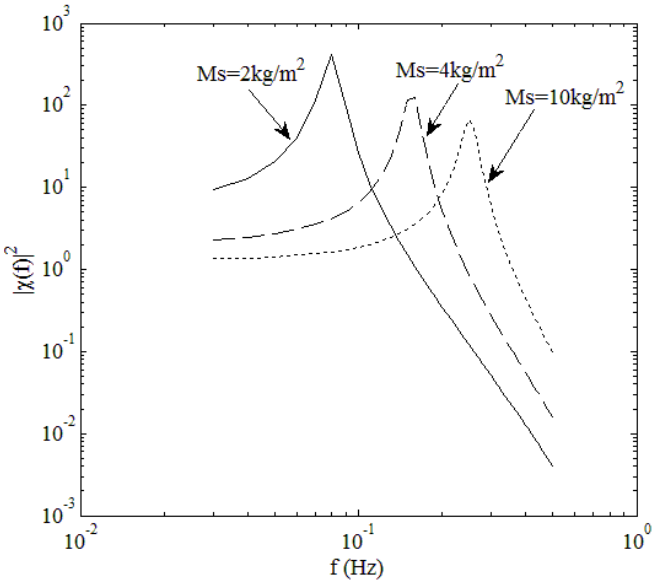

Fig.7 Variation of mechanical admittance function with roof's mass

5 CFD SIMULATION

The unsteady aerodynamic force acting on a vibrating roof in the first anti-symmetric mode is numerically simulated by using a commercial software 'STAR-CD'. As the first step of study, the wind tunnel experiment using a model with r/L=0.15 is reproduced. The amplitude x_0 of vibration is fixed to 4.0mm in this study.

5.1 *Computational conditions*

The large eddy simulation (LES) with the Smagorinsky sub-grid model (C_s=0.12) is used to simulate the flow field around the model. The computational conditions are summarized in Table 2. The computational domain and mesh arrangement are shown in Fig.8. It is important to provide proper inflow condition for predicting the wind loads on structures precisely, particularly for LES. In this study, the inflow turbulence is generated in a preliminary computational domain where roughness blocks are arranged to generate a turbulent boundary layer similar to the wind tunnel flow [7, 8]. The profile of the mean wind speed and turbulent intensity at the inlet of the computational domain are compared with those of the wind tunnel flow in Fig. 9. Although there exists a difference between CFD simulation and wind tunnel experiment for the profile of mean wind speed, the agreement is quite good for the turbulence intensity.

5.2 *Results and discussion*

Fig.10 shows the distributions of the mean wind pressure coefficients along the centerline of the vibrating roof obtained from the CFD simulation and the wind tunnel experiment, in which the results for the frequencies of 10Hz and 20Hz are plotted. A generally good agreement between these two results can be seen. The difference is somewhat larger near the top of the roof; the CFD values are approximately 10% larger in magnitude than the experimental ones. This difference

may be due to a difference in surface roughness of the roof between CFD simulation and wind tunnel experiment.

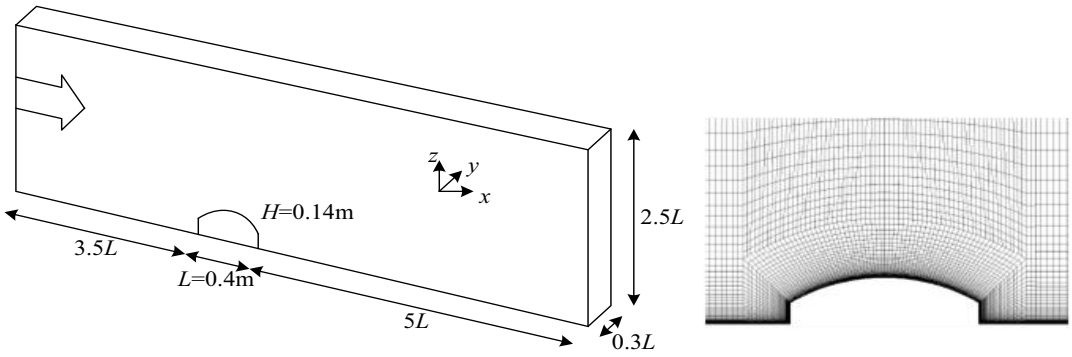

Fig.8 Computational domain and mesh arrangement

Table 2 Computational conditions

Computational domain	$9.5L(x)\times0.3L(y)\times2.5L(z)$
Inlet boundary	Inflow turbulence is generated in preliminary computational domain
Upper boundary	Zero normal velocity and zero normal gradients of other variables
Side boundary	Cyclic boundary conditions
Outlet boundary	Zero normal gradients of all variables
Floor and model surfaces	no-slip condition
Grid discretization	260 (x) ×12 (y) ×64 (z) = (199680)
Convection schemes	Second-order centered difference scheme
Time differential schemes	MARS method
Numerical algorithm	PISO algorithm
Time step	Δt = 2.0E-04 second (Courant Number：9.1E-02)

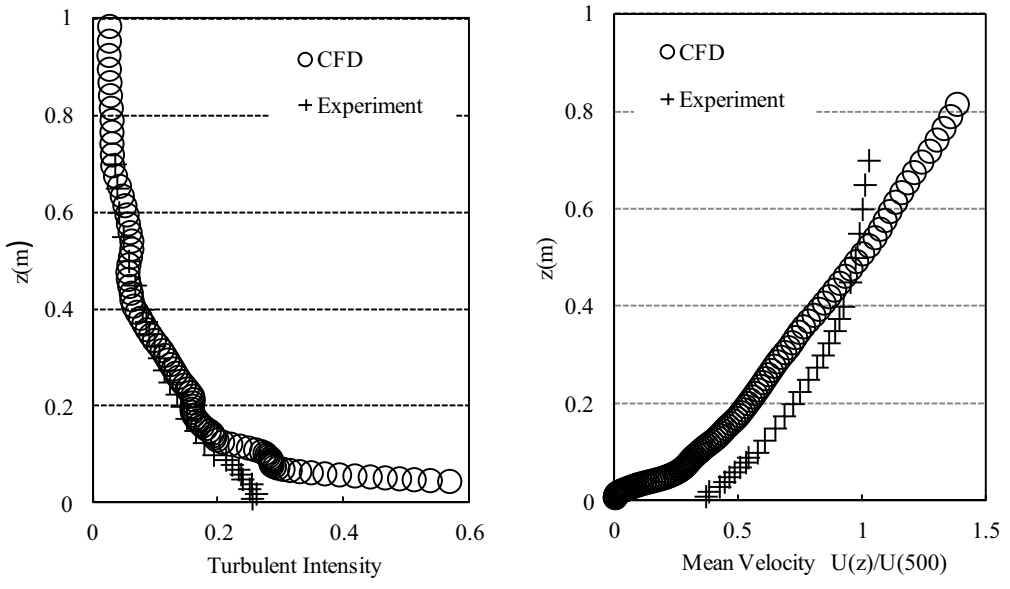

Fig.9 Comparisons of mean wind speed and turbulent intensities of CFD with wind tunnel test

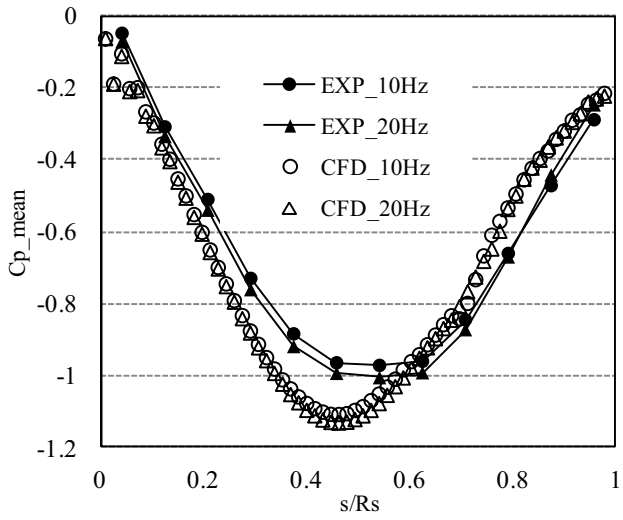

Fig.10 Comparisons between CFD simulation and wind tunnel experiment for the mean wind pressure coefficient

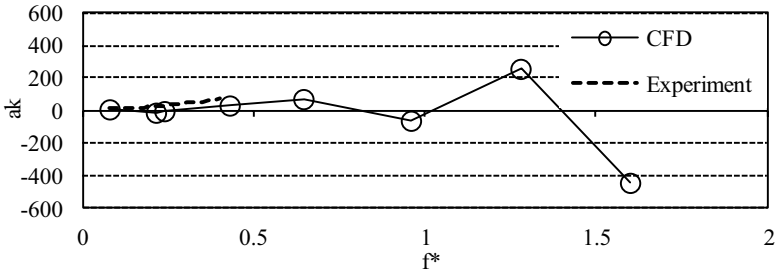

Fig.11 Comparison of aerodynamic stiffness coefficient computed by CFD with wind tunnel test

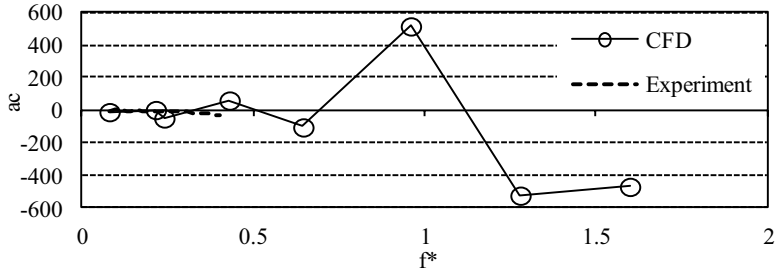

Fig.12 Comparison of aerodynamic damping coefficient computed by CFD with wind tunnel test

Based on the results of the CFD simulation, the aerodynamic stiffness and damping coefficients are calculated by using Eqs. (7) and (8). The aerodynamic stiffness coefficients a_k obtained from the LES and wind tunnel experiment are plotted in Fig. 11 for several reduced frequencies. The both results for the reduced frequency range of 0 to 0.4 are generally consistent with each other. A comparison for the aerodynamic damping coefficients a_c between the LES and wind tunnel experiment is shown in Fig. 12. Although the simulation value of a_c at f^*=0.4 is positive, the general trend of a_c with f^* in the lower f^* range is consistent with the experimental result. In a higher reduced frequency range, such as f^*>0.5 for example, the magnitudes of a_k and a_c obtained from the CFD simulation fluctuate significantly with increasing f^*. It is due to the flow-structure interaction. Such an interaction may be related to the convection velocity of pressure field on the

roof as well as to the roof's vibration speed relative to the wind speed [9]. Future studies will be necessary to discuss this problem in detail.

6 CONCLUSIONS

The unsteady aerodynamic force on a long-span vaulted roof has been investigated based on a wind tunnel experiment as well as on a CFD simulation. The main results obtained in the present study may be summarized as follows:

1) The aerodynamic stiffness and damping coefficients vary with the reduced frequency. The coefficients are influenced by the wind speed, rise/span ratio and vibration amplitude only slightly.
2) Within the limits of the present experiment, the aerodynamic stiffness is generally negative, which decreases the total stiffness of system. However, the aerodynamic damping is positive, which may result in an increase of the total damping of system.
3) As the mass of the roof increases, the effect of the unsteady aerodynamic forces on the roof's response to turbulent winds becomes less significant. And the unsteady aerodynamic forces reduced the resonant frequency and change the resonant peak.
4) The CFD simulation is a useful tool to evaluate the unsteady aerodynamic forces on the vibrating roof in a turbulent flow. The general trends of the aerodynamic stiffness and damping coefficients with the reduced frequency obtained from the CFD simulation are consistent with that from the wind tunnel experiment.

In our future study, we will construct a model of the unsteady aerodynamic force and incorporate it into the wind-resistant design of long-span curved roofs.

Internal stresses in cladding support members of long-span arched roof under wind load

Zhibin Ding [a], Yukio Tamura [a], Akihito Yoshida [a]

[a] *Tokyo Polytechnic University, Iiyama 1583, Atsugi, Kanagawa, Japan*

ABSTRACT: This paper discusses the largest wind load effects on roof cladding support members of a large-span arched roof. The contributions to member stresses due to overall wind effects and local wind effects were investigated using finite element model (FEM) analysis. Wind-induced pressures including mean and fluctuating components were measured on the roof of a 1:400 scale model under a suburban boundary layer wind flow. Measured wind pressures from limited measurement points were expanded to all the structural nodes using the orthonormal coordinate system obtained from the Proper Orthogonal Decomposition (POD) method. The largest load effects (focusing on member stresses) due to overall wind effects were estimated based on the quasi-static method and compared with those estimated by the time-domain analysis of the complete finite element model directly applying the expanded wind load. The contributions due to overall wind effects and local wind effects were compared.

KEYWORDS: Roof cladding-support members; Large-span arched roof; Overall wind effects; Local wind effects; Largest wind load effects; Contributions to largest load effects.

1 INTRODUCTION

Large-span roof structures usually have the characteristics of light mass, high flexibility, slight damping and low natural frequencies. Consequently, their structural systems are more wind sensitive than conventional roofs, and wind load is very important in structural design. Extensive investigations on the characteristics of wind loads and wind-induced responses of conventional roof structures have been conducted in the past [1-4]. Recently, equivalent static wind load methods based on the quasi-steady assumption have been widely used to reproduce largest load effects for structural members [5-7] and adopted in the building codes and laws of many countries, e.g. AIJ-RLB (2004) [8], ASCE/SEI 7-10 (2010) [9], and AS/NZS 1170.2 (2002) [10]. The researches mentioned above focused mostly on estimation of overall wind effects on main structural frames of conventional roof structures.

Large-span roof structures generally consist of main structural frames, roof cladding support members and roofing members. Obviously, stresses in roof cladding support members are affected by local wind pressures and tributary areas. They may also be affected by deformations of main structural frames due to overall wind effects. However, in current wind load codes, both roof cladding support members and roofing members are usually classified as components and cladding, and the wind load effects on such members are determined by local wind pressures and tributary areas only. By ignoring the influence of wind-induced responses of main structural frames, stresses in roof cladding support members are underestimated by current wind load codes.

Arched roofs are widely used for large-span structures such as entertainment or exhibition centers, closed sport buildings, aircraft hangars, etc. The largest wind load effects on roof cladding support members on these roofs are investigated in this paper, focusing on the contributions to member stresses due to overall wind effects and local wind effects. Mean and fluctuating wind pressures were measured simultaneously from the roof of a 1:400 scale model under suburban

boundary layer wind flow. Measured wind pressures were expanded from limited measurement points to all the structural nodes using the orthonormal coordinate system obtained from the Proper Orthogonal Decomposition (POD) method. The largest member stresses due to overall wind effects were estimated based on the quasi-static method. By extracting member stresses due to overall wind effects from those estimated by time-domain analysis of the complete finite element model applying the expanded wind load directly, member stresses due to local wind effects can be obtained. This paper compares the contributions to the largest load effects (maximum and minimum member stresses) due to overall wind effects and local wind effects.

2 MEMBER STRESSES DUE TO OVERALL WIND EFFECTS OR LOCAL WIND EFFECTS

Since the roof cladding support members of large-span roofs support the roofing members, the local wind pressures acting on the tributary areas can cause member stresses, called stresses due to local wind effects. However, roof cladding support members are themselves supported by the main structural frame. The wind-induced responses of the structural frame can also influence roof cladding support member stresses, called stresses due to overall wind effects. The extent of this influence depends on the characteristics of the connections between the roof cladding support members and the main structural frame (e.g., stiffness). The actual member stresses in these members under wind load are the combined stresses due to overall wind effects and local wind effects.

The actual member stresses were calculated by time-history analyses using the Newmark-β method with a completed FE model including a main structural frame and roof cladding support members. The deformations of the main structural frame were also analyzed. Generally, roof cladding support members are much smaller than main structural frame members. The additional stiffness to the main frame due to the roof cladding support members can be neglected, so the deformation of the main structural frame can be assumed to represent the overall wind effect on the entire structure. Since the roof cladding support members were supported by the main frame, the displacements of the supporting points will cause internal stresses in the cladding support members, which were assumed as the stresses due to overall wind effects. Compared with the main structural frame, the natural frequencies and damping of such members were relatively high, and member stresses can be obtained by the quasi-static method. For a static displacement d_i occurring at a support point i, a specific load effect r (e.g. member stress) can be derived as:

$$r = R_i d_i . \tag{1}$$

Here, R_i is the value of the load effect r caused by unit displacement at a support point i. For displacements occurring at all support points i, the load effect r can be indicated as a superposition of Eq. (1). Following the quasi-static assumption, the load effect $r(t)$ can be expressed by:

$$r(t) = \sum_{i=1}^{N} R_i d_i(t) = \{R\}^T \{D(t)\} . \tag{2}$$

The largest load effect $\hat{r}$ can be indicated by:

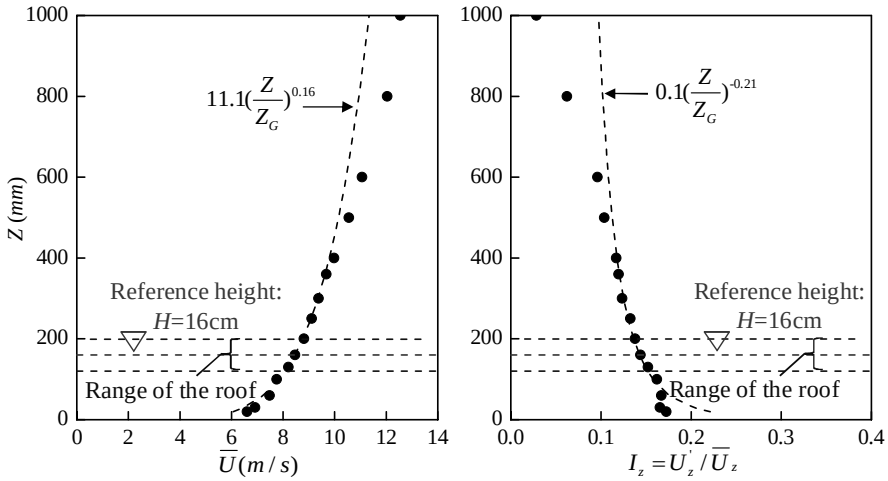
$$\hat{r} = \{R\}^T \{\hat{D}\} . \tag{3}$$

As mentioned before, the actual member stresses in roof cladding support members under wind load are the combination of stresses due to overall wind effects and to local wind effects. Since the member stresses due to overall wind effects calculated based on the quasi-static method result from the actual member stresses, the components due to local wind effects can be extracted.

3 WIND TUNNEL EXPERIMENTS

3.1 *Experimental arrangements*

The wind tunnel experiment was carried out in a boundary layer wind tunnel at Tokyo Polytechnic University, Japan. The test section was 2.2 m wide and 1.8m high. Suburban terrain characteristics were simulated by spires and roughness elements with the power law exponent of mean wind speed α=0.16. A velocity scale of 1/5 was adopted. The mean wind speed at reference height of the model (average height of the curved roof) was 8.5m/s and the corresponding turbulence intensity was approximately 14%, as shown in Fig. 1. The measured longitudinal spectrum of wind velocity at the reference height is shown in Fig. 2.



(a) Mean wind speed profile (b) Turbulence intensity profile

Figure 1. Measured longitudinal mean wind velocity and turbulence intensity profiles.

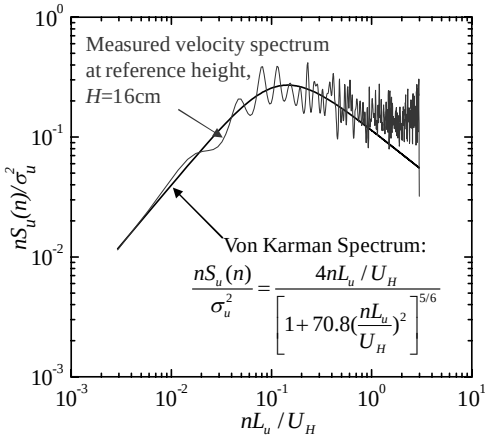


Figure 2. Measured longitudinal spectrums of wind velocity.

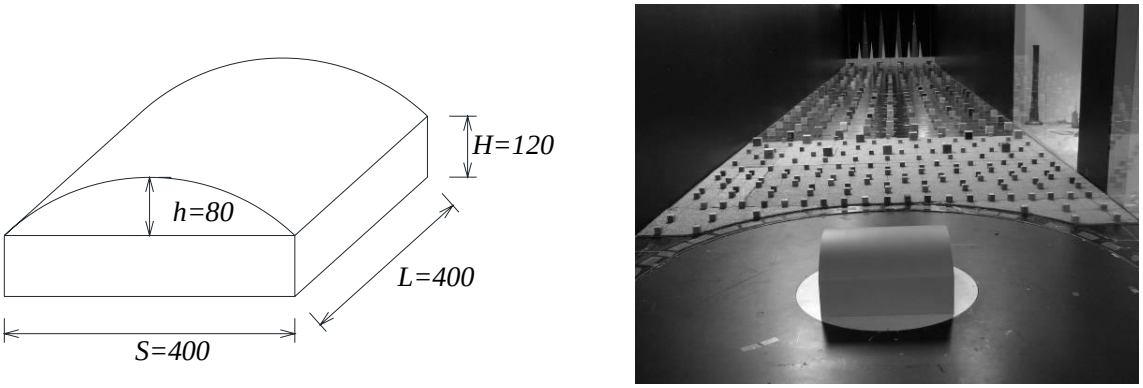
The geometric variables relevant to the wind loads on arched-roof buildings were: span, S; length, L; rise, h; and height of walls to eaves level, H. The geometry of the 1:400 scale wind tunnel model is illustrated in Fig. 3(a) together with the coordinate system used in this study. The model has the span S equal to 40cm, corresponding to 160m in full scale. The rise/span ratio h/S was set to 0.2 while the length to span aspect ratio L/S was 1. The wall-height was 12cm. Fig.

3(b) shows a photo of the model mounted on a turning table in the wind tunnel. Pressure taps installed on the roof's upper surface are marked with • and numbers as shown in Fig. 4.



(a) (b)

Figure 3. Experimental model (unit: mm). (a) Geometric variables of arched roof model, (b) photo of model in wind tunnel.

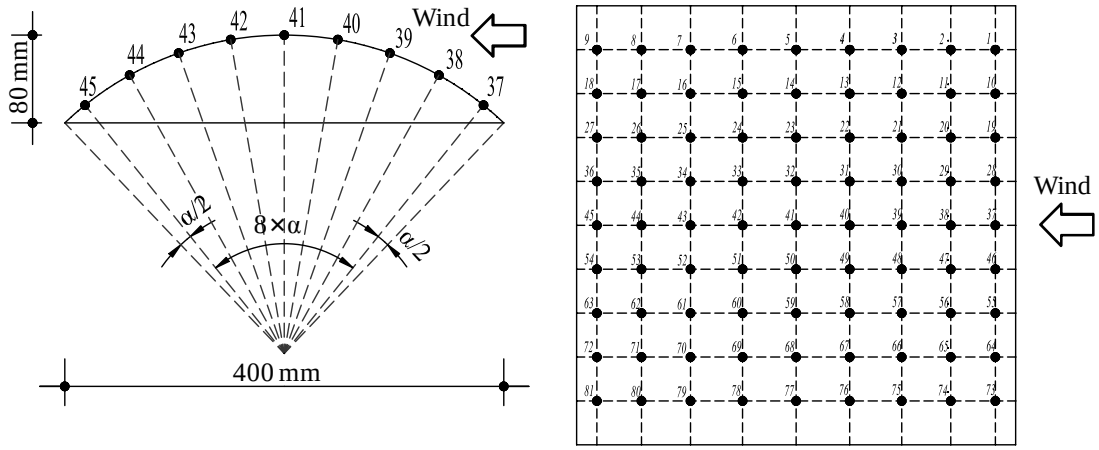


Figure 4. Distribution and numbering of measuring pressure taps for arched model.

Wind pressures were measured with a sampling frequency of 781 Hz using a multi-channel simultaneous fluctuating pressure measurement system. As the time scale of prototype vs. wind tunnel model was 1/80, the sampling frequency of the prototype was equivalent to 10 Hz. The tubing effects were numerically compensated by the gain and phase-shift characteristics of the pressure measuring system [11].

3.2 *Proper orthogonal decomposition*

Since the effect of load distribution is important to the dynamic analysis of an arched roof[12], it is necessary to expand the measured mean or fluctuating wind pressure data at limited measurement points to all the structural nodes on the surface of the roof by applying a proper orthogonal decomposition (POD) method. The eigenvalues λ_k and eigenmodes $\{\Phi\}_k$ were obtained by solving the following equation:

$$[R]\{\Phi\} = \lambda\{\Phi\} \tag{4}$$

where, $[R]$ represents the pressure space correlation matrix. The fluctuating wind pressure field $\{p\}$ can be expressed by:

$$\{p\} = \sum_{k} a_k(t)\{\Phi\}_k \tag{5}$$

where, $a_k(t)$ represents the kth orthonormal coordinate. The eigenvalue λk is the measure of the contribution of each eigenmode to the pressure mean squares, and is normalized as:

$$P_k = \frac{\lambda_k}{\sum_{j=1}^{N} \lambda_j} \tag{6}$$

The normalized eigenvalues P_k are plotted against the mode index k in Fig. 5 for wind directions θ = 0°, 45° and 90°. The accumulated values of P_k up to the 20th eigenmode were approximately 0.9 when the wind direction was 0°. In the following analysis, the wind pressures at the nodes were simulated by the first 20 eigenmodes. The values of $\{\Phi\}_k$ at the nodes of the structural model were interpolated or extrapolated from those at the tap locations given by the POD analysis.

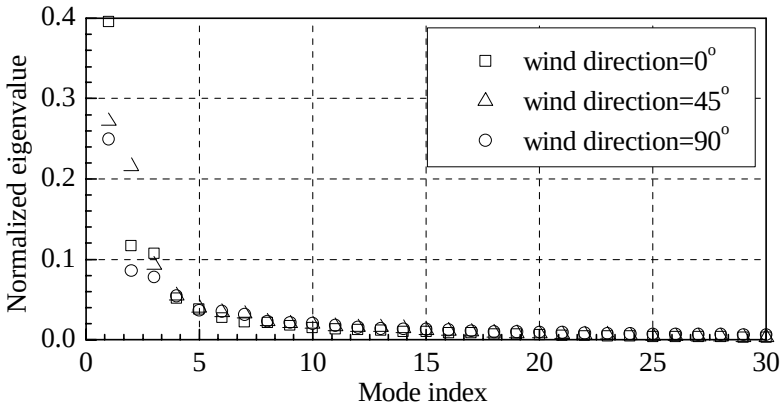

Figure 5. Normalized eigenvalues of fluctuating pressure.

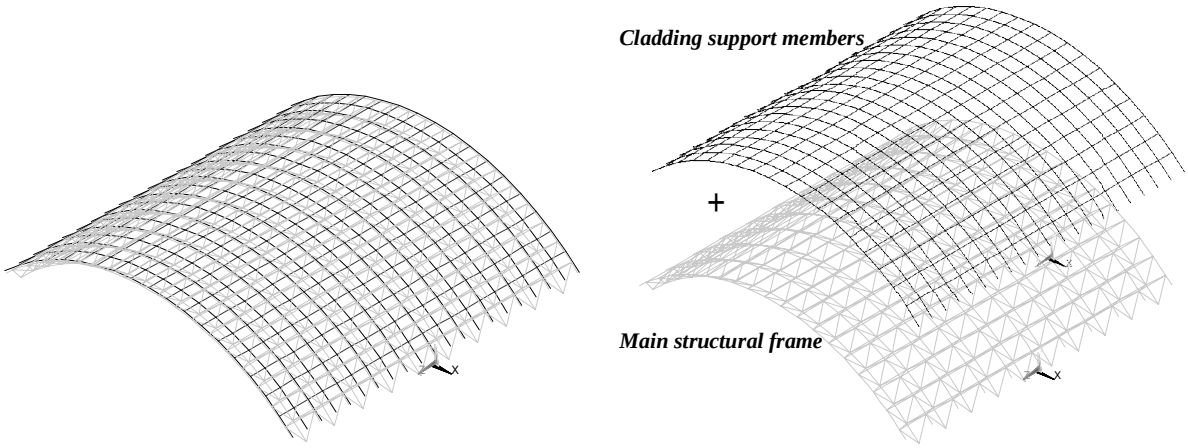
4 ESTIMATION OF LARGEST STRESSES IN ROOF CLADDING SUPPORT MEMBERS

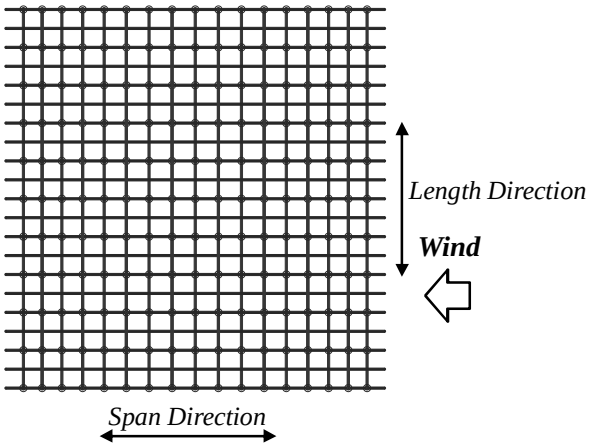
4.1 *Structural model*

As shown in Fig. 3, the wind tunnel test model was an arched roof model including walls, and pressure taps were installed only on the roof's upper surface. The prototype structure was assumed as a closed arched roof structure, in which the roof part was supported by walls or columns. Since the target in this study was the stresses in the roof cladding support members, only the roof structure was modeled by ANSYS software, following the length scale in the wind tunnel of 1:400. The finite element (FE) model of the roof structure was made up of a main structural frame and cladding support members, as shown in Fig. 6(a)-(b). All the joints on the bottom of the roof model were assumed fixed for all six degrees of freedom.

The cladding support members can also be classified as members along the length direction and members along the span direction. The members along the length direction were treated as continuous beams supported by the main structural frame. The support points are marked with ○ in Fig. 6(c). Seventeen beams were arranged at equal intervals of arch length. On the other hand, members along the span direction were connected to adjacent beams and the connection conditions were assumed as rigid.



(a) Completed FE model (b) Composition of arched roof FE model



(c) Model of cladding support members

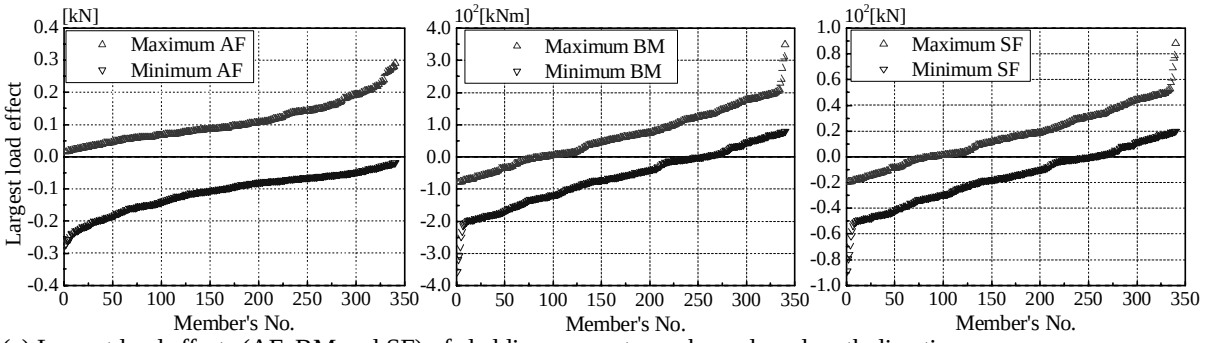
Figure 6. Structural model of arched roof structure: (a) completed FE model; (b) composition of arched roof FE model; (c) model of cladding support members.

4.2 *Computation of largest load effect in time-history analyses*

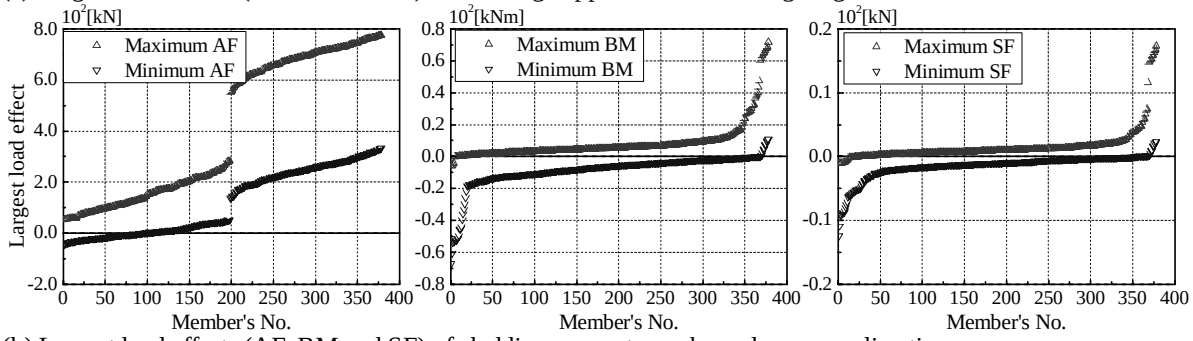
As mentioned in Sec. 2, the actual member stresses for cladding support members were computed in time-history analyses. The mean wind speed at the reference height (H=64m) was set at 42.5m/s. The critical damping ratios for the first and second modes were set to 1% to determine the two coefficients for the Raleigh damping equation. In the present study, the effects of aerodynamic damping and stiffness were not considered. Member stresses were analyzed for a duration of 11 min and the result for the first 1 min was not used for the statistical analysis because of the non-stationary state.

The loads on the arched roof were transmitted mainly by means of member axial force (hereafter referred to as AF), bending moment (hereafter referred to as BM) and shear force (hereafter referred to as SF). Torsional moment was neglected. Axial stresses in members were evaluated based on the combination of AFs and BMs, while shear stresses in members were evaluated based on SFs. Figure 7 shows the largest AFs, BMs and SFs of the cladding support members obtained from time-history analyses. In the figure, the member number is given in the order of the largest effects. Comparison of Fig. 7(a) and Fig. 7(b) shows that BMs had a more remarkable effect on

the axial stresses for members along the length direction than for members along the span direction. Correspondingly, AFs had a more remarkable effect on the axial stresses for members along span direction than for members along the length direction. Shear stresses due to SFs were more remarkable for members along the length direction.



(a) Largest load effects (AF, BM and SF) of cladding support members along length direction



(b) Largest load effects (AF, BM and SF) of cladding support members along span direction

Figure 7. Comparison of largest AFs, BMs and SFs obtained from time-history analyses of cladding support members.

4.3 *Contribution ratios for largest member stresses*

The displacements $\{D(t)\}$ in Eq. (2) of the support points connecting the main structural frame and the cladding support members were also obtained during the time-history analyses of the completed FE model. Only the FE model of cladding support members was used to obtain the $\{R\}$ in Eq. (2), under constraint conditions consistent with those in the completed FE model. The member stresses due to overall wind effects can be obtained with the known $\{R\}$ and $\{D(t)\}$, as mentioned in Sec. 2.

The contribution ratios of overall wind effects and local wind effects for the largest member stresses are defined by:

$$\gamma_o = \frac{\hat{r}_o}{\hat{r}}, \quad \gamma_l = 1-\gamma_o = 1-\frac{\hat{r}_o}{\hat{r}}. \tag{7}$$

Here, γ_o and γ_l are the contribution ratios of overall wind effects and local wind effects respectively. $\hat{r}$, $\hat{r}_o$ represent the actual largest load effect and the largest load effect due to the overall wind effects only, which were focused on the member stresses (maximum and minimum member stresses).

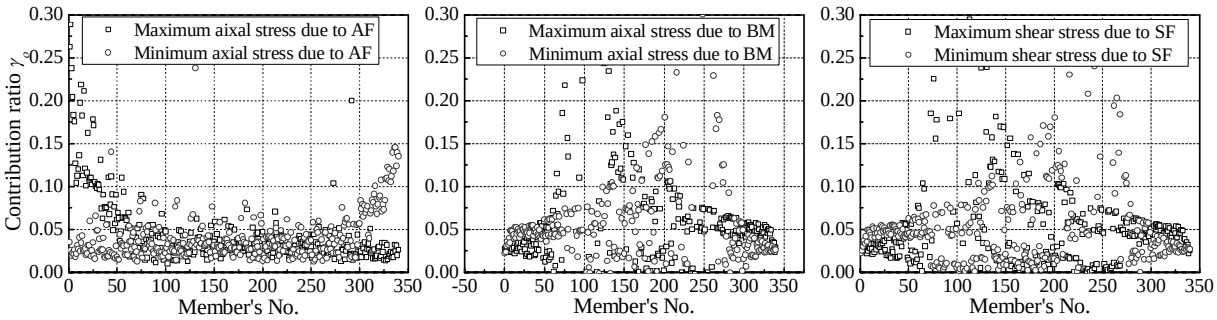


Figure 8. Contribution ratios of overall wind effects for the largest member stresses of members along length direction

Contribution ratios of overall wind effects for the largest member stresses of members along length direction are shown in Fig. 8. As in Fig. 7, the member number is given in the order of the largest effects obtained from the time-history analyses in Fig. 8. The contribution ratios of overall wind effects for the largest member stresses were less than 0.15 for most cladding support members. This means that current wind load codes are not so bad for most cladding support members, which don't take account of the contribution of overall wind effects for largest member stresses. However, the contribution ratio γ_o can be larger than 0.15 for several members and the largest value of γ_o was about 0.3, also shown in Fig. 8. Considering only the contribution of local wind effects for such members would remarkably underestimate the largest member stresses.

5 CONCLUDING REMARKS

Internal stresses in cladding support members of long-span arched roofs under wind load were investigated by time-history analyses of the completed FE model, including main structural frame and cladding support members. Contributions of overall wind effects and local wind effects to the largest member stresses were discussed:

1) The displacements of the supporting points connecting the main structural frame and cladding support members were assumed to represent the overall wind effects of the long-span roof structure.
2) Cladding members stresses due to the overall wind effects were evaluated by a quasi-static method.
3) The contribution ratios of overall wind effects to the largest member stresses were less than 0.15 for most cladding support members. However, there were members for which the contribution ratio can be larger than 0.15 and the largest value was about 0.3. Considering only the contribution of local wind effects to such members would remarkably underestimate the largest member stresses.

Moving downburst effects on long-span roof structure

Chen Yong, Liu Guoguang, Sun Bingnan

College of Civil Engineering and Architecture, Zhejiang University,
No. 388, Yuhangtang Road, Hangzhou, China.

ABSTRACT: Taking the interaction of moving downbursts with buildings into consideration is rather difficult in moving-downbursts-induced structure vibration analysis. By assuming that the jet velocity is proportional to the wind velocity in the fluid field, deterministic-stochastic hybrid model is utilized to generate the fluctuating jet velocity. Consequently, by using the time-varying mean wind pressure coefficients, the wind loading that considers the fluid-structure interaction is attained. Furthermore, the relationship between the mean wind pressure coefficient and the ratio of jet velocity to the translating speed is studied. The comparison of structural dynamics response caused by moving downburst and atmosphere bound layer wind is conducted through a defined downburst factor. It is found that the downburst factor increase with the increment of the structural natural frequency.

KEYWORDS: moving downbursts, CFD simulation, dynamic mesh, wind loading, structural vibration, deterministic-stochastic hybrid model.

1 INTRODUCTION

Thunderstorm downburst is a transient extreme wind, which is a strong downdraft spreading form the center to periphery and occurs during the thunder weather usually. It caused numerous structural destructions worldwide [1]. The studies in recent decades had shown that the thunderstorm downbursts would cause a higher near-surface wind velocity than that in atmosphere bound layer (ABL) winds. And the corresponding wind loading caused has gained many attentions.

The characteristic of wind field of steady thunderstorm has achieved comprehensive understanding. Experimental and numerical results those attained by utilizing the impinging wall jet model rather than vortex mode, showed reasonable agreements with the limited full-scale data [2-4]. For convenience of wind loading studies, many researchers (e.g. Oseguera and Bowles [5], Vicroy[6], Wood[7], etc.), proposed empirical models to describe the wind profiles. With consideration of wind load caused by moving downbursts, vector summation method and deterministic-stochastic hybrid model (DSHM) are mostly used. The former was proposed by Holmes and Oliver to simulate the mean time history of horizontal wind velocity in a travelling downburst [8]. The latter was proposed by Chen and Letchford to simulate the time history of horizontal wind velocity with random fluctuation [9]. So far, the study on the wind field of moving thunderstorm and its effects to structure is scarce. By utilizing a moving wall jet experimental device, Letchford and Chay obtained the transient pressure field on a cube immersed in a moving downburst [10]. Sengupta contributes to computational fluid dynamics (CFD) study on moving down bursts effecting on buildings by using dynamic mesh method [11]. For purpose of using a uniformed equation to consider both gust front wind and conventional wind, Kwon and Kareem presented a new framework of wind loading [12].

In this paper, the dynamics of buildings subjected to moving downbursts are studied. The surface wind pressure of buildings, which is obtained by dynamic-mesh-method-based CFD simulation, is utilized to determine wind loading. By assuming that the quasi-steady assumption is satisfied in moving down burst, the fluctuation component of the wind pressure is simulated ac-

cording to DSHM. The structural dynamics caused by moving downbursts are compared with that by ABL winds, through using a designated downburst factor. In addition, the downburst factor varying with the characteristic of structure dynamics and moving downburst are analyzed.

2 DOWNBURST FACTOR

The conventional gust loading factor (G_{GLF}) is defined as

$$G_{\mathrm{GLF}} = \frac{\hat{x}_{\mathrm{B\text{-}L}}}{\overline{x}_{\mathrm{B\text{-}L}}} \tag{1}$$

where $\hat{x}_{\mathrm{B\text{-}L}}$ and $\overline{x}_{\mathrm{B\text{-}L}}$ represent maximum and mean displacement of a structure subjected to ABL wind. G_{DB} is defined as a ratio of maximum displacements in the moving downbursts to that in ABL winds. Thus

$$G_{\mathrm{DB}} = \frac{\hat{x}_{\mathrm{DB}}(z,t)}{G_{\mathrm{GLF}} \cdot \overline{x}_{\mathrm{B\text{-}L}}(z)} \tag{2}$$

where $\hat{x}_{\mathrm{DB}}(z,t)$ is the maximum displacement of a structure subjected to moving downbursts; z and t are height and time respectively.

In order to comparing the downburst factors those computed using different jet velocities V_{jet}, the displacement of structure under the boundary layer wind load is therefore

$$\overline{x}_{\mathrm{B\text{-}L}}(z) = \left(\frac{V_{\mathrm{jet}}}{V_{\mathrm{jet\_0}}}\right)^2 \overline{x}_{\mathrm{B\text{-}L\_0}}(z) \tag{3}$$

where $\overline{x}_{\mathrm{B\text{-}L\_0}}(z)$ is the displacement of structure subjected to the reference ABL wind; $V_{\mathrm{jet\_0}}$ is the jet velocity when the wind pressure at the height of 10 m is equal to the reference wind pressure in code.

The displacement of structure under downburst can be decomposed into mean displacement $\overline{x}(z,t)$ and fluctuating displacement $\tilde{x}(z,t)$.

$$x_{\mathrm{DB}}(z,t) = \overline{x}_{\mathrm{DB}}(z,t) + \tilde{x}_{\mathrm{DB}}(z,t) \tag{4}$$

Then, the maximum displacements in the downburst can be rewritten as

$$\hat{x}_{\mathrm{DB}}(z,t) \approx \max\left[\overline{x}_{\mathrm{DB}}(z,t)\right] + \max\left[\tilde{x}_{\mathrm{DB}}(z,t)\right] \tag{5}$$

By substitution of Equation 6 into Equation 2, we have

$$G_{\mathrm{DB}} \approx G_{\mathrm{DB\_Sum}} = \overline{G}_{\mathrm{DB}} + \tilde{G}_{\mathrm{DB}}, \quad \overline{G}_{\mathrm{DB}} = \frac{\max\left[\overline{x}_{\mathrm{DB}}(z,t)\right]}{G_{\mathrm{GLF}} \cdot \overline{x}_{\mathrm{B\text{-}L}}(z)}, \text{ and } \quad \tilde{G}_{\mathrm{DB}} = \frac{\max\left[\tilde{x}_{\mathrm{DB}}(z,t)\right]}{G_{\mathrm{GLF}} \cdot \overline{x}_{\mathrm{B\text{-}L}}(z)} \tag{6}$$

where $\overline{G}_{\mathrm{DB}}$ and $\overline{G}_{\mathrm{DB}}$ are designated as mean and fluctuating downburst factors, respectively; the sum of them is the synthesis downburst factor $G_{\mathrm{DB\_Sum}}$.

By using the truncated modes, the displacement has a form of

$$x(z,t)=\phi(z)q(t)=\left[\phi_1(z),\phi_2(z),\cdots,\phi_i(z)\right]\times\left[q_1(t),q_2(t),\cdots,q_i(t)\right]^T \tag{7}$$

Where $\phi_i(z)$ is the *i*th mode; $q_i(t)$ is the corresponding time varying modal displacement. Thus we define the modal-decomposition-based downburst factor $G^{\mathrm{D}}_{\mathrm{DB}\_i}$ as

$$G^{\mathrm{D}}_{\mathrm{DB}\_i}=\frac{\max\left[\phi(z)q_{\mathrm{DB}}(t)\right]}{\phi(z)q_{\mathrm{B\text{-}L}}}=\frac{\max\left[\phi_1(z)q_{\mathrm{DB1}}(t)+\phi_2(z)q_{\mathrm{DB2}}(t)+\cdots+\phi_i(z)q_{\mathrm{DBi}}(t)\right]}{\phi_1(z)q_{\mathrm{B\text{-}L1}}+\phi_2(z)q_{\mathrm{B\text{-}L2}}+\cdots+\phi_i(z)q_{\mathrm{B\text{-}Li}}} \tag{8}$$

3 NUMERICAL SIMULATION

3.1 *Setup and numerical simulation parameters*

We utilized Fluent 6.2, which is commercial CFD software, to achieve a numerical approach. The moving downburst with a jet diameter of 500 m is simulated based on impinging wall jet model, as shown in Figure 1. The jet height is equal to the jet diameter. A long span flat roof whose size is 200×200×20m (length×width×height) is put in the fluid field.

Figure 1 shows the computational model and boundary conditions for downburst simulation. The downburst is modeled as a round jet, impinging onto a flat plate. The size of the three-dimensional computational domain is 18×8×5 D_{jet}, where D_{jet} is the jet diameter. The downburst is simulated to move a distance of 10 D_{jet} in the longitudinal direction.

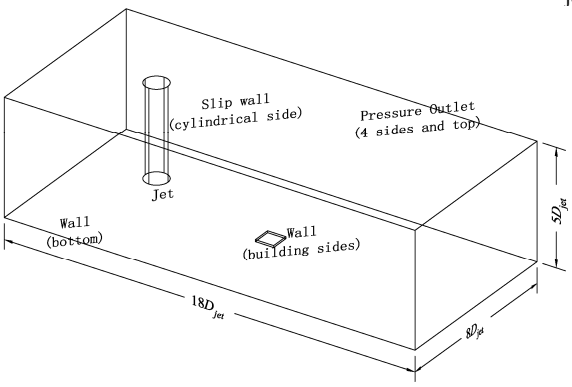

Figure 1. Computational model.

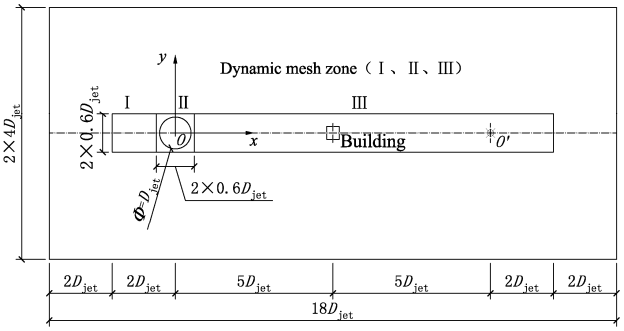

Figure 2. Schematic diagram of dynamic mesh zone.

The dynamic mesh model can be used to simulate the flows where the shape of the domain is changing with the time due to the motion of the boundaries [13]. The motion of the boundary is described by utilizing either boundary profiles, user-defined functions (UDFs), or some specific equations. Based on the motion of boundary, the volume mesh of the domain is automatically updated. Accordingly, the dynamic mesh model is capable of simulating the moving downbursts.

As shown in Figure 2, a dynamic mesh zone is separated from the domain by some non-conformal mesh interface. The dynamic mesh zone is divided into three parts: Ⅰ, Ⅱ and Ⅲ. The part Ⅱ is a rigid body motioning region, and the others are deforming regions. The velocity of the part Ⅱ is specified by UDF. In order to study the wind pressure distribution of the roof, the downburst moves from point *O* to the point *O'*. Due to the motion of part Ⅱ, the cells in part Ⅰ and Ⅲ would be distorted. The layering method is used to update the volume mesh based on predefined split and collapse factors. The split and collapse factors are 0.4 and 0.4, respectively.

The air density is set to be 1.225 kg/m^3 and viscosity 1.7894×10^{-5} kg/ (m·s). The RNG k-ε model is used to simulate the moving downburst. The default model constants in RNG k-ε model are used. For RNG k-ε model, the SIMPLE algorithm is used for solving the pressure-velocity

coupling equations. A standard scheme is employed for pressure discretization, and a 1st order upwind scheme is employed for momentum, TKE and TDR. The residual errors for all the variables are set to be 1×10^{-4}, except for continuity 1×10^{-3}.

All grids are structured grids, except for the meshes in part Ⅱ. Because of the curved boundary in part Ⅱ, the adaptable unstructured grids are used. For the region near the ground and the building faces, enhanced wall treatment is adopted and a fine mesh is used to ensure the $y^+ \le 1$. Figure.3 shows the mesh used in this simulation and the local mesh around wall.

The validity of the numerical simulation is verified by using different domain and grid sizes in the steady-state simulations. For unsteady cases, time steps dependency tests are performed and a non-dimensional time steps are chosen.

$$\Delta t^* = V_t \Delta t / D_{\text{jet}} = 0.008 \tag{9}$$

The jet velocity ratio V_{TJ} is defined as the ratio of the jet translating speed V_{T} to jet velocity V_{jet}. In order to numerically predict the effects of jet velocity ratio of a moving downburst on the roof, two groups of simulations are conducted. In the first group, the jet velocities are kept as 47.5 m/s, and the translating speeds are taken from the followings: 5.0, 10.0, 12.5, 15.0, 17.5, 20.0, 22.5, 23.75, 25.0 m/s. In the other group, the translating speeds are kept as 10.0 m/s, and the jet velocities are varied from the followings: 28.3, 30.0, 40.0, 50.0 m/s.

As shown in the Figure.3, a total of 81 measuring points are uniformly distributed on the roof, and 9 critical measuring points are marked with numbers. The time-varying mean wind pressure coefficient in moving downbursts is defined as

$$\bar{C}_{\text{P}i}(t) = \bar{P}_i(t) / \left(0.5\rho V_{\text{jet}}^2\right) \tag{10}$$

where $\bar{P}_i(t)$ and $\bar{C}_{\text{P}i}(t)$ are mean wind pressure and wind pressure coefficient of the *i*th measuring point, respectively.

The displacement of downburst is non-dimensionalized by the jet diameter.

$$l^* = V_{\text{t}} t / D_{\text{jet}} \tag{11}$$

where V_{t} is the translating speed.

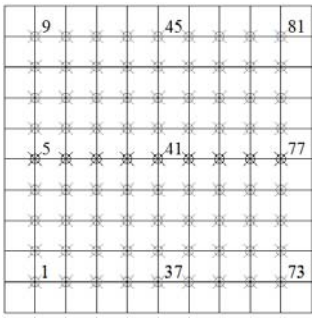

Figure 3. Layout of the measuring points.

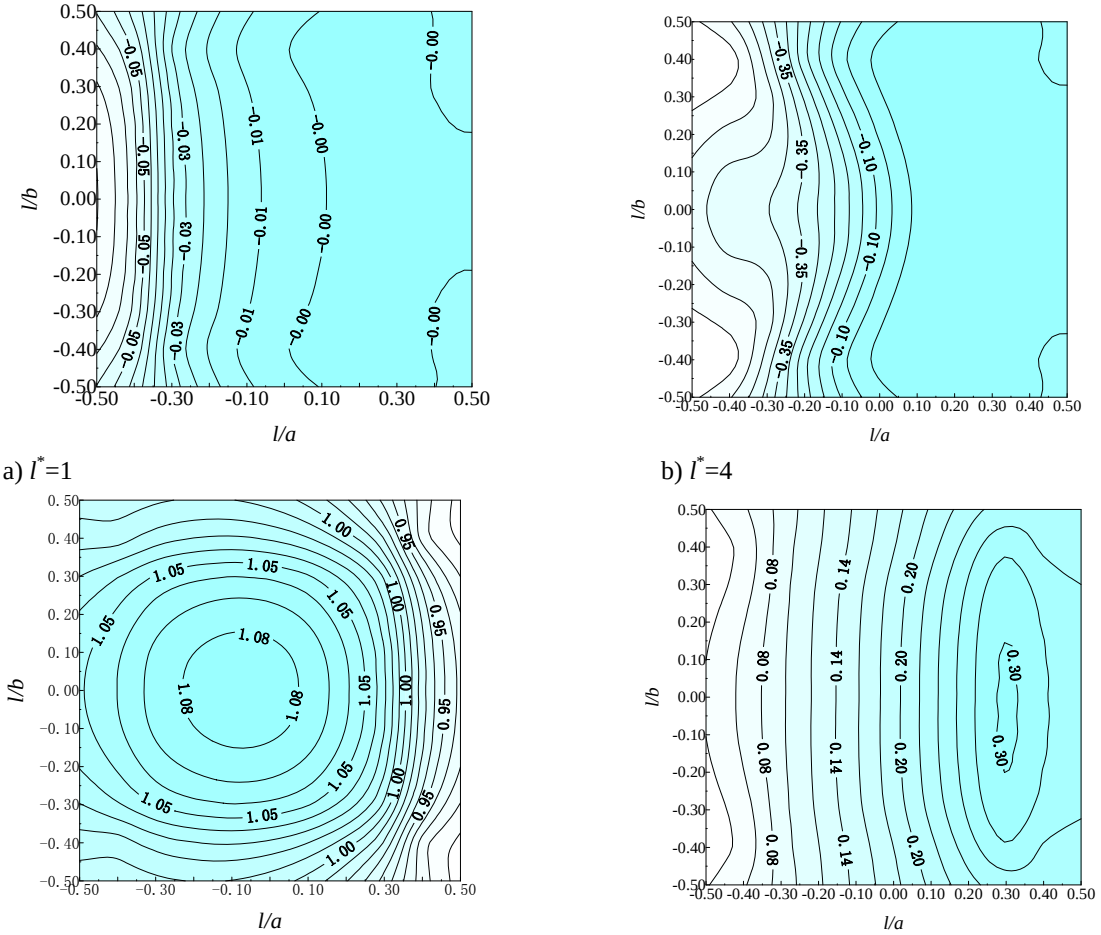
3.2 *Results*

At the initial time, the distance ($r_{\text{D-R}}$) from the center of downburst to the center of roof is $5D_{\text{jet}}$. Then, it would be varied with the motion of the downburst. Consequently, and the mean wind pressure distribution on the roof would be time varying. The mean wind pressure distribution on the roof varied with the motion of downburst is shown in Figure.4.



a) l^*=1 b) l^*=4

c) l^*=5 d) l^*=6

Figure. 4 Wind pressure distribution on the roof

While the downburst travels $1D_{jet}$, the roof is still far away from the downburst. The pressure of the most regions on the roof is nearly zero, whereas there is a relatively large negative pressure in the windward area. While the downburst travels $4D_{jet}$, that is say $r_{D\text{-}R}$ is equal to $1D_{jet}$, the pressure distribution is similar to the case of l^*=1, but the negative pressure area get bigger and the minimal negative pressure value become smaller. When the downburst travels $4D_{jet}$, the roof is quite under the center of the downburst, and the pressure distribution is significantly different from others. The whole roof is subjected to positive pressure and the maximum value is about 1.0. When the downburst travels $6D_{jet}$, $r_{D\text{-}R}$ is again equal to $1D_{jet}$, but the distribution is quite different from the case that l^*=1. The values of the pressures in whole roof are positive.

The time histories of mean wind pressures of the measuring points 1, 37, 73 (these three points is on the outmost side line), 5, 41, and 77 (these three points is on the middle line) are chosen to be surveyed. The time histories of mean wind pressure coefficients of all six measuring points for V_{jet}=47.5 m/s and V_t=10.0 m/s are shown in Figure 5. The trend of all six curves are similar, and they all reach their peak values around l^*=5.0.

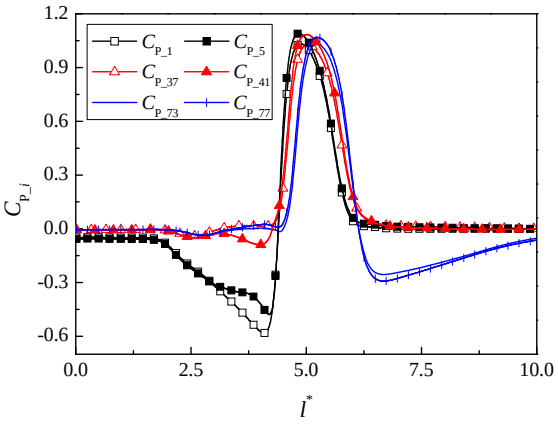


Figure. 5 Time histories of $\overline{C}_{Pi}$.

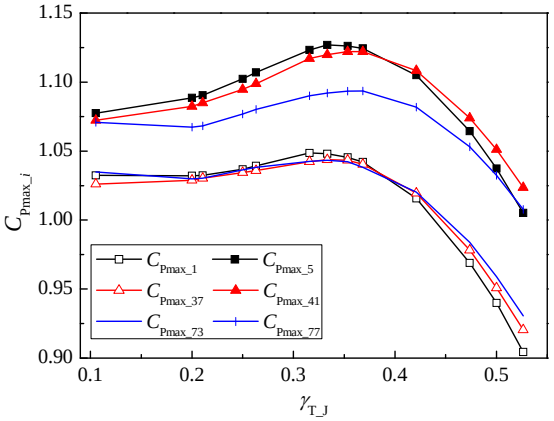

Figure. 6 γ_{T_J} versus the peak value of $\overline{C}_{Pi}$.

The relationship between the jet velocity ratios and the peak value of mean pressure coefficient are shown in Figure 6. It is shown that the peak pressure near middle line is greater than that near the side line. The peak pressure increases with the increment of the jet velocity ratio while the jet velocity ratio is less than 0.316. And it decreases in case of that the jet ratio is greater.

4 DYNAMIC RESPONSE OF THE ROOF

4.1 *Simulation of wind loading*

By using $\overline{C}_{Pi}$, it is easy to achieve the time history of mean wind pressure, according to Equation 10. Nevertheless, in order to conduct structural dynamic analysis, the fluctuation characteristics of wind should be considered. It is assumed that the quasi-steady assumption is still satisfied in a moving downbursts field. Accordingly, the fluctuation component of the wind pressure is proportional to the jet velocity. Thus, we have

$$P_i(t) = 0.5\rho V_J^2 \overline{C}_{Pi}(t) \tag{12}$$

where P_i is the wind pressure of the *i*th surface zone of the building, and V_J is the jet velocity with fluctuation. Note that the jet velocity is proportional to the wind velocity (or horizontal wind velocity) in the fluid field. It is known, DSHM is capable of simulating the horizontal wind velocity in the fluid field of moving downburst. It assumes that the wind speed could be decomposed into a mean wind speed and a fluctuating wind speed. That is to say

$$U(z,t) = \overline{U}(z,t) + \tilde{U}(z,t) \tag{13}$$

where $U(z,t)$ is the wind speed at position *z* and time *t*; $\overline{U}(z,t)$ is a deterministic function and means the mean wind speed; $\tilde{U}(z,t)$ is the fluctuation with zero mean and a stochastic process.

In DSHM, it is also assumed that the fluctuation can be obtained by a stationary random process multiplied by a modulation function. That is to say

$$\tilde{U}(z,t) = a(z,t)\lambda(z,t) \tag{14}$$

where $a(z,t) = 0.10\overline{U}(z,t)$ and is a modulation function; $\lambda(z,t)$ is a stationary Gaussian stochastic process, and could be numerically generated by utilizing the Kaimal spectrum, as shown in Figure 7.

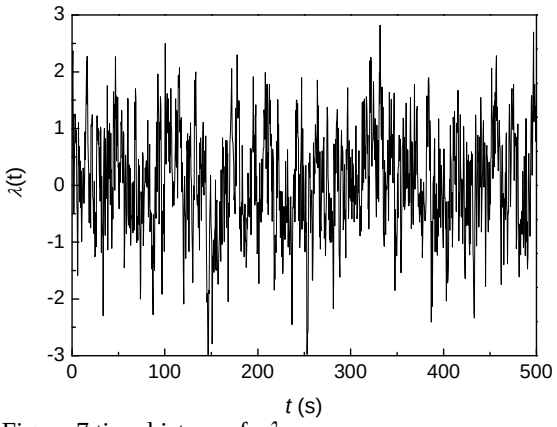

Figure.7 time history of λ.

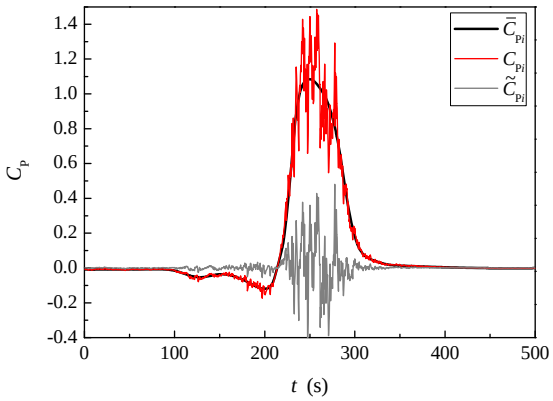

Figure.8 Time histories of wind pressure coefficients.

Note that $U(z,t)$ is proportional to V_J, we have

$$V_J = V_{jet} \cdot [1 + 0.1\lambda(t)] \tag{15}$$

By substituting Equation 15 into Equation 12, the time histories of wind pressure that contains the fluctuation could be attained. Then the wind pressure coefficient would be

$$C_{Pi}(t) = P_i(t) \Big/ \left(0.5\rho V_{jet}^2\right) \tag{16}$$

Figure 8 shows the time histories of three wind pressure coefficient C_{Pi}. And the fluctuation wind pressure coefficient in Figure 8 is defined as

$$\tilde{C}_{Pi} = C_{Pi} - \bar{C}_{Pi}. \tag{17}$$

Finally, the concentrated load on the *i*th node of the roof can be expressed as:

$$F_i(t) = P_i(t) \cdot A_i \tag{18}$$

where A_i is the represented area of the *i*th node.

4.2 *ABL wind load and the finite element model (FEM) of the roof*

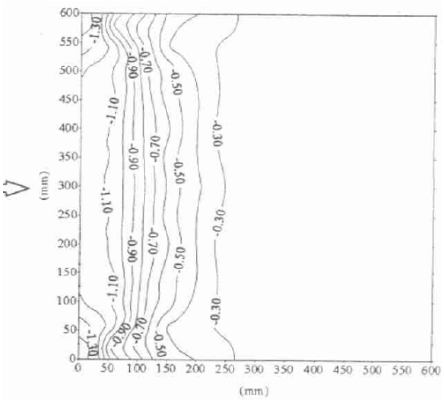

Figure. 9 Wind pressure distribution of the Lu's roof [14].

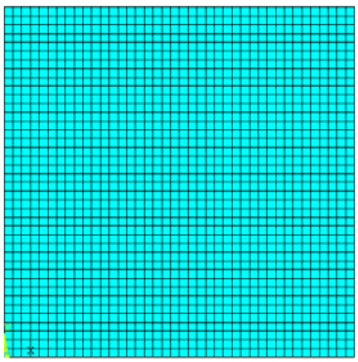

Figure. 10 Element division of the roof.

The result from a rigid model wind tunnel test for a roof, which is conducted by Lu [14], is tread as ABL wind load for the roof. The wind pressure distribution of the Lu's roof is shown in the

Figure9. In addition, Lu proposed an empirical estimation of gust loading factor that is a function of the natural frequency of the structure. It is

$$G_{\mathrm{GLF}} = -0.1348 f^5 + 1.0241 f^4 - 3.1205 f^3 + 4.855 f^2 - 4.046 f + 2.8668 \quad (19)$$

where f is the natural frequency.

The dynamic response of the roof is analyzed in ANSYS 10.0. The roof is simply supported on four sides, and the effects of primary and secondary beam are ignored. The elastic modulus and Poisson's ratio are, respectively, 3.0×10^{10} N/m^2 and 0.31, and the damping ratio of the roof is 0.05. The roof is divided into 1600 element, by using the shell 63.

According to the shell theory, the frequencies of plate are affected by its thickness and surface density. The thickness and density of the roof are changed to get the different natural frequency. Totally, 9 plates are studied and their natural frequency varied from 0.467 Hz to 2.015 Hz.

4.3 *Results and discussion*

With consideration of a moving downburst whose jet velocity and translating speed are 47.5 m/s and 10 m/s respectively, the time histories of displacement and acceleration at the middle of the roof are shown in Figure11 and Figure 12 respectively. In case of moving downbursts, larger displacement and acceleration are observed. The parameters of the moving downburst in following Figures 13-16 are fixed at that V_{jet}=47.5 m/s and V_{t}=10 m/s.

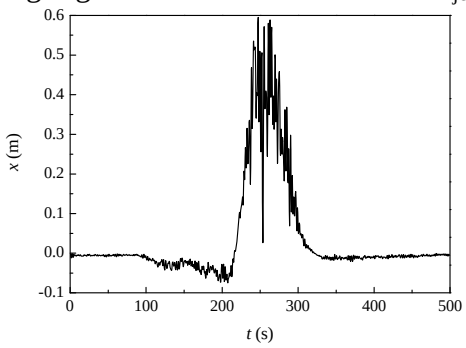

Figure. 11 Time history of the displacement.

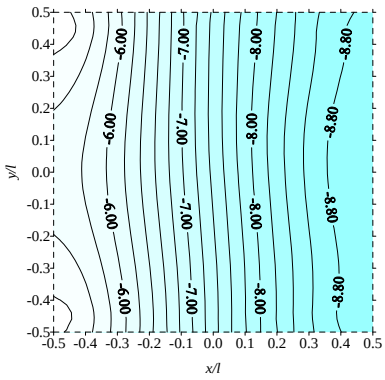

Figure. 13 distribution of G_{DB0} on the roof.

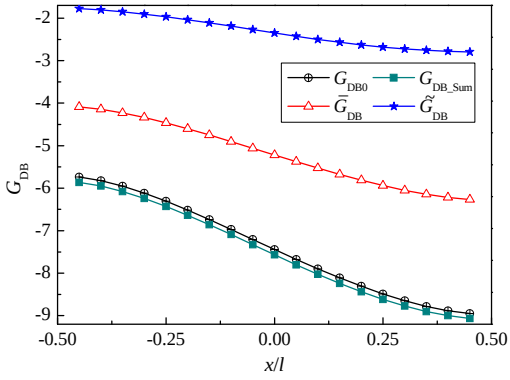

Figure. 14 G_{DB} on the along-wind middle line.

Figure 13 shows the distribution of G_{DB0} on the roof. G_{DB0} is obtained directly according to Equation 2, and is designated as direct downburst factor. Figure 14 shows four kinds of downburst factors of the along-wind middle line. The four downburst factors increase with the in-

crease of x, and the synthesis downburst factor is close to the direct downburst factor. So the dynamic response of downburst on structure could be decomposed into two parts: mean and fluctuation. Additionally, the absolute value of the direct downburst factor are quit larger than 1. It means that the effect of the moving downburst is quit larger than that of ABL wind.

Figure.15 shows the distribution of G_{DB0} and $G_{\mathrm{DB}i}^{D}$ on the along-wind middle line. The G_{DB1}^{D} is a constant at any point. With the increase of the order, the $G_{\mathrm{DB}i}^{D}$ gets closer to the G_{DB0}. The curves of $G_{\mathrm{DB}i}^{D}$ intersect at the middle point of the roof (x/l=0). It means that using the first mode would accurately capture the factor for the center point, whereas first four modes should be taken into consideration for the other locations.

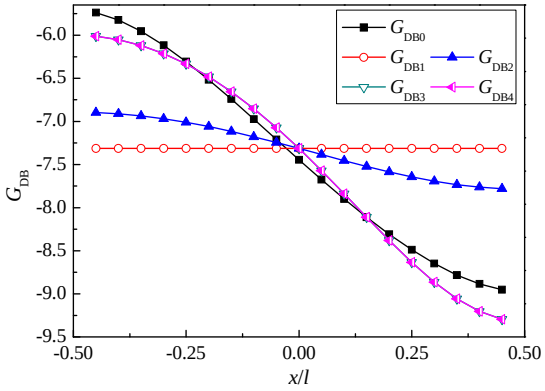

Figure. 15 Comparisons of G_{DB0} and $G_{\mathrm{DB}i}^{D}(z)$.

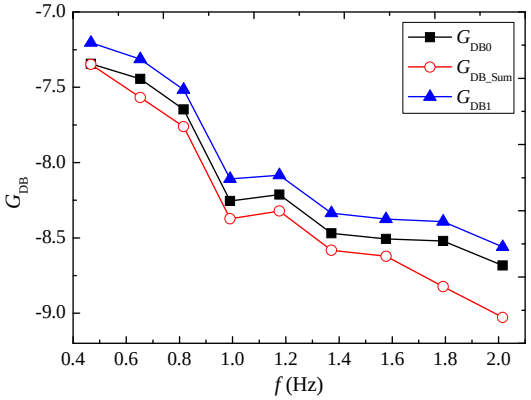

Figure. 16 G_{DB} Varied with natural frequency.

Figure.16 shows the variation of G_{DB0}, $G_{\mathrm{DB\_Sum}}$ and G_{DB1}^{D}, at the middle point of the roof, with the natural frequency of the roof. It is observed all three downburst factors increase with the increasing of natural frequency.

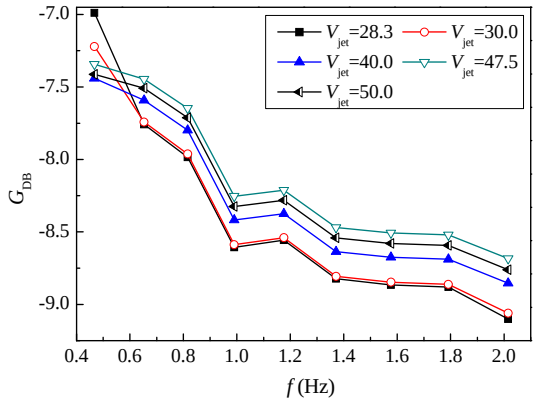

Figure. 17 G_{DB0} varied with jet velocities

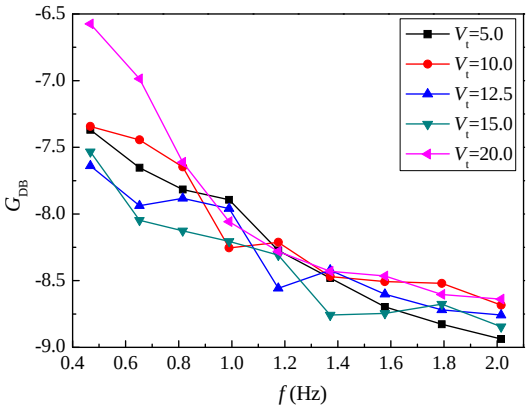

Figure. 18 G_{DB0} varied with translating speeds

Fixing the translating speed at V_{t}=10 m/s, Figure 17 shows the variation of G_{DB0} of the center-point with jet velocities and the natural frequency of the roof. The absolute value of downburst factor increases slightly with the increase of V_{jet} in a range of 28.3 to 50 m/s. Also it increases with the increasing of natural frequency.

Fixing jet velocity at V_{jet}=47.5 m/s, Figure18 shows the varying of G_{DB0} of the center-point with the natural frequency of the roof. The absolute value of downburst factor increases with the increasing of natural frequency, whereas it has little correlation with the translating speed.

5 CONCLUTIONS

In the determination of the wind loading, the wind pressure on the building surface, which is acquired through numerical moving downbursts test, is employed directly. For the purpose of ensuring that the simulated fluctuation component of wind velocity coincides with the field observation, it is assumed that the quasi-steady assumption is satisfied during the simulation of fluctuation component of the wind pressure. Accordingly, the wind pressure simulated would more accurately represent the fluid-structure interaction.

The variation of the wind pressure distribution on the roof with the moving of the downburst is surveyed. It is found that the wind pressure would reach its peak value in case of the center of the roof coinciding with the center of downburst. It is also found that the maximum wind pressure coefficient is merely related to the ratio of jet velocity ratio to translating speed.

In order to compare the results with that obtained from ABL wind, the downburst factor, which is the ratio of the maximum displacement response due to moving downbursts to that due to ABL wind, is introduced. The study revealed that using first four modes would satisfy the accuracy requirement in downburst factor computing, whereas first one mode merely could be utilized to computing the downburst factor of the center-point of the roof. It is found the downburst factor is in a range of 6.5 to 9.0, which means that a moving downburst would cause a serious vertical response. Furthermore, the factor would increase with the increment of the natural frequency of the structure.

Database-assisted design for large span roofs

Ying SUN, Yue WU and Shi-Zhao SHEN

School of Civil Engineering, Harbin Institute of Technology, Harbin 150090, China

ABSTRACT: With the almost limitless possibilities of building shapes, the randomness and time-space correlation of wind loading for large span roofs, the characteristics of wind loading will rarely understood or reached by a researcher or a designer. The determination of wind loading becomes key problem during structural design of space structures. This necessitates the development of Database-assisted Design (DAD) method for large span roofs. The DAD approach entails the use of large databases of aerodynamic pressures. In this paper, wind loading models for fluctuating pressure are statistically summed up and sorted into wind loading database system, which can be able picked up by building designers. The program frame and application of wind loading database system are also introduced in this paper.

KEYWORDS: *wind loading database, large span roofs, characteristics of wind pressure, database-assisted design.*

1 INTRODUCTION

Wind loading on large-span roofs is influenced not only by approaching flow, but also by body-induced turbulence. The quasi-steady assumption is not applicable in this condition. The complexity of wind loading on large span roofs stems from its variability of building shape, time/space and spatial characterization of pressure fluctuations. It is blank for wind loading guide for large-span roofs in wind loading standard and codes in China.

In the past, the scientific data used to disseminate in summary form through published papers or reports. Until 1990s, there emerged some expert systems as guideline of design for simple structures, which was only based on logic judge depending on developer's understanding and lack of robust practicability. Recently, with the development of software and hardware, wind loading database technique has great promotion. Database-assisted design for wind loads is in a state of development. Time series of instantaneous pressure distributions for different wind directions are an essential component of the database. Measurements with SM-PSSs have made pressure (aerodynamic) databases accessible for simple low-rise buildings. Exploratory studies of database-assisted design have demonstrated that such designs can be risk-consistent and may be more resistant to damage as well as more economical. Use of BLWT tests with SM-PSS data acquisition for creation of pressure databases is expected to increase for some classes of building geometry. In this paper, wind loading models for fluctuating pressure are statistically summed up and sorted into wind loading database system, which can be picked up by building designers expediently. The program frame and application of wind loading database system are also introduced in this paper.

2 THE DESIGN OF WIND LOADING DATABASE SYSTEM FOR LARGE SPAN ROOFS

The function of Wind Loading Database System (WLDS) is to collect wind loading data of all kinds of structures, summarize and sort these data into reasonable wind loading models, which can become a convenient reference for the wind-resistant design of structures.

The Wind Loading Database System (WLDS) has the following advantages compared with the

traditional method:

(1) Compared with the wind loading design code, WLDS has greater amount of information and more accurate representation of data. Moreover, it facilitated people's queries greatly;

(2) Although the preliminary work to establish the database system is heavy, the WLDS will lead to much lower cost and shorter design cycle in the using process;

(3) The system has flexible modular construction, which make it easy to develop and manage. We will add some artificial intelligence module so that to achieve the forecast of wind load of undocumented shapes;

(4) We can realize the procedural structure of wind-resistant design by combining the WLDS and structural analysis/design software.

The main works of the establishment of WLDS are as follows:

(1) **Data collection**. Mainly from: wind tunnel test data, national load standards, relevant published papers and tests results of CFD simulation;

(2) **Data analysis**. For the data collected in different way is often disorganized and incomplete. The role of the data analysis is to extract the identifiable and useful information such as the probability density distribution of pulse wind pressure, power spectrum information and spatial correlation information, which can greatly reduce data storage space and improve efficiency. The key work of this part is to build a universal wind loading roof model so that we can achieve accurate description of the wind load on roof by identifying several characteristic parameter;

(3) **Data representation**. This part of work like a bridge that connect the database system and user. The designer want to get the most direct and concise form of information while not the complex internal database system. Therefore, it's an important part to improve the availability of the system.

2.1 *The design of function modules*

According to the above ideas, the WLDS should have the following basic functions:

(1) Store and effectively organize data of different basic-shape structures;

(2) Achieve the visualization of data, especially for the wind tunnel test data;

(3) Compare similar structures with different parameters (consult relevant design code and paper) and get the variation trend of wind load according to different parameters, which could help to establish the numerical model of wind load in the future;

(4) Make statistical analysis for the pulse component of the wind load in order to provide a theoretical basis for the structure wind vibration response;

(5) The neural network will be added and wind pressure prediction mechanism will be established.

The wind loading database system should include the following modules based on the above features: data input module, data analysis module, additional modules and output module.

2.2 *Interface design*

In order to make efficient Wind Loading Database System, We use Visual C++ and MySQL compile the analysis module and input module, which achieve inter-invocation of different parts. The data input system was designed in accordance with features such as simple interface, complete content and easy-to-search (see Figure 1). The system is divided into seven menu bars:

standard options, wind information, structure information, design type, result display, system query and help system. In addition, there are some shortcut icons lead to different graphics and data query interface quickly. The relevant site (http://wlds.hit.edu.cn) built up by JSP+MySQL was designed as dynamic web site, which gain the following advantages: small and delicate code, easy maintenance, high efficiency and high adaptability. All of the above make the system easy to deal with the problems such as the data entry, inquiry, editing operation, see Figure 2.

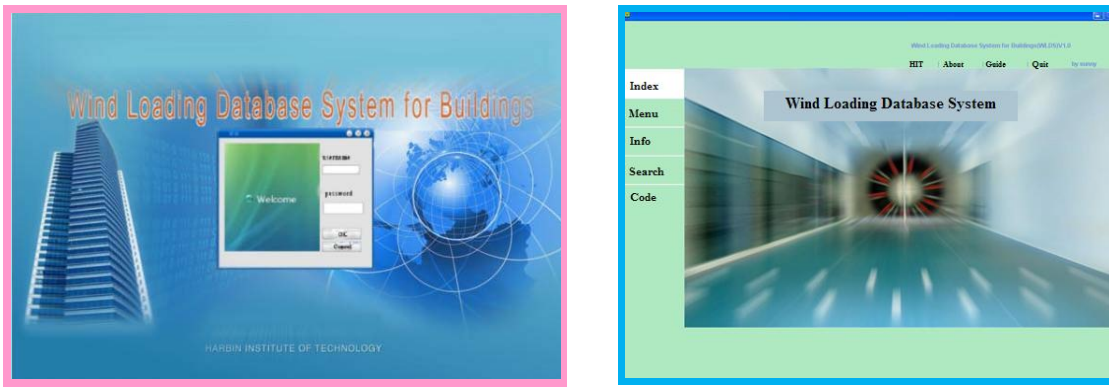

Figure 1 The interface of WLDS

Figure 2 The web page of WLDS for Large-span roof (http://wlds.hit.edu.cn)

3 THE CHARACTERISTICS OF WLDS FOR LARGE-SPAN ROOF

Based on previous research, we can find the flow around large-span roofs has the following features:

(1) Most of wind load on the roof surface is suction. The wind suction is larger near the front of blunt body shape roof and the suction decreases with the increase of distance to the front part. It indicates that the vortex shedding caused before the front of roof is the key factor of the wind load characteristics.

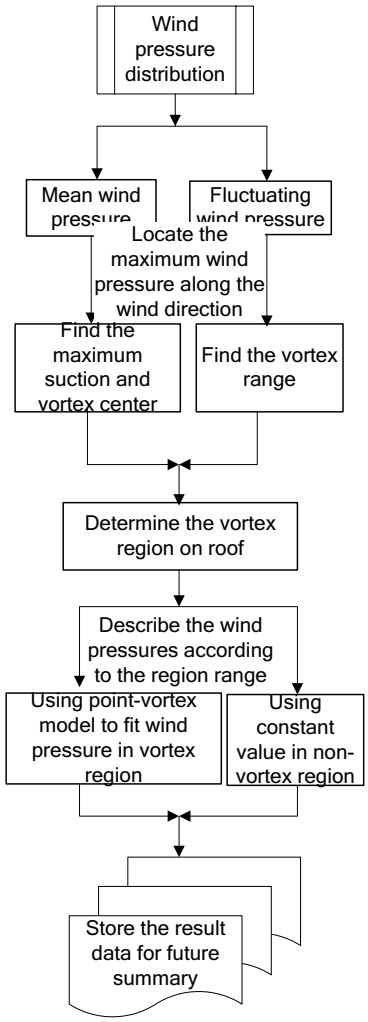
(2) The wind angle has important role in the wind load on roof. The flow separation, vortex shedding phenomena and the position of the maximum wind pressure are different under different wind directions. Therefore, the most adverse wind direction angle of wind load

effect should be took attention in design.

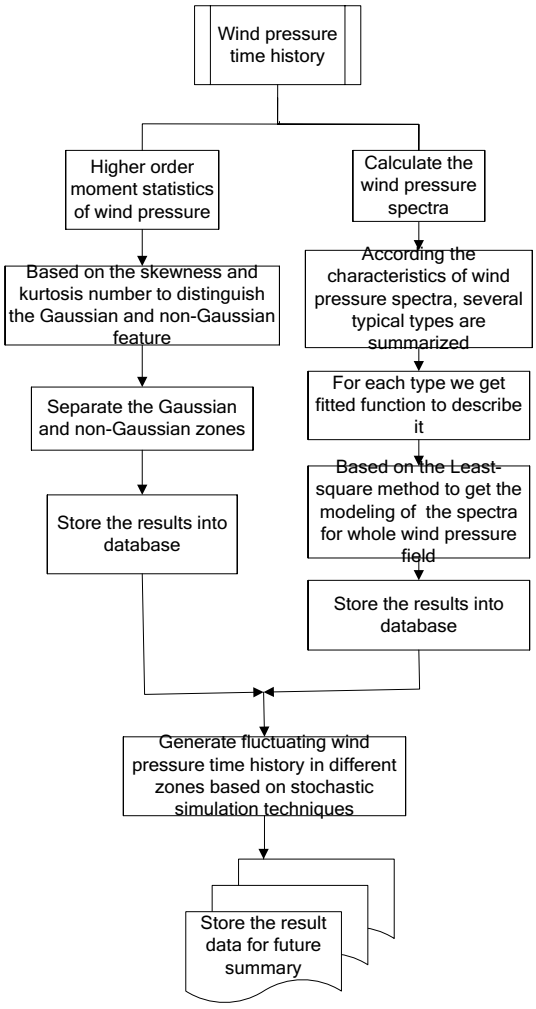
(3) Wind load is sensitive to the change of curvature/slope of the roof.

(4) The flow wind speed, turbulence and rise-to-span ratio is less important to the distribution of overall wind pressure on roof. But these parameters will influence the local wind pressure.

According to the above wind tunnel test results and relevant paper, the large-span roofs can be classified into the following basic shapes: closed straight edge building (Bluff body), closed curved edge building, open buff body building. Body-induced turbulence is the main feature of wind load on the first type of roof. The separation to attach phenomenon is obvious (most are featured as cylinder vortex and conical vortex) in the incoming flow. Flat roof and saddle-shape roof are typical examples. Wind load on the second type of roof will not happen a lot of flow separation effect,. Distribution of wind load is parallel to the shape of roof edge such as spherical shells and round flat roof. The wind load on the third type of roof is complex because of the combined influence of wind pressure on upper and lower surfaces. But most of the open buff body buildings have relevant simple geometry shape, the flow field around them could be simplified into 2D forms. Typical example is cantilevered roof.



(a) mean wind pressure



(b) fluctuating wind pressure

Figure 1 The use of WLDS

3.1 *Description of mean wind loading*

First of all, the mean wind pressure and distribution of fluctuating wind pressure on the roof surface are got based on the wind tunnel test data. Secondly, we can get the position of maximum wind suction and the position of maximum wind pressure fluctuation value by slice the pressure profile along the line that perpendicular to the windward roof, which are the centre and edge of the vortex correspondingly. Then we will investigate the trends of maximum wind suction values on the vortex axis and provide basis for the derivation of wind pressure model. Thirdly, we can define the vortex region on roof according to the above research. Fourthly, we can get fitted parameters by using point vortex model to describe the data in the vortex region and use constant value out of the vortex area. Finally, the results are sorted into the database for future comparison and usage. The operation is shown in Figure 3a.

3.2 *Modelling of fluctuating wind load*

The fluctuating characteristics of roof wind pressure are influenced by both approaching turbulence and body-induced turbulence. According to the analysis of wind pressure distribution and wind pressure spectrum, we get the fluctuating feature of different zones on the roofs and make sure the contribution of different turbulences. So we can build up wind pressure spectrum model including influence of approaching turbulence and body-induced turbulence. Since numerical simulations of fluctuating wind pressures are different in Gaussian zone and non-Gaussian zone, the descriptions of wind pressure model should be different based on Gaussian and non-Gaussian zones. Firstly we get high-order statistical moment of wind pressure time series on measure points of roof. The description of the fluctuating wind load need to consider each-order statistical moment of wind pressure time series, Gaussian/non-Gaussian zone partition, wind pressure spectra formula and the accumulation of a large amount of data. For the specific operation procedure, refer to Figure 3b. In addition, because the overall correlation of wind pressure on large-span roof is weak and it's hard to find the law of the correlation, the spatial correlation of the pulse wind pressure model is not list in this paper.

4 CONCLUSIONS

This paper introduce the main flow of WLDS for large-span roof ; make discussion about main function modules, data storage method, data analysis and comparison, process of the usage of system. Make discussion about some technical difficulties of the system. This work will help the development and further supplement of the WLDS for large-span roof.

Structural optimization of long span portal-rigid frames under wind action

J. R. Wu [a], C. C. Dong [a], A. Xu[a], J. Y. Fu [a]

[a] *School of Civil Engineering, Guangzhou University, Guangzhou, China*

ABSTRACT: A procedure for wind-resistant optimization design of long-span portal-rigid frame was proposed in this paper by adopting the Optimality Criteria (OC) method and SAP2000 Application Programming Interface (API) for Matlab developing environment. The Equivalent Static Wind Load (ESWL) for the long-span portal–rigid frame was obtained from the measured wind pressure from wind tunnel tests and application of Load Response Correlation (LRC) method. The virtual-work principle was utilized to construct the wind-induced displacement constraint condition. A rigorously derived iteration procedure was proposed to obtain the optimized minimum sections of long-span portal frames while satisfying all the constraint conditions. The optimized results from different types and combinations of ESWL were compared with those corresponding optimization results from wind load by Gust Loading Factor (GLF) method. The effect of connection stiffness of semi-rigid joint and the stiffness of support restraint on the optimization results were also discussed. Only a few iteration numbers for convergence were found in the proposed optimization procedure, and comparison results showed that the OC procedure proposed in this paper was very effective for the wind-resistant optimization design for such long-span portal-rigid steel frames.

1 INTRODUCTION

The low-rise buildings with long-span portal steel frames represent one of the most commonly used structures in commercial and industrial applications. As its long-span, small dimension in cross section and varied height of elements in form of tapered section, the wind loading and wind-induced response are the major factors to be considered for the structural design of such buildings. They have traditionally been designed for wind loads by using simplified code and standard procedures which involve a series of reductive tables and plots that were determined from summary research information or design experiences [1]. It is now practical to incorporate aerodynamic databases and allow the calculation for routine designs of considerably more realistic wind load effects than those based on conventional methods [2].

In the meantime, the design process for such structures is time-consuming. Satisfying strength, stability and flexibility constraints for such structures under wind action is very complex, and is often not done at all or done poorly. For every change in a statically indeterminate structure, a redistribution of internal force occurs which cannot be accurately predicted without reanalyzing the structure. This makes it impossible to determine member sizes in a single step, and iterative methods are required. Even though great advances have been made in automating the design process [3], an effective structural optimization method is not available for such structural systems under dynamic wind action. Structural optimization of structures under seismic load has been ongoing for the past few decades. Truman and Petruska proposed the Optimality Criteria (OC) method for 2D structures using linear elastic time history analysis procedures coupled with actual seismic base excitations [4]. Different earthquake records were considered and

the dynamic responses of structures were monitored at each time step. Compared with structural optimization of structural systems under static load, the wind resistant optimization design of long span portal frame system under dynamic wind loading is much more expensive. As the time variable is typically involved in linear dynamic response optimization, the objective function and the constraints are typically time-dependent functions. Theoretically, the structural optimization process should be conducted at each time instant for dynamic response optimization. Peak values of those functions are usually considered in optimization. Various methods exist to handle the peak values by modifying the conventional methods for linear static response optimization.

On the other hand, optimization methods using Equivalent Static Loads (ESLs) have been proposed to solve various structural optimization disciplines. The disciplines include linear dynamic response optimization [5]. In the equivalent loads method, ESLs are evaluated from the displacement field, the dynamic external loads are transformed to the Equivalent Loads (EL) for linear static analysis, and linear response optimization is carried out based on the EL. The design is updated by the results of linear response optimization.

Most of the modern structural synthesis methods can be classified as being one of two major approaches. One is based on Mathematical Programming (MP) techniques, while the other uses Optimality Criteria (OC). The OC approach has gained tremendous popularity due to its high efficiency. The approach is particularly suitable for large-scale structures since it only has a weak dependence on the size of the structure [6]. Moreover, the convergence of the OC approach does not depend on the starting design and weakly depends on the number of design variables. Chan et al. developed a virtual work formulation approach for wind induced serviceability design of tall buildings [7]. The virtual work expression represents a good approximation of the behavior constraints. Furthermore, the explicit approximate formulation is sufficiently accurate so that this generally leads to smooth and rapid solution convergence. Another advantage of the virtual work formulation approach is that the existing finite analysis software can be directly employed based on internal element forces and moment readily available by common structural analysis programs such as SAP2000 so that the approach can be applied to large scale building structures.

A wind-resistant structural optimization procedure for long-span portal rigid steel frame with tapered section was proposed in this study based on the OC method and the combined SAP2000 Application Programming Interface (API) [8] for Matlab developing enviorment. With the obtained ESWLs, the structural optimization of structures under dynamic wind load was transformed to the integrated process of updating ESWLs and structural optimization under static load. A rigorously derived iteration procedure was selected to obtain the optimized minimum sections of long-span portal frames while satisfying all the constraint conditions. The effect of semi-rigid stiffness of connection joint and the stiffness of support restraint on the optimization results were also discussed.

2 MATHEMATICAL MODEL OF STRUCTURAL OPTIMIZATION IN LONG-SPAN PORTAL RIGID STEEL FRAME WITH TAPERED SECTION

2.1 *Mathematical model of structural optimization*

In order to conduct the wind resistant optimization design of long-span portal steel frame, a mathematical model of structural optimization should be first established, which mainly includes the design variables, constraint conditions and objective functions. For the specified case in this study, the objective function is normally adopted by minimizing the total weight of all the structural elements in the studied structural system, which can be formulated in the following form:

$$W = \rho \sum_{i=1}^{N} L_i (2 w_i^F t_i^F + \frac{t_i^W}{2} \sum_{j=1}^{2} D_{ij}^W) \quad (1)$$

where ρ is the material density, L_i is the length of the *i*-th element, w_i^F, t_i^F, t_i^W are the corresponding width, thickness of flange and the thickness of web for the *i*-th element, D_{i1}^W and D_{i2}^W are height of the web for the ***i***-th element with taped section. *N* is the total number of the design variables.

The constraint conditions were usually selected by limiting the wind-induced displacements as they can reflect the wind effects of studied structure directly. Therefore the wind-induced horizontal displacement (g_1) atop of the column and vertical displacement (g_2) at the mid-span of rafter were set to meet the following constraint conditions:

$$g_k \le g_k^U \quad (k=1, 2) \quad (2)$$

The displacement constraints described in Eq. 2 can be obtained from the following equation by the virtual work principle [7].

$$g_k = \sum_{i=1}^{M} \int_0^{L_i} (\frac{F_{Xk} f_X}{EA} + \frac{F_{Yk} f_Y}{GA_Y} + \frac{F_{Zk} f_Z}{GA_Z} + \frac{M_{Xk} m_X}{GI_X} + \frac{M_{Yk} m_Y}{EI_Y} + \frac{M_{Zk} m_Z}{EI_Z}) dx \quad (k=1,2) \quad (3)$$

where *M* is total structural elements in the optimized structure, *E* and *G* are the elastic and shear modulus of the steel material, A, A_Y, A_Z are the area of cross section, the shear areas about two major axis of cross section respectively. GI_X, EI_Y, EI_Z are torsional stiffness and flexural stiffness for the design section, F_{Xk}, F_{Yk}, F_{Zk}, M_{Xk}, M_{Yk} and M_{Zk} are the internal forces resulted from the applied unit force in the direction at the specified displacement, while f_X, f_Y, f_Z, m_X, m_Y and m_Z are the internal force (axial force, shear force and bending moment in the direction of three major axes) induced from external wind loading.

All the above mentioned internal forces of the elements could be obtained from the finite element analyzed results by SAP2000 API. As the geometry properties could be expressed in the function of a series of design variables, the integration and derivation of the constraint conditions in Eq. (3) with the design variables could be solved easily by the corresponding internal functions in Matlab software system.

For a reasonable optimization design result, the lower and upper bounds of design variables should be defined which are expressed by the following unequal formula:

$$X_i^{\min} \le X_i \le X_i^{\max} \quad (i=1, 2 \ldots N_d) \quad (4)$$

where N_d is the total number of design variables, X_i is the *i*-th design variable, $X_i^{\min}$, $X_i^{\max}$ are its corresponding lower and upper bounds, which is usually obtained from the local, global stability and strength check by the local steel structural design code.

2.2 *Optimality criteria method in structural optimization*

In order to obtain the optimized results, solution for the objective function specified in Eq. (1) should be proposed by the suitable structural optimization method. An effective approach for optimal element sizing design of large-scale structures was adopted in this study, which was based on the Optimality Criteria (OC) method and has been shown to be particularly suited to the design of structural systems with many design variables [6]. A Lagrange function was first con-

structed by combining the objection function and constraint functions with a series of Lagrange multipliers in the following form:

$$L(X_i, \lambda_k) = W(X_i) + \sum_{k=1}^{m} \lambda_k (g_k - g_k^u) \tag{5}$$

where the λ_k is the Lagrange multiplier for the *k*-th constraint function, *m* is the total constraint conditions in the optimization case.

Rather than using an intuitive optimality assumption; the Karush–Kuhn–Tucker (KKT) necessary condition is rigorously derived and employed in the OC method. For KKT condition, Differentiating Eq. (5) with respective to the design variable X_i and rearranging terms to obtain the stationary conditions:

$$(-\sum_{k=1}^{m} \lambda_k \frac{\partial g_k}{\partial X_i}) / \frac{\partial W}{\partial X_i} = 1 \qquad (i=1, 2 \ldots N_d) \tag{6}$$

A recursive algorithm is applied to drive an initial design for satisfying Eq. (6). Multiplying both sides of Eq. (6) by X_i and taking the η-th root, then applying a first-order binominal expansion to obtain the linear recursive relations

$$X_i^{\upsilon+1} = X_i^{\upsilon} \{1 + \frac{1}{\eta}[(-\sum_{k=1}^{m} \lambda_k \frac{\partial g_k}{\partial X_i}) / \frac{\partial W}{\partial X_i} - 1]\}_{\upsilon} \tag{7}$$

where υ+1 and υ indicate the successive iterations, and η is a step-size factor whose value is assumed to 3 in this study. Before the value of design variable $X_i^{\upsilon+1}$ could be found, the unknown Lagrange multipliers λ_k (*k*=1, 2, …, *m*) must first be determined. Considering the change $(g_k^{\upsilon+1} - g_k^{\upsilon})$ in the *k*-th constraint due to the change $(X_i^{\upsilon+1} - X_i^{\upsilon})$ in the design variables, the following expression could be obtained

$$g_k^{\upsilon+1} - g_k^{\upsilon} = \sum_{i=1}^{N} (\frac{\partial g_k}{\partial X_i})(X_i^{\upsilon+1} - X_i^{\upsilon}) \tag{8}$$

Supposing that the *k*-th becomes active after the (υ+1)th iteration so that $g_k^{\nu+1} = g_k^U$, then substituting Eq. (7) into Eq. (8) and rearranging terms to obtain a set of simultaneous equations, it can be expressed in the following

$$\sum_{s=1}^{m} \lambda_s^{\upsilon} (\sum_{i=1}^{N} \frac{\frac{\partial g_k}{\partial X_i} \frac{\partial g_s}{\partial X_i}}{\frac{\partial W}{\partial X_i}}) = -\sum_{i=1}^{N} (\frac{\partial g_k}{\partial X_i})_{\upsilon} X_i^{\upsilon} - \eta (g_k^U - g_k^{\upsilon}) \tag{9}$$

During the evaluation of the OC iterations using Eq. (7), some design variables may be found to exceed their limitations defined in Eq. (4). If these cases occur, they are not allowed to change any further and are deemed to be inactive. Therefore Eq. (9) is modified to include only active design variables in the design optimization in the following form

$$\sum_{s=1}^{m} \lambda_s^{\upsilon} (\sum_{i=1}^{Na} \frac{\frac{\partial g_k}{\partial X_i} \frac{\partial g_s}{\partial X_i}}{\frac{\partial W}{\partial X_i}}) = -\sum_{i=1}^{Na} (\frac{\partial g_k}{\partial X_i})_{\upsilon} X_i^{\upsilon} - \eta (g_k^U - g_k^{\upsilon}) \tag{10}$$

where N_a is the current number of active design variables, the solution of the set of simultaneous equations defined in Eqs. (9) and (10) could be obtained by Gauss-Seidel iteration method. Once $\lambda_k^{\tau+1}$ is found to be less than zero, it indicted that the *k*-th constraint is an inactive con-

straint, then $\lambda_k^{\tau+1}$ is set to be zero during the iteration process. The whole set of recursive formulae for the set of simultaneous equations could ne expressed in the following form:

$$\lambda_k^{\tau+1} = (1/a_{kk})(b_k - \sum_{s=1}^{j-1} a_{ks}\lambda_k^{\tau+1} - \sum_{s=k+1}^{m} a_{ks}\lambda_k^{\tau}) \qquad (k=1, \cdots, m) \tag{11}$$

where k and s are k-th and s-th constraints, $\tau+1$ and τ are two successive iterations of the Gauss-Seidel process and

$$a_{kk} = [\sum_{i=1}^{N} (\frac{\partial g_k}{\partial X_i}\frac{\partial g_k}{\partial X_i} / \frac{\partial W}{\partial X_i})]_\tau \quad a_{ks} = [\sum_{i=1}^{N} (\frac{\partial g_k}{\partial X_i}\frac{\partial g_s}{\partial X_i} / \frac{\partial W}{\partial X_i})]_\tau \quad b_k = -\sum_{k=1}^{N} (\frac{\partial g_k}{\partial X_i})_\upsilon X_i^\upsilon - \eta(g_k^U - g_k^\upsilon) \tag{12}$$

It is noted that the ESWLs for optimized structure are also changed if the design variables are modified in each optimization design cycle. Thus the updating ESWLs must conducted at the first step during each design cycle, which is different from the structural optimization for structures under only static load. Meanwhile the derivation of each constraint could be conducted by utilizing Eq. (3) through SAP2000 API and MATLAB symbolic calculation module in MATLAB developing enviorment.

3 THE PROCESSING OF DYNAMIC WIND LOADING

3.1 *The characteristics of wind loading on long-span portal frame system*

For long-span portal frame system, the wind-induced displacement under dynamic wind loading is mainly contributed from the background response. In this case, the resonant response is negligible, the Load Response Correlation (LRC) method can be used to obtain the ESWLs from the mean and background components.

3.2 *Equivalent Static Wind Loads* (*ESWLs*)

Based on the LRC method of Kasperski and Niemann[9], the ESWLs for long-span portal frame system could be obtained from the following formula

$$[p(z)]_{\hat{r}} = \overline{p}(z) + p_B(z) = \overline{p}(z) + g_B\rho_{pr}(z)\sigma_p(z) \tag{13}$$

where g_B is the peak factor, $\overline{p}(z)$ is the mean wind load, $\sigma_p(z)$ is the standard deviation of the fluctuating wind load, $\rho_{pr}(z)$ is the correlation coefficient between the fluctuating wind load $p'(z)$ and the specified wind-induced response (r), which could be expressed in the following

$$\rho_{pr}(z) = \frac{\sigma_{pr}}{\sigma_p(z)\sigma_{r,B}} = \frac{p'(z,t)\int_0^L p'(z_1,t)I_r(z_1)dz_1}{\sigma_p(z)\sigma_{r,B}} \tag{14a}$$

$$\sigma_{r,B} = \left[\int_0^L\int_0^L \overline{p'(z_1,t)p'(z_2,t)}I_r(z_1)I_r(z_2)dz_1dz_2\right]^{1/2} \tag{14b}$$

where "B" denotes the background response, "L" denotes the length of structural element, $I_r(z)$ is the influence coefficient, i.e. the value of r when a unit load is applied at position z. If the structural system is divided into several discrete elements, Eqs. (14a) and 14(b) can be rewritten as a finite summation:

$$\rho_{pj,r} = \frac{\sum_{j=1}^{N} \overline{p_i'(t)\,p_j'(t)}\beta_i}{\sigma_{pj}\sigma_{r,B}} \tag{15a}$$

$$\sigma_{r,B} = \sum_{i=1}^{N}\sum_{j=1}^{N} \overline{p_i'(t)\,p_j'(t)}\beta_i\beta_j \tag{15b}$$

Then the ESWLs defined in Eq. (13) can also be written as a finite summation:

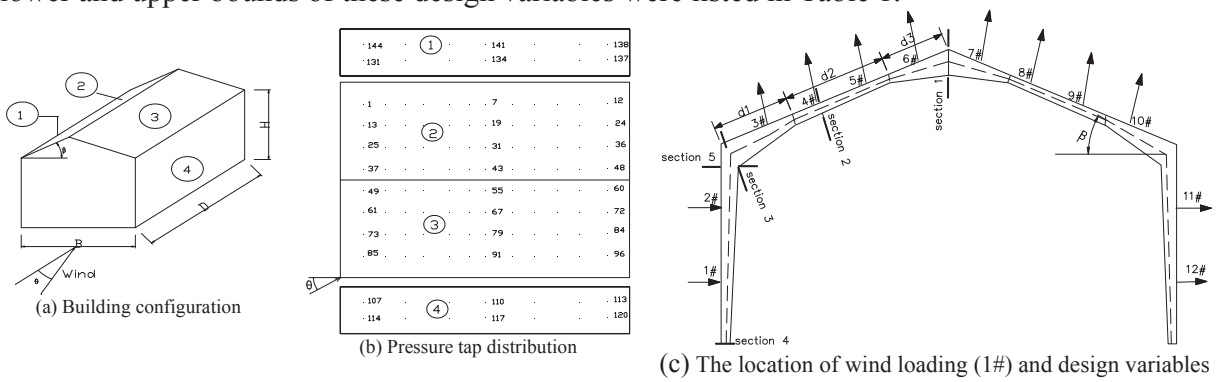
$$P_{B,j} = g_B \rho_{pj} \sigma_{pj} = \frac{\sum_{i=1}^{N} \overline{p_i'(t) p_j'(t)} \beta_i}{\sigma_{r,B}} = \frac{\sum_{i=1}^{N} \overline{p_i'(t) p_j'(t)} \beta_i}{\sum_{i=1}^{N} \sum_{k=1}^{N} \overline{p_i'(t) p_k'(t)} \beta_i \beta_k} \tag{16}$$

where i and j are element no., N is total number of elements and β_i is the influence coefficient.

4 WIND RESISTANT OPTIMIZED DESIGN OF PORTAL RIGID FRAME UNDER EQUIVALENT STATIC WIND LOAD

4.1 *The source of dynamic wind load and optimized mathematical model description*

The dynamic wind loading was extracted from the aerodynamic database of wind tunnel test on wind pressure of low rise buildings with gable roof type, which was conducted by the Tokyo Polytechnic University [10]. The design mean wind speed is 28*m*/*s* at the height of 10 meter. A long-span portal steel frame building with same scale as the model in the wind tunnel test was selected in this study, whose dimension is 24*m* (length)×16*m* (width)×4*m* (height atop of column), the inclined angle for rafter is β=9.4° , a 2-D long-span portal frame longitudinal direction was selected as the research object for wind resistant structural optimization. The building configuration and the corresponding analyzed model were shown in Figure 1, which indicated the location of wind loading, the dimension size of rafter and column with taped "I" section. For the optimized model in this study, the height of the rafter varied along its span with ratio of d_1:d_2:d_3=0.2:0.6:0.2. For rafter the width, thickness of flange are 0.25*m* and 0.01*m,* the thickness of web is 0.006*m*. The corresponding values for steel column are 0.28*m*, 0.01*m* and 0.008*m* respectively. Two displacement constraints are set during optimization process: the horizontal displacement atop of the column should be less than *H*/60*m* (*H* is the height of the column), the vertical displacement at the mid-span of the rafter should be less than *B*/180*m* (*B* is the span of the rafter). The heights of cross sections 1~5 are set to be optimized design variables. The initial, lower and upper bounds of these design variables were listed in Table 1.



(a) Building configuration

(b) Pressure tap distribution

(c) The location of wind loading (1#) and design variables

Figure 1 The building configuration, pressure taps in wind tunnel test and analyzed model

Table 1 Initial, lower and upper bounds of design variables

Height of web (unit: m)	Section 1	Section 2	Section 3	Section 4	Section 5
Initial values	0.88	0.53	0.83	0.38	0.88
Lower bounds	0.3	0.2	0.3	0.1	0.3
Upper bounds	1.5	1.1	1.4	0.8	1.5

The time history of pressure taps in the middle part of the building (Taps no. 141,134, 7,…,117 in Figure1b) in the wind direction at 45^o were extracted from the aerodynamic database. By multiplying their related tributary areas, the time history of wind loading acting on the nodes (No. 1$^{\#}$~12$^{\#}$ is Figure 1c) can be obtained. With the corresponding mean and standard deviation component of wind loads at these nodes, the equivalent static wind loads can be obtained simply but roughly from the GLF method[11]. The LRC method could be applied to obtain the ESWLs more precisely. The corresponding ESWLs obtained from these two methods were shown in Figure 2, and these ESWLs will be applied as the acting wind loading for the structural optimization process in the following sections. The ESWLs-A indicated the form of equivalent static load distribution that could generate the same maximum horizontal displacement atop of column as dynamic wind load, while ESWLs-B is the corresponding ESWLs for vertical displacement at the mid-span of rafter. It was shown from this figure that there is little difference between ESWLs-A and ESWLs-B, but the absolute values of ESWLs obtained from GLF method are normally larger than those from LRC method.

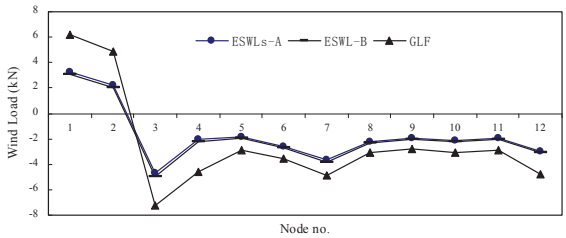


Figure 2 The obtained ESWL series

4.2 *The structural optimization results under single load case from GLF-based or LRC-based ESWLs*

In order to evaluate the effects of different types of ESWLs on the optimized results, these three types of ESWLs were applied on the long-span portal frame separately. The optimized results for the height at cross sections 1~5 were illustrated in Figs. 3(a) ~3(c) respectively.

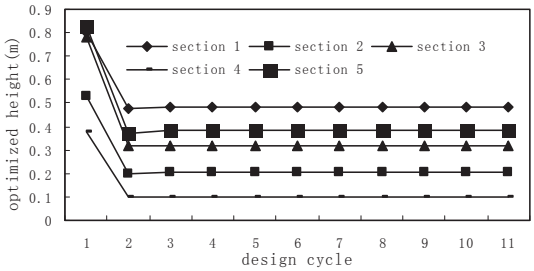

Figure 3a Optimized results for ESWLs-A

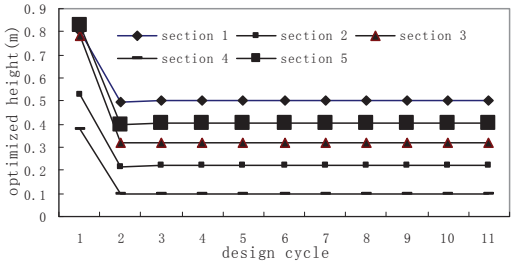

Figure 3b Optimized results for ESWLs-B

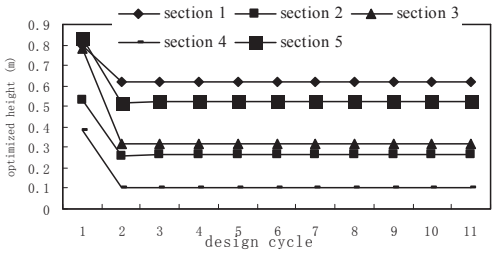

Figure 3c Optimized results for GLF-based EWSL

From the above figures, it was found that there is little difference in the optimized web heights for cross sections 1~5 between the ESWLs-A and ESWLs-B loading cases. However, many differences were shown between the optimized results for ESWLs-A loading case and those optimized results for ESWLs from GLF method. The reason for these differences was that larger values in acting wind loads was applied to the optimized structure by the GLF method. Compared with GLF-based ESWLs, the ESWL obtained from LRC method is defined as the static load that generates the same displacement field by an analysis which is not linear static. It is more possible and suitable static wind load distribution for producing the equivalent wind-induced response from dynamic wind load. Therefore it is more reasonable to conduct the structural optimization of such structures under LRC-based ESWLs.

It was also found from the above figures that all the design variables almost reached their optimized results after only 2 optimized design cycles. Thus it indicated the proposed OC method is very effective for the structural optimization of such long-span portal frames.

4.3 *The structural optimization results under multiple load cases from different forms of LRC-based ESWLs*

As indicated from previous section, the constraints in Eq. (3) and their derivations with the design variables in Eqs. (6)~(11) and (12) could be obtained by the virtual work principle and Matlab symbolic calculus function once the specified ESWLs were applied on the optimized structure. The load distribution with the form of ESWLs-A could generate the exact horizontal displacement atop of column, but it may not produce the same vertical displacement at the mid-span of the rafter as the dynamic wind load. Considering the most unfavorable loading state for the optimized structure, ESWLs-A and ESWLs-B were supposed to be two independent loading cases during the structural optimization process. Thus ESWLs-A was utilized to evaluate the first constraint (horizontal displacement) and its derivation with design variables, while ESWLs-B was used to obtain the second constraint (vertical displacement) and its related derivations simultaneously during the whole optimization process. The optimized heights for cross sections 1~5 under the multiple ESWL cases were shown in Figure 4. Larger values of the optimized height in cross section 2 was found in this wind loading state, while optimized heights for other cross sections were almost the same as those optimized results for ESWLs-A or ESWLs-B. The total weight of the optimized structure was listed in Figure 5 for different ESWL cases in previous sections. It was found that the optimized weight for GLF method is the largest. It was followed by the results for multiple load cases with different forms of LRC-based ESWLs, the related values for ESWLs-A and ESWLs-B are almost the same and least among these wind loading cases.

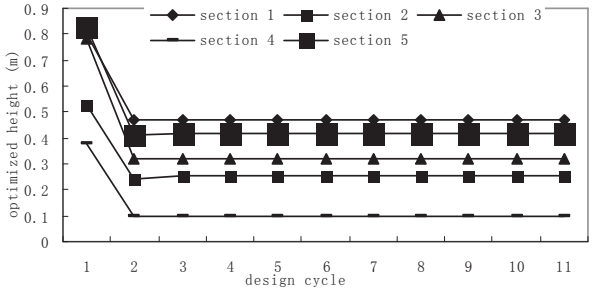

Figure 4 Optimized results for multiple ESWL cases

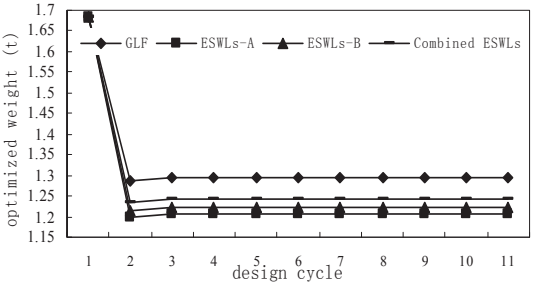

Figure 5 Optimized weights for different ESWLs

4.4 *The effect of support stiffness at column base on optimized results*

The support is normally assumed to be hinged or fixed at column base in numerical finite element analysis on long-span portal frame. However the column base is actually partially-fixed

connection with the ground, its connection stiffness is a certain value between zero and infinite depending on its connecting detail. The internal force distributions of structural elements, especially for the vertical columns, were greatly affected by the support stiffness. Larger values in support stiffness would normally reduce the internal force in some elements but increase the construction cost of the column base. Assuming the support stiffness to be a series of discrete values varied from zero to infinite, the effect of support stiffness at column base on the optimized total weight of the long-span portal steel frame was conducted in this study. The corresponding optimized results were shown in Figure 6. If the construction cost of the column base is excluded in the optimization process, the optimized total weight generally reduce from 1.22*t* to 1.16*t* when the connection stiffness increases from 10 to 2000*kN.m/rad*. Then the optimized total weight of the structure remains unchanged even if the connection stiffness increases to infinite values (i. e. fully-fixed support in SAP2000 analyzed model). Therefore the detailed construction drawing of the column base could be designed according to the optimized results of the studied frame structure.

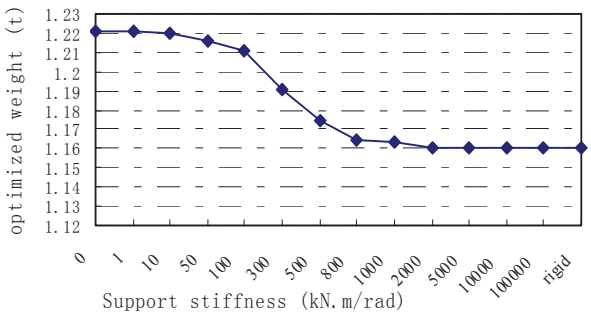

Figure 6 Optimized results with support stiffness

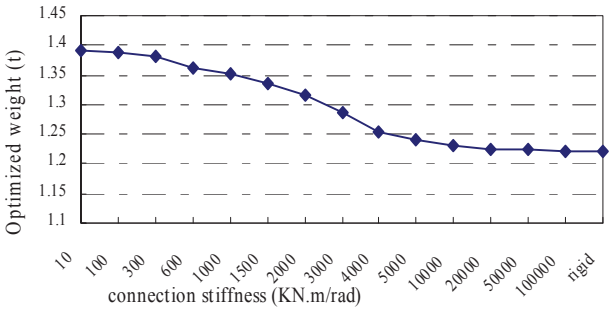

Figure 7 Optimized results with semi-rigid connection stiffness

4.5 *The effect of semi-rigid connection at beam-column joint on optimized results*

Each segments of the rafter, column or beam-column connection joint are regarded to be fully rigid connection for simplicity in numerical finite element analysis on long-span portal frame, but the connection joint between the structural elements are usually partially rigid-connected[12] . The value of connection stiffness for the semi-rigid joint depends on the construction detail of the connection type, the number of connection bolts or the depth of welding. The internal force distributions of structural elements were also greatly affected by the value of connection stiffness. Assuming the connection stiffness of the semi-rigid joint to be a series of discrete values varied from zero to infinite, the effect of semi-rigid connection on the optimized total weight of long-span portal steel frame was also studied. The corresponding optimized results were shown in Figure 7. If the construction cost of the semi-rigid connections is excluded in the optimization process, the optimized total weight sharply reduced from 1.39*t* to 1.226*t* when the connection stiffness of semi-rigid joint increases from 10 to 20000*kN.m/rad*. Then the optimized total weight of the structure reduced very slowly to 1.22*t* until the connection stiffness increases to infinite values (i. e. fully-rigid connection in SAP2000 analyzed model). Based on the empirical formula or information about the relationship between the connection stiffness of semi-rigid connection and the detail of connection type, the semi-rigid connection could be designed according to the optimized results of the studied frame structure.

5 CONCLUSIONS

By utilizing SAP2000 API for Matlab developing environment, a rigorously derived OC method was proposed in this paper to conduct the wind resistant optimization design of a long-

span portal rigid steel frame. The effect of different forms and combination of ESWLs, the stiffness of support restraint and semi-rigid connection on the optimized results were analyzed. The optimized height in cross section for rafters and columns, the optimized total weight of the structural system were obtained, the main conclusions could be summarized in the following:

(1) The proposed OC method was seamlessly integrated with SAP2000 API into wind resistant structural optimization for the long-span portal frame in MATLAB developing environment.

(2) The optimized total weights for the three static wind load cases (ESWLs-A, ESWLs-B and their combination form) are very close; the optimized total weight reduced to its initial values by about 26%~28%. However the distributions in the cross section size were slightly different.

(3) The optimized weight for the static wind load from GLF method reduced by only 23%, which indicated that it was more reasonable to conduct the structural optimization for the portal rigid frame by adopting the ESWLs from LRC method.

(4) The optimized weights generally reduced in a nonlinearity style with the increased support stiffness and the connection stiffness of semi-rigid connection. But the optimized weights almost unchanged when the support or connection stiffness reached above a certain specified value.

Cross spectra of wind pressures on domed roofs in boundary layer wind tunnel

Yuan-Lung Lo [a], Jun Kanda [b]

[a] *Tamkang University, Tansui, New Taipei City, Taiwan*
[b] *Nihon University, Chiyoda, Tokyo, Japan*

ABSTRACT: This research intends to investigate the cross spectrum characteristics of wind pressure fluctuations on the surface along the meridian of domed roofs under turbulent wind flows. Wind pressure experiments of domed roofs are conducted considering two roof curvatures and three heights of side walls. From the experimental results, various distribution types of co-coherences are examined and the traditional exponential decaying form is shown insufficient to approximate the general characteristics of co-coherences. By combining the proposed models by Uematsu et al ([1]) and Kanda et al ([2]) and also a phase shift parameter included, the approximation model is then improved to represent the observed coherences generally.

KEYWORDS: Domed roof, Roof curvature, Wind pressure fluctuation, Cross spectrum, Root-coherence, Phase distribution

1 INTRODUCTION

The curved geometric appearance makes the estimation of wind loads a difficult task for wind resistant design of a dome structure. Wind pressure distributions on the roof become more complicated due to the occurrence of separation and the formation of wake. Researches regarding the curved roofs or domed roofs have been investigated for the past two decades, typically the hemispherical domed roofs. Taylor ([3]) measured mean and R.M.S. pressures on the surfaces of domed roofs. Ogawa et al ([4]) investigated mean and R.M.S. wind pressures and spectrum characteristics of domed roofs with three height span ratios in one laminar and two turbulent boundary layer flows. Uematsu et al ([1]) proposed a computer-assisted wind load evaluation system for the design of roof cladding of hemispherical domes. Cheng et al ([5]) conducted a series of wind tunnel tests to investigate the effects of Reynolds number on the aerodynamic characteristics of hemispherical dome in smooth and turbulent boundary layer flows.

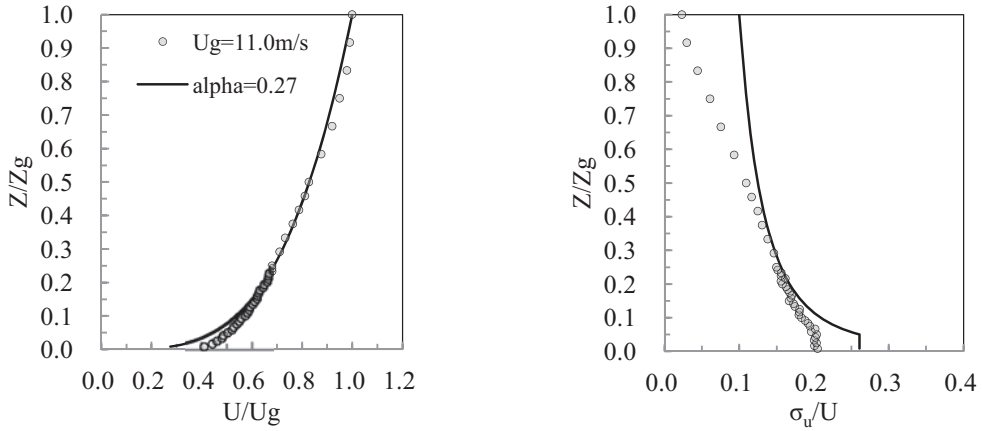
However, discussions on cross spectra of wind pressures on domed roofs have not been made sufficiently and usually only one uniform exponential decaying distribution is assumed for all cross spectra on one specific dome roof (Hongo [6]). In this research, wind pressure characteristics and distribution types of cross spectra are examined and the effects of roof curvatures and height-span ratios are investigated. A general approximation model is then proposed to achieve better agreement of approximation, especially for the cross spectra near the separation point.

2 SIMULATED TURBULENT WIND FLOW

2.1 Experimental setting of simulation of turbulent flow and acrylic domed models

The indoor closed-circuit Eiffel type wind tunnel simulator in University of Tokyo is used to generate turbulent boundary layer flow for the wind pressure experiments in this research. The geometric size of the working cross section is 1.8m×1.8m×15.6m. Turbulent wind flow is simu-

lated by the arrangement of spires and roughness blocks to fit the urban terrain (terrain IV, power law index $\alpha = 0.27$) specified in AIJ recommendation ([7]). Wind speed at boundary layer height is 11.00m/sec (U_g). I-type hot wire probe is used for measurements of wind profiles and fluctuating wind speeds. Figure 1 shows the normalized mean wind profile and the turbulence intensity profile compared to the distribution for terrain IV in AIJ model.



(a) Mean wind speed profile (b) Turbulence intensity profile

Figure 1 Normalized profiles of mean wind speeds and turbulence intensities

Wind pressure measurements in this research are conducted by the micro-pressure measuring system manufactured by Kyowa Electronic Instruments Co., Ltd. Fluctuating pressures on the surface of domed models are simultaneously recorded and then digitalized for saving and further analyses. Each domed model is composed of two acrylic models, a roof model and a cylinder model. The geometric definitions of a testing model are shown in Figure 2. The span of the roof models is fixed to be 300mm. Vinyl tubes for pressure measurements are arranged to taps along the meridian parallel to the wind direction. Two roof curvatures and three side wall heights are selected to understand generally the geometric effect. Table 1 lists the nomenclature of domed models in this research. 1/400 is assumed for the length scale ratio, 1/70 for the time scale and 1/5.7 for the wind speed scale ratio. Figure 3 shows the coordinates inside the wind tunnel.

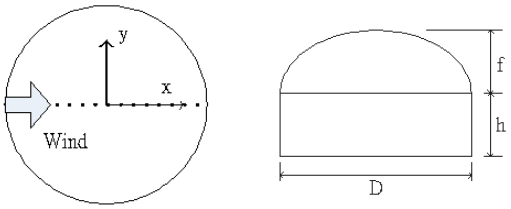


Figure 2 Geometric definitions of a domed model

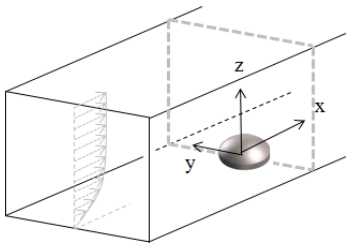

Figure 3 Coordinates inside wind tunnel

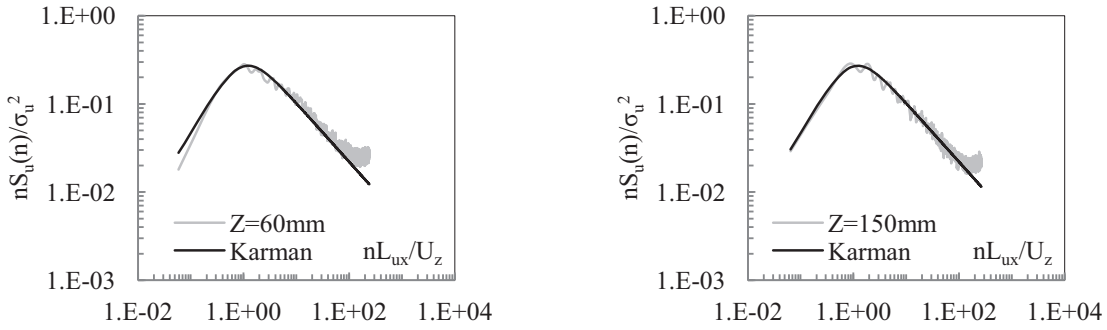
Table 1 Nomenclature of domed models

D = 300mm		f/D (roof height to span) 0.2	0.5
h/D (cylinder height to span)	0.0	C0	F0
	0.2	C2	F2
	0.5	C5	F5

Reynolds numbers of domed models are defined as the hemispherical domes by the roof span, mean wind speed at model height, air density, and viscosity constant ([1]). Mean wind speed at the height of the models is varying from 5.1m/sec to 7.5m/sec. The range of Reynolds numbers is 1.1×10^5~1.6×10^5. According to Cheng et al ([5]), when the turbulence intensity of approaching wind is high enough (>18%~20%), the Reynolds number effect is less significant when it is larger than 10^5.

2.2 Basic characteristics of fluctuating wind speeds

Power spectra of fluctuating wind speeds along the vertical profile are examined. Two examples at z=60mm and 150mm are plotted with Karman's model in Figure 4 to show fairly good agreements. σ_u represents standard deviation of fluctuating wind speeds; $S_u(n)$ represents the power spectral density; n represents the frequency; L_{ux} represents the length scale in the along-wind direction; U_z represents the mean wind speed at elevation z.



(a) Z = 60mm (b) Z = 150mm

Figure 4 Power spectra of fluctuating wind speeds at elevations

For fluctuating wind speeds at any two points, the cross spectrum of two fluctuating wind speeds or pressures between two points can be defined as follows.

$$S_{12}(r,n) = S_{12}^{C}(r,n) + iS_{12}^{Q}(r,n) \tag{1}$$

where r represents the distance between point 1 and 2; $S_{12}^{C}(r,n)$ represents the real part, co-spectrum; and $S_{12}^{Q}(r,n)$ represents the imaginary part, quadrature-spectrum. Coherence functions can be further defined as the following equations, equation (2) for co-coherence, (3) for root-coherence, and (4) for phase function.

$$C_{12}(r,n) = \frac{S_{12}^{C}(r,n)}{\sqrt{S_1(n)\cdot S_2(n)}} \tag{2}$$

$$R_{12}(r,n) = \frac{\left|S_{12}^{C}(r,n) + iS_{12}^{Q}(r,n)\right|}{\sqrt{S_1(n)\cdot S_2(n)}} \tag{3}$$

$$\theta_{12}(r,n) = \tan^{-1}\left(\frac{S_{12}^{Q}(r,n)}{S_{12}^{C}(r,n)}\right) \tag{4}$$

where $S_1(n)$, $S_2(n)$ represent power spectrum of fluctuating wind speeds at point 1, 2.

Davenport ([8]) proposed a model for root-coherence between two points at different elevations. As the distance increases, the coherence decreases.

$$R_{12}(r_z, n) = \exp\left(-k_z \frac{r_z \cdot n}{\overline{U}_{10}}\right) \tag{5}$$

where k_z is the decay factor around 7.7 and r_z is the vertical distance of two points; U_{10} is the mean wind speed at 10 meter height. Kanda et al ([2]) investigated the variation of coherence near zero frequency and then proposed a modified frequency term for a better modeling. Equation (6) represents the modified co-coherence model.

$$R_{12}(r_y, r_z, n) = \exp\left(-\frac{\sqrt{k_{1y}^2(z_m)\cdot r_y^2 + k_{1z}^2(z_m)\cdot r_z^2}}{\overline{U}_{10}} \cdot n^*\right) \tag{6}$$

$$n^* = \sqrt{\left(\frac{\overline{U}_{10}}{k_2 L(z_m)}\right)^2 + n^2}$$

$$k_{1y}(z_m) = k_y(10)\cdot\left(\frac{z_m}{10}\right)^{-\alpha_{Dy}} = 7.0\left(\frac{10}{z_G}\right)^{-\alpha_{Dy}+\alpha}\left(\frac{z_m}{10}\right)^{-\alpha_{Dy}}$$

$$k_{1z}(z_m) = k_z(10)\cdot\left(\frac{z_m}{10}\right)^{-\alpha_{Dz}} = 6.0\left(\frac{10}{z_G}\right)^{-\alpha_{Dz}+\alpha}\left(\frac{z_m}{10}\right)^{-\alpha_{Dz}}$$

$$\alpha_{Dy} = \alpha_{Dz} = 0.3 + \frac{\alpha}{2}$$

where the subscript, m, represents the geometric average of two points. L(z) is length constant; k_1 and k_2 are the decay factors determining the decaying tendency and the root-coherence value at zero frequency. Co-coherences of two fluctuating wind speeds vertically or horizontally are calculated and compared with root-coherence models of (5) and (6) to verify the consistent characteristics of the simulated turbulent wind flow. Figure 5 and Figure 6 respectively show two cases of vertical co-coherences and two cases of horizontal co-coherences. The coordinates of two points are indicated as Figure 3. It is indicated that Kanda's model provides both better fittings at zero frequency and the whole tendency. It is also known that the decay factor increases with the distance of two points increases since the coherence become weaker. The decay factors are estimated 9.8 and 12.9 in Figure 5(a) and 5(b); 8.8 and 16 in Figure 6(a) and 6(b).

3 CHARACTERISTICS OF FLUCTUATING WIND PRESSURES

3.1 Distributions of wind pressure coefficients

Wind pressure measurements of domed models are conducted under the simulated turbulent wind flow mentioned in the previous section. The sampling rate is 1000Hz for a 2 minute record. According to the time scale ratio assumed, 14 segments are averaged for the observation results. Moving averaging is also conducted by 1 second average. The definitions of mean and R.M.S. wind pressure coefficients are as follows.

$$C_{p,i} = \frac{p_i - p_s}{q_H} \tag{7}$$

$$C_{p,mean} = \frac{1}{N}\sum_{i=1}^{N} C_{p,i} \tag{8}$$

$$C_{p,rms} = \sqrt{\frac{1}{N}\sum_{i=1}^{N}\left(C_{p,i} - C_{p,mean}\right)^2} \tag{9}$$

$$q_H = \frac{1}{2}\rho\overline{U}_H^2 \tag{10}$$

where p_i and p_s represent instantaneous wind pressure at the i-th point and reference static pressure at model heights. ρ is air density. U_H is the mean wind speed at model heights.

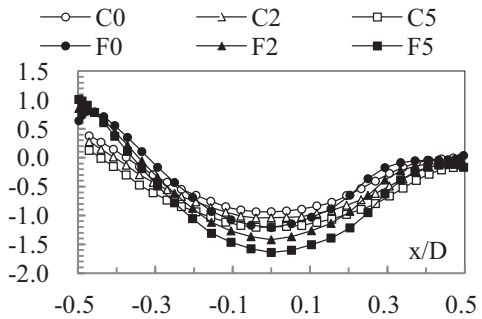

Figure 7 Distributions of mean wind pressure coefficients, $C_{p,mean}$

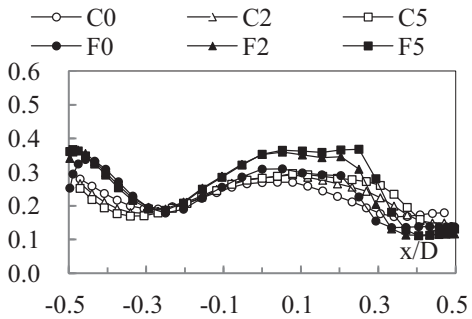

Figure 8 Distributions of R.M.S. wind pressure coefficients, $C_{p,rms}$

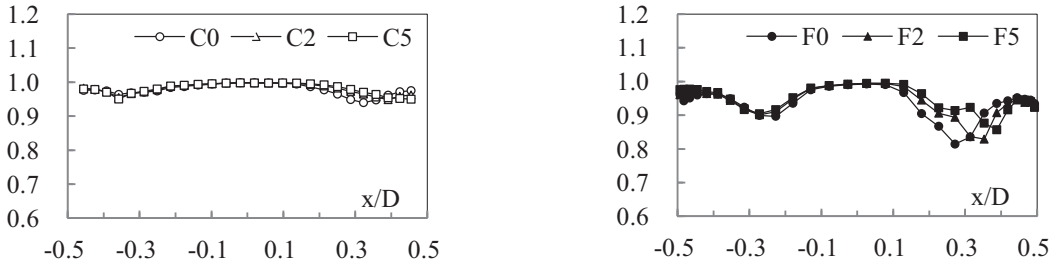
Pressure coefficients are plotted in Figure 7 and 8 with respect to f/D and h/D for the mean and RMS respectively to indicate the effects caused by roof curvature and the side wall height. Wind pressures along the meridian can be roughly divided as the windward region, the apex region, and the leeward region. Positive mean wind pressure coefficients can be expected since wind pressure fluctuations in the windward region are mostly affected by the approaching wind. As the flow moves downstream, a thin shear boundary layer forms along the roof surface and negative mean wind pressures are generally distributed in the apex region and leeward region. The apex region and the leeward region are divided by the occurrence of flow separation. Maximum negative pressures can be observed in the apex region. Small mean and R.M.S. coefficients in the leeward region are also indicated. To clarify the wind flow changes on the roof surface, the correlation coefficients between any two neighboring taps are calculated to show the three zones with different patterns as Figure 9.



(a) f/D=0.2 models (b) f/D=0.5 models

Figure 9 Distributions of correlation coefficients between two neighboring vinyl tubes

As shown in Figure 9, relatively lower correlation coefficients are observed whenever the wind flow changes. For f/D=0.2 models, the range of the apex region is larger than that for f/D=0.5 models. However, three regions can be more clearly distinguished in those models with higher roof curvatures. It is also indicated that the increase of side wall height slightly pushes the separation point downstream. The three regions can also be named as “windward zone”, “separation zone” and “wake zone” according to the dominant characteristics in each region. Such zoning concept is further used for demonstrating various distribution types of spectrum characteristics in the next two sections. Table 2 lists the channel numbers in each zone/region (zone, hereafter) based on the observations results in this research.

Table 2 Identified channel numbers in three zones based on experimental results

Domed model		Windward zone	Separation zone	Wake zone
f/D=0.2	C0	1~4	5~21	22~27
	C2	1~4	5~24	25~27
	C5	1~4	5~25	26~27
f/D=0.5	F0	1~8	9~20	21~29
	F2	1~8	9~20	21~29
	F5	1~8	9~21	22~29

3.2 Power spectrum characteristics of along the meridian of domed roofs

Power spectrum characteristics of fluctuating wind pressures have been discussed in many publications. Ogawa et al ([4]) proposed fitted parameters for power spectra in three domed models

with different roof curvatures. Qiu et al ([8]) proposed typical power spectra for Gaussian and non-Gaussian zones and weighting factors to approximate power spectra along the meridian. Lo ([9]) then applied the similar idea to find typical power spectra in three zones and provided the fitted parameters of typical power spectra with respect to f/D and h/D for a database work.

Figure 10 shows the power spectra in F0 model to illustrate the dominant characteristics in each zone. The distribution shape of power spectral densities gradually varies from upstream to downstream. Three distinct zones can clearly be identified by several obvious features. For the power spectra in the windward zone, the distribution shape is similar to that of approaching wind speeds. When wind flow moves to the separation zone, a hump at lower frequency appears because of the formation of the thin shear boundary layer. After the occurrence of separation, turbulence energy is dominated by the component resulted from the thin shear boundary and the component resulted from the wake. Two humps are characteristically observed in the wake zone.

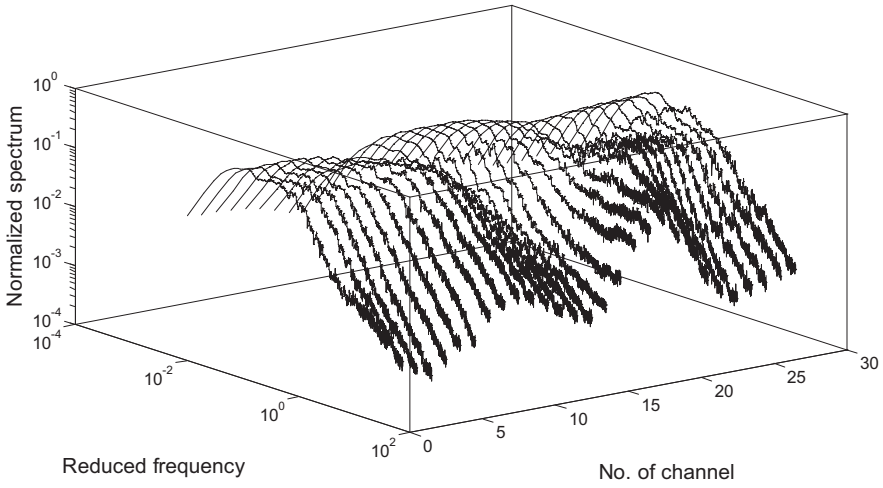


Figure 10 Power spectra along the meridian of F0 model with respect to channel numbers

3.3 Cross spectral characteristics of along the meridian of domed roofs

Cross spectral characteristics of two fluctuating wind pressures can also be examined by co-coherences, root-coherences, and phases, which are defined by equations (2) ~ (4). As discussed in the previous sections, it is clearly noted that each zone contains its specific dominant features in the distributions of wind pressure coefficients and power spectra. Based on the same zoning concept, cross spectra are examined within one zone and across two zones. Typical domed models, C0 model and F0 model, are selected for demonstrating various distribution types of co-coherences in Figure 11.

For co-coherences of two fluctuating wind pressures within the windward zone, a consistent decaying distribution is generally observed. The co-coherence values at zero frequency decrease as the distances between two points increase. It is also indicated that roof curvature results in less significant effect. Within the separation zone, co-coherences are observed to decay quicker with increasing roof curvature and the distance. Within the wake zone, co-coherences remain almost consistent as distance or roof curvature varies. For the co-coherences across the windward zone and separation zone, it is interesting to observe two different patterns when the distance of two points across the apex of the domed model or not. The co-coherence value at zero frequency is negative when the distance across the apex. A clear hump is indicated around reduced frequency

equals 0.1, where a hump can also be pointed out in the distributions of power spectra in the separation zone at lower reduced frequency range. For the co-coherences across the separation zone and wake zone, dramatic decaying is generally observed, especially the cases with larger roof curvature. Low and almost unvaried co-coherences are observed when the distance across the windward zone and the wake zone.

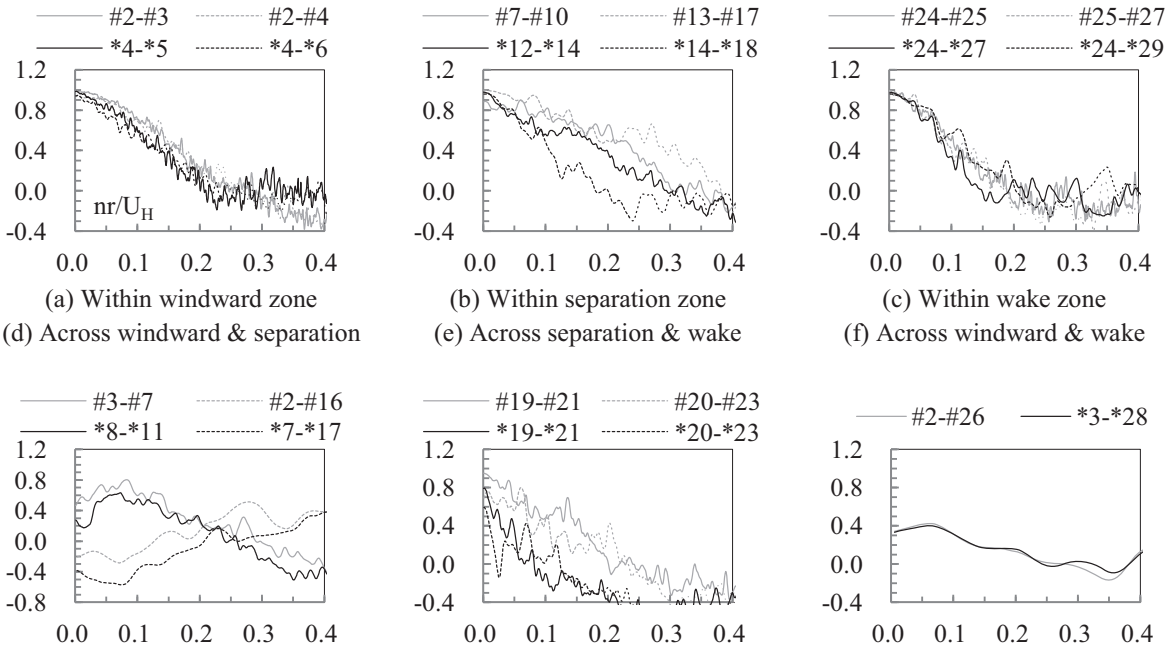

Figure 11 Co-coherences within one zone and across two zones (#: C0 model, *: F0 model)

It is summarized from the aforementioned observations that several features should be focused once the approximation of co-coherence is considered: (1) decaying tendency; (2) co-coherence value at zero frequency; (3) the hump at low reduced frequency corresponding to the dominant power spectrum characteristics in the separation zone; (4) negative co-coherence value when the distance of two points across the windward zone and the separation zone, especially two points are at the upstream side and downstream side of the apex respectively.

4 APPROXIMATION MODELS OF CO-COHERENCES

Different from approximation of fluctuating wind speeds, co-coherences of wind pressures cannot be conveniently replaced by root-coherence and described by Davenport's or Kanda's model. In order to generally approximate the features shown in Figure 11, a formula is proposed by representing first root-coherence and phase separately and then combining by the following equation.

$$C_{p,12}(n) = R_{p,12}(n) \cdot e^{i\theta_{p,12}(n)} \tag{11}$$

where $C_{p,12}(n)$, $R_{p,12}(n)$, and $\theta_{p,12}(n)$ represent co-coherence, root-coherence, and phase of two pressures respectively. Ogawa et al ([4]) and Uematsu et al ([1]) ignore the imaginary part of phase and rewrite (11) as (12):

$$C_{p,12}(n) = R_{p,12}(n) \cdot \cos\left(\theta_{p,12}(n)\right) \tag{12}$$

To satisfy the observations of decaying tendency of co-coherence and the value at zero frequency, Kanda's model is slightly modified and substituted to equation (12) for approximating the root-coherence part. Further, to satisfy the hump observed at lower frequency ranges and two opposite patterns shown in Figure 11(d), two parameters are proposed for better approximation agreement. Equation (12) can then be re-written as follows.

$$\begin{aligned} C_{p,12}(r,n) &= \exp\left(-\frac{\sqrt{k_1{}^2 r^2}}{D}\cdot n^*\right)\cdot\cos\left(2\pi\cdot k_t\cdot\left|\frac{n\cdot r}{\overline{U}_H}-\hat{n}_{cr}\right|-d\theta\right) \\ n^* &= \sqrt{1+\left(\frac{n\cdot D}{k_2\overline{U}_H}\right)^2}-\hat{n}_{st} \end{aligned} \tag{13}$$

where k_1 and k_2 are decay factors determining the decaying tendency and the root-coherence value at zero frequency; k_t is a slope constant of the phase and dθ is a shift constant of phase at zero frequency. $\hat{n}_{cr}$ is the observed dominant reduced frequency of power spectra in the separation zone. $\hat{n}_{cr}$ is around 0.08~0.1 in this research and assumed 0.1 in general. For the co-coherences not across the windward zone and separation zone, $\hat{n}_{cr}$ and dθ can be assumed zero simply.

Approximation of co-coherences of F0 model shown in Figure 11 are conducted and plotted in Figure 12. Fairly good agreement of approximation is achieved by the improved model of equation (13) rather than the exponentially decaying model. Observed features of co-coherences can be satisfied by providing two more parameters, $\hat{n}_{cr}$ and dθ. The fitted parameters in Figure 12 are listed in Table 3 to indicate that only one unique distribution of co-coherence is insufficient for describing the spectrum characteristics, especially integration of wind loads is conducted among certain surface where the separation of wind flow occurs.

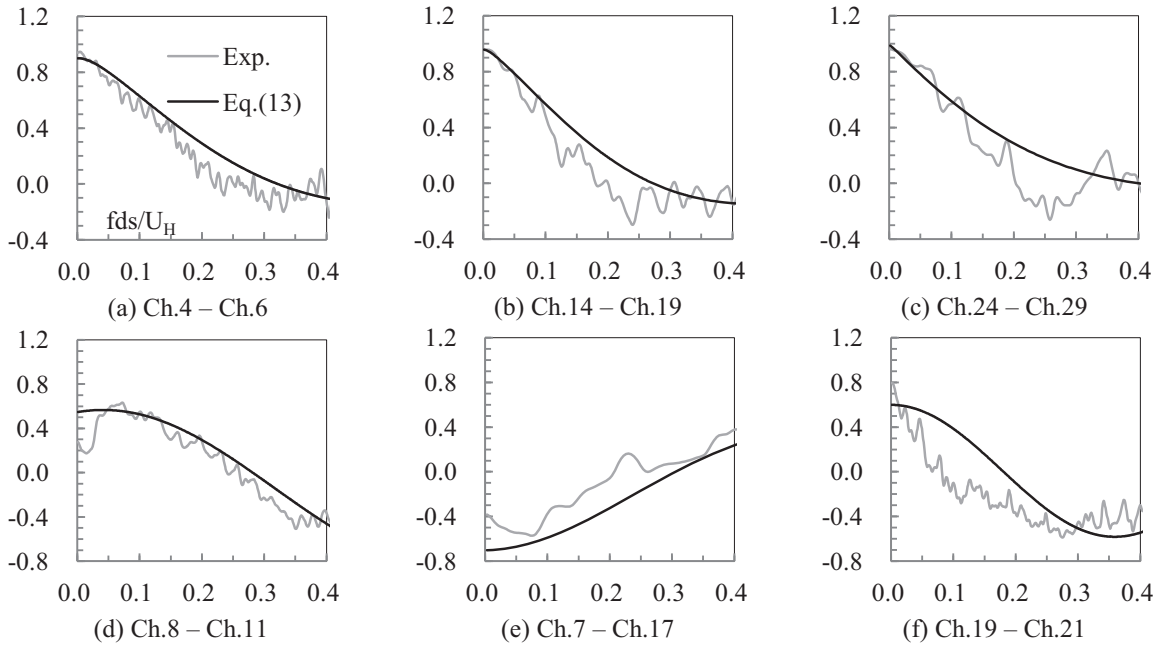

Figure 12 Approximation results of co-coherences in F0 models

Table 3 Fitted parameters of co-coherences in Figure 12 based on equation (13)

	k_1/k_2	k_t	n_{cr}	$d\theta$
Ch.4 – Ch.6	3.24	0.78	0.00	0.00
Ch.14 – Ch.19	3.88	0.92	0.00	0.00
Ch.24 – Ch.29	4.52	0.62	0.00	0.00
Ch.8 – Ch.11	0.56	0.86	0.10	-0.42
Ch.7 – Ch.17	1.48	0.43	0.10	2.61
Ch.19 – Ch.21	0.48	1.39	0.00	0.00

5 CONCLUSIONS

In this research, distribution types of co-coherences were examined and an improved approximation model was proposed by adding two more parameters considering the dominant characteristics of power spectrum and the phase shift when positive pressures convert to significant negative pressures. From the fitted parameters of the proposed model and the approximation results, it is clearly shown that only one unique exponential decaying term is insufficient to represent various coherence features of fluctuating wind pressures on the domed roofs. And it may be considered desirable for integrating wind loads to provide a general co-coherence form based on the zoning concept of wind flow changes.

ACKNOWLEDGEMENTS

Kajima Foundation is acknowledged for its financial support to the wind tunnel experiment in this research. Kyowa Electronic Instruments Co., Ltd. is also acknowledged due to its technological assistance on wind pressure measurement maintenance.

Wind-induced static performance of cooling tower considering multiple loading effects

X.X. Cheng [a], L. Zhao [a], Y.J. Ge [a]

[a] *State Key Laboratory for Disaster Reduction in Civil Engineering, Tongji University, Shanghai,China*

ABSTRACT: The pressure-measuring tests for certain super large cooling towers are first reported, so the static wind loads on the cooling towers can be easily illustrated with some parameters, such as the surface extreme value pressure distribution, the tower group factor; and the wind-vibration factor. With the help of the finite element method (FEM) numerical simulation, the performance of cooling towers due to the static wind loads, including stress, displacement and local elastic stability are presented. Then, considering material and geometrical non-linearities about the reinforced concrete, the ultimate bearing capacity of the structures under static wind action is also discussed. The analysis process focuses on considerations of some key effects concerning structural design works, i.e., the internal pressure effect, the distribution mode of external surface pressure, the boundary effect, the wind profile index and the group tower interference effect.

KEYWORDS: Cooling tower; Pressure-measuring test; Finite element numerical simulation; Local elastic stability; Material and geometrical non-linearity; Ultimate load bearing capacity

1 INTRODUCTION

Super large hyperbolic cooling towers are extremely sensitive to wind loads, which are usually the control load in structural design and construction. As China stages its fast-growing performance in construction of super large cooling towers and tower groups today, more expectations relating to these huge structures' wind resistance designs are given from engineering circles. However, it seems that the present technical supports can hardly meet current requirements based on the following facts. First, the current Chinese codes (e.g. NDGJ5-88 and GB/T 50102-2003) stipulate that the terms for computation of important design parameters, such as the tower-group factor and the wind-vibration factor, can only be applied to towers under a height of 165-meters. Besides, it is also stipulated in the Chinese codes that group tower interference effects can be ignored for those with bottom center distances above 1.5 times tower diameter, which is different from some other countries' codes (e.g. BTR VGB'Richtlinie Bautechnik bei Kühltürmen and Règles Professionelles applicable à la Construction des Réfrigérants Atmosphériques en Béton Armé) and has been proved to be imperfect by some wind tunnel experimental studies.

Rigid model pressure-measured wind tunnel tests of a 176-meter super large cooling tower and some group towers of different combinations were described briefly in the beginning of this study. Loading the extreme value wind pressure distribution patterns obtained from wind tunnel tests, which are taken as strong wind loads with design wind speed in certain return period, the static structural performances of the cooling towers with different condition combinations based on FEM numerical simulation introducing a bilinear material constitutive model and large deformation geometric nonlinearity considerations are presented. Then, results of the numerical studies including the structural response (internal force and displacement), the tower shell's local elastic stability performance as well as the total structure's ultimate load-carrying capacity are studied. The research process focus on studies of some key effects influencing the structural static performance, i.e. internal pressure effect, considerations for external pressure distribution, boundary effect, wind profile effect and group tower interference effect. The conclusions drawn are of practical significance to relating structural design works.

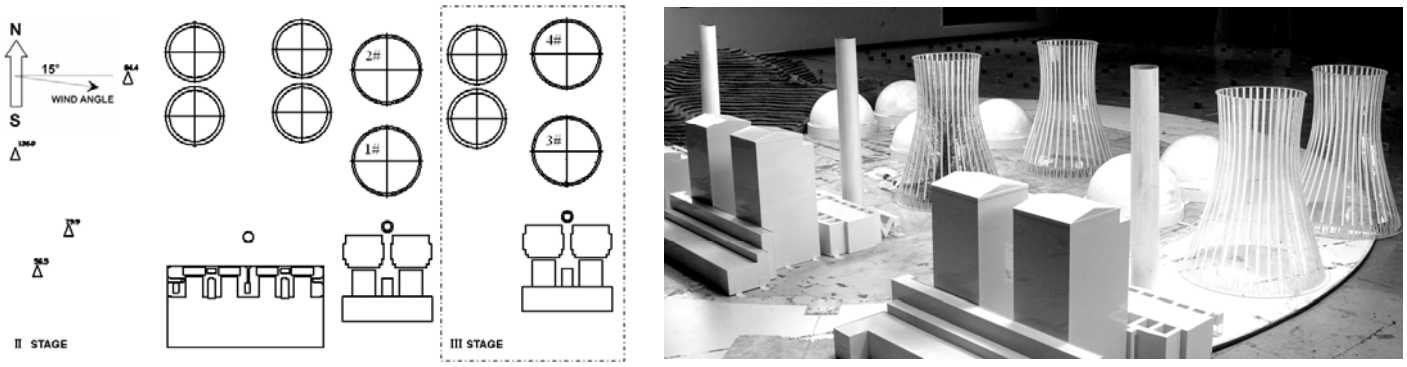
2 WIND TUNNEL TEST AND DATA PROCESSING

In a practical electric power plant situation in southeast China, a set of designing cooling towers are part of a dense arrangement of large buildings, which are of comparable size with the cooling towers. As a result, the influence of adjacent buildings or towers on cooling towers cannot be ignored, even though the towers' center distances conform to the basic requirements of the Chinese Codes (> 1.5 times the single tower diameter).

Table.1 Building dimensions in the electric power plant

Cooling tower height	177.147m
Tower top diameter	82.260m
Throat diameter	78.216m
Tower base diameter	134.694m
Minimum distance of towers	≥1.5 tower base diameter
Height of half sphericity bunker	80.0m
Chimney height	210.0 m
Hill height	56.5～136.0 m
Other building height	35.0～135.0m

The second stage of the project features two 177-meter super large cooling towers. To the west, there are four 80-meter hemispherical coal bunkers and an 80~140-meter high continuous mountain, and to the south, there is an industrial complex which includes two 210-meter tall chimneys. During the third stage of the project, two new towers, two additional new hemispherical coal bunkers and an industrial complex will also be constructed (see Fig.1 and Table.1 for building dimensions and site plan respectively).



Site plan Site model

Fig.1 Ⅱ and Ⅲ stage cooling tower groups

The test was conducted in the TJ-3 atmospheric boundary layer wind tunnel, which belongs to Tongji University's State Key Laboratory for Disaster Reduction in Civil Engineering. As a closed return-flow wind tunnel with rectangular cross section, the dimensions of its test section are: 15m in the lateral direction, 14m in the longitudinal direction, and it has a height of 2m. Both external and internal pressure-measuring models of the super large cooling tower are 1:200 scale rigid models (see Fig.2), the blockage ratios of the cooling tower and surroundings are less than 7%.

The surrounding landscape of the project is type A according to NDGJ5-88 or GB/T 50102-2003. Measurement of atmospheric boundary layer uses a Streamline hot-wire anemometer of DANTEC Corp. It shows the following: the wind profile exponent a =0.12, the ground surface turbulence intensity is 15%, and the turbulence intensity at the height of the tower top is 10%.

The locations of the taps are shown in Fig.3. For the external pressure measuring tower model, 36 (around the circumferential direction) ×12 (along the meridian direction) taps are arranged. For the internal pressure measuring model, 36 (around the circumferential direction) ×6 (along the meridian direction) taps are arranged. DSM3000 electronic pressure scanners of Scanivalve Corp. are used for mean and fluctuating pressure measurements on model surface. The signal data are acquired at a sampling rate of 312.5Hz, and for each measuring point, the total sampling length is

6000.

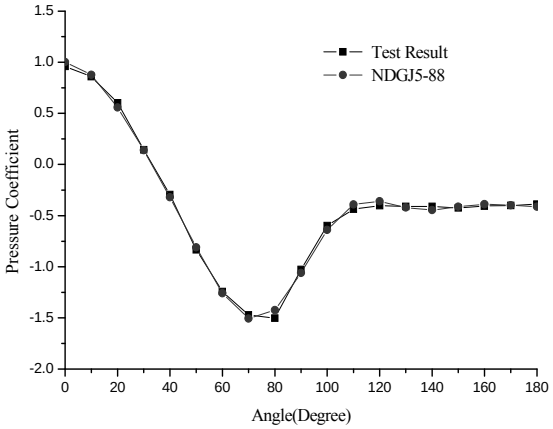

Fig.4 Pressure comparison of test and Codes

The Reynolds number scope ranges from 1.5×10^8 to 3.5×10^8 for the actual super large cooling tower of this project considering design wind speed. However, it is difficult to simulate the actual flow characteristics around the model tower's surface with a super-high Reynolds number by increasing the experimental wind speed and maximizing the models' geometric dimensions for the limitations of wind tunnel technique. The general practice in solving this problem is to adjust the surface roughness of tested cooling tower models to obtain the super-high Reynolds number effects for flow around the surface (see Fig.2), which is successfully done in this study as is shown from a good fitting between two pressure coefficient curves in Fig.4 which are acquired based on tests and code NDGJ 5-88 respectively. In Fig.4, the test results are the mean value of several pressure coefficient distribution patterns around some intermediate pressure-measured cross-sections on the surface of the external pressure measuring model and the data from code NDGJ 5-88 are based on some actual measurement works. The external pressure distribution patterns around a single tower's surface fit a curve in the form of eight-termed trigonometric series according to NDGJ5-88 or GB/T 50102-2003:

$$m_p(q) = \sum_{k=0}^{m} a_k \cos kq \tag{1}$$

in which, fitting parameters a_0=-0.779，a_1=0.313，a_2=1.016，a_3=0.737，a_4=0.044，a_5=-0.1429，a_6=0.074，a_7=0.086.

The definition of a cooling tower's total aerodynamic drag force coefficient (along-wind direction) is as follows:

$$C_D = \frac{\sum_{i=1}^{n} C_{Pi} A_i \cos(q_i)}{A_T} \tag{2}$$

in which, C_D is the structural total drag force coefficient, A_i is the coverage area of the pressure measuring point i, θ_i is the separation angle between the pressure action direction on point i and the wind axis, A_T is the whole structure's projection area along the wind axis.

Considering the time-history correlation between the shape coefficient on the taps and the total structural drag or lift force, the mean results of the pressure extreme value distribution patterns on several intermediate cross-sections are obtained. Fig.5 compares the distribution patterns between the general envelope of test extreme values and codes, which demonstrates that although the pressures in the wake zone and the separation points are the same, there exist certain differences: the maximum and minimum values in the test pressure coefficient extreme value distribution pattern are 1.298 and -2.307 respectively, which equal to 78% and 87% of the code extreme values (1.668 and -2.603, respectively), and the difference of the corresponding angles of maximum negative pressure reaches 10 degrees.

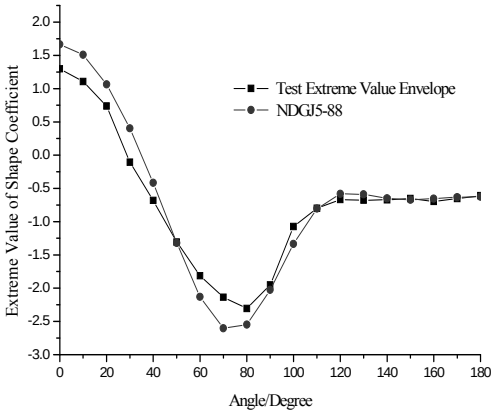

Fig.5 General envelope of test values and codes

According to time domain dynamic analysis based on multipoint fluctuating pressure time history data and aeroelastic model wind tunnel tests (prior works), the wind-vibration factors have been obtained for this project: 1.70 for single tower, 2.22 for two-tower group combination (at the most adverse incoming flow condition), and 2.50 for four-tower group combination (at the most adverse incoming flow condition).

If the tower surface pressure distribution pattern provided by NDGJ5-88 is adopted, the mean value of drag coefficient is 0.437 for uniform flow. For comparison study, the tower group factor is defined as:

$$K_m = \frac{C_{D,\max,single} \cdot P_{ch} \cdot K \cdot M_{if}}{C_{D,mean,single,code} \cdot b_{single,test}} \tag{3}$$

in which, $C_{D,max,single}$ is the extreme value of the drag force coefficient for a single tower in turbulence flow field (0.541); for type A atmospheric flow, P_{ch}=0.541/0.397=1.36 is the ratio of drag force coefficient for a single tower in uniform flow to that in turbulent flow; K is the maximum ratio of the ultimate value of the drag force coefficient of an interfered tower to that of the single tower; M_{if}=1.0+$\beta_{single,test}/\beta_{single,code}$ is the correction term of the tower's wind-induced inertia force, $\beta_{single,test}$ and $\beta_{single,code}$ are the wind-vibration coefficient results based on experimental results (1.70) and code NDGJ5-88 (1.60), respectively; $C_{D,mean,single,code}$ is the mean value of a single tower's drag force coefficient in uniform flow of NDGJ5-88 (0.437). Intrinsically, K_m can be interpreted as the ratio of the experimental value of the total static wind loads for all conditions to total wind load on a single tower based on the codes.

For both the second stage project and the third stage project, the most adverse incoming flow conditions both feature a direction of a clockwise 15° included angle from the east. According to formula (3), tower group factors for a two tower group and a four tower group are 1.226 and 1.385, respectively.

The penetration ratio of the packing layer is modeled using a uniformly pierced organic glass board placed at the bottom of the tower's main body. Experimental results in type A turbulent flow show that the penetration rate has no significant effect on internal pressure distribution patterns, but it is closely related to the internal pressure value. The internal pressure mean value increases when decreasing the draught penetration ratio (see Table.2). For some experimental conditions, the draught penetration ratio is 30%, so the internal pressure distributes uniformly inside the tower shell with the extreme value of -0.656.

Table.2 Internal pressure coefficients of single cooling tower

Draught penetration ratio	100%	55%	30%	15%	3%	0%
Internal pressure mean value*	-0.375 × 1.6	-0.382 × 1.6	-0.410 × 1.6	-0.524 × 1.6	-0.590 × 1.6	-0.761 × 1.6

3 FINITE ELEMENT MODEL

The main body of the FEM model is comprised of discrete spatial shell elements, and the top stiffening ring and 48 pairs of herringbone columns connected to a ring foundation with fixed bottom ends are modeled using space beam elements. Two different models using a different number of shell elements (one applies 504 shell elements, the other applies 19008 shell elements) are compared. Results show that none of the relative errors among their corresponding 1st~ 8th modal frequencies is less than 3%, and their corresponding vibration modes are the same. For simplification, the simple model, which applies 504 (36*14) shell elements, is adopted. The main structural characteristics are presented in table.3. Natural frequencies and vibration shapes of the 1st~4th modes are presented in table.4.

Table.3 Main structural characteristics of cooling tower

Component	Height/m	Shell thickness/m	Radius/m	Concrete grade	3D View of cooling tower FE model

4 SOME KEY EFFECTS ON COOLING TOWERS' WIND-INDUCED STATIC PERFORMANCE USING LINEAR ELASTIC FEM ANALYSES

For this part of the study, the 100 years basic design return period wind speed is 33m/s, the wind profile index is 0.12, and the dead weight is taken into account in load combination.

4.1 Internal pressure effect

Table.5 Response of cooling tower for different internal pressure conditions

Condition		Internal pressure extreme value	Maximum total deformation /m	Maximum primary tensile stress /MPa	Maximum primary compressive stress /MPa
Draught penetration Ratio	100%	-0.637	0.0366	0.733	4.23
	30%	-0.658	0.0366	0.729	4.23
	10%	-0.717	0.0366	0.717	4.23
	0%	-1.082	0.0367	0.644	4.22
No internal pressure		0.0	0.0364	0.868	4.23
General consideration in practical design (NDGJ5-88)		-0.8 (-0.5×1.6)	0.0366	0.701	4.23

The pressure on the external surface of the cooling tower applied for analyses follows the single tower's extreme value distribution pattern obtained in the wind tunnel test mentioned above. Table.5 compares the cooling tower's response under static wind of different internal pressure conditions, demonstrating that with the increase of the draught penetration ratio of the stuffing layer, the absolute value of the negative internal pressure decreases, and the cooling tower's maximum total displacement and the primary compressive stress undergo little change. The maximum primary tensile stress drops smoothly with the increase of the absolute value of the internal pressure as shown in Table.5 (a 12.14% decrease from 100% to 0% draught penetration ratio condition). An analysis based on a representative code (NDGJ5-88) renders results of all structural performances between those of 0% and 10% draught penetration ratio. It is also proved that disregarding the internal pressure is a risky practice in view of the maximum total deformation response.

4.2 Effect of the external pressure extreme value distribution patterns

Through correlation analysis of multipoint fluctuating wind loads on the cooling tower's external surface, the extreme value distribution patterns of the tower's external pressure are obtained (see Fig.5). Compared with the traditional methodology using the mean surface wind pressure distribution pattern from NDGJ5-88 multiplied by a wind-vibration factor, it is found that the method of loading the experimental extreme pressure distribution causes favorable overall structural responses, demonstrating the safe consideration of code NDGJ5-88 (see Table.6). From Table.6, there exists a little disagreement of the occurrence positions of maximum responses between the two methodologies, which is also a major concern in structural design.

Table.6 Response of cooling tower for different external pressure modes

External pressure distribution pattern	Maximum total deformation			Maximum primary tensile stress			Maximum primary compressive stress		
	Response magnitude/m	Occurrence position		Response magnitude/MPa	Occurrence position		Response magnitude/MPa	Occurrence position	
		relative to tower height	Included angle from incoming flow		relative to tower height	Included angle from incoming flow		relative to tower height	Included angle from incoming flow
Experimental result	0.0388	0.746	0°	0.786	0.848	±85°	4.34	0.286	±70°
Traditional consideration (NDGJ5-88)	0.0475	0.783	0°	1.260	0.885	±75°	4.77	0.286	±70°

4.3 Group tower interference effect

Applying the two methodologies mentioned above to consider the external surface pressure distribution, Table.7 shows the cooling towers' responses with different group tower combinations. The responses obtained by loading the pressure distribution pattern obtained from the codes (hereinafter referred to as the traditional methodology) are stronger than the corresponding results obtained by loading pressure distribution patterns based on wind tunnel tests. The occurrence positions of both the maximum total deformation and the primary tensile/compressive stress of the traditional methodology are slightly higher than the computational results using experimental pressure distributions. Difference around 10 to 15 degrees exists between the circumferential occurrence points of the maximum primary tensile stress on the curves calculated using different methodologies considering corresponding group tower combination conditions.

It is notable that by loading the experimental extreme value wind pressure distribution patterns acquired through correlation analysis, the magnitudes of the structural responses of different group tower conditions demonstrate a variation trend different from that of the tower group factors (i.e. the tower group factor for the four tower group condition > that for the two tower group condition > that for the single tower condition, see Section 2). For both the maximum total deformation and the maximum primary compressive stress, the trend is: the responses of the four tower group condition > those of the single tower condition > those of the two tower group condition. The phenomenon can be interpreted that although tower group factors and wind-vibration factors are both increasing when adding tower numbers in the tower group, the lateral load distribution and the load action center of vertical wind loads both change, and the shell thickness at the height of the total load action position changes accordingly, reflected by the descending trends of the heights of the maximum response positions, which is favorable in view of wind effects on the structures.

Table.7 Response of cooling tower with group tower interference effects

External pressure distribution pattern	Condition	Maximum total deformation			Maximum primary tensile stress			Maximum primary compressive stress		
		Response magnitude /m	Occurrence position		Response magnitude /m	Occurrence position		Response magnitude /m	Occurrence position	
			relative to tower height	Included angle from incoming flow		relative to tower height	Included angle from incoming flow		relative to tower height	Included angle from incoming flow
Extreme value (from experiment)	Single tower	0.0388	0.746	0°	0.786	0.848	±85°	4.34	0.286	±70°
	Two towers (second stage)	0.0335	0.746	0°	1.020	0.921	＋90°	4.29	0.247	±70°
	Four towers (third stage)	0.0453	0.709	0°	1.390	0.848	＋90°	4.75	0.247	±70°

4.4 Effect studies based on local elastic stability check

As a large thin-walled shell structure, local elastic stability check should be included in a cooling

tower's structural design. According to NDGJ5-88, the following formulae are applied for analyzing of the shell's local elastic stability:

$$0.8K_B(\frac{s_1}{s_{cr1}}+\frac{s_2}{s_{cr2}})+0.2K_B^2[(\frac{s_1}{s_{cr1}})^2+(\frac{s_2}{s_{cr2}})^2]=1 \tag{4}$$

$$s_{cr1}=\frac{0.985E}{\sqrt[4]{(1-n^2)^3}}(\frac{h}{r_0})^{4/3}K_1;\quad s_{cr2}=\frac{0.612E}{\sqrt[4]{(1-n^2)^3}}(\frac{h}{r_0})^{4/3}K_2 \tag{5a,b}$$

in which, σ_{cr1} is circumferential critical pressure; σ_{cr2} is meridian critical pressure; σ_1、σ_2 are circumferential and meridian compressive stresses considering internal suction respectively; E，v are the elastic modulus and the Poisson ratio of shell concrete, respectively; r_0 is the throat radius of the tower body; h is the shell thickness at the tower throat; K_1、K_2 are both determined by the tower body's geometric parameters (in this study, K_1=0.138，K_2=1.267); K_B is the local stability safety factor.

Table.8 compares the cooling tower shell's local stability performances with the effect combinations of different group tower conditions, two kinds of external pressure distribution patterns and different considerations for internal pressure. The minimum K_B on the tower body (the occurrence position is about 0.286 relative to tower height where shell thickness is 0.330 meters) considering different effect combinations are listed in Table.8. For all effect combinations in Table.8, minimum K_B are above 5, meeting the requirements of code NDGJ5-88. Taking into account the internal pressure effects, the circumferential compressive stresses stage an increase of 35.6%, and the meridian compressive stresses are insensitive to the change. As a result, local stability decreases. For consideration of external pressure distribution patterns, the local stability check results based on the traditional methodology is lower than those based on the methodology applying results of prior wind tunnel tests. It is obtained by quantifying the local stability of the cooling tower shell that: single tower's stability >four tower group's stability > two tower group's stability, which is still different from the variation trend of tower group factors (see Section 4.3). The difference should mainly be attributed to changes to the vertical center of total wind action.

Table.8 The local elastic stability due to several effect combinations

Effect combination			Circumferential compressive stress/MPa	Meridian compressive stress/MPa	Angle of minimum K_B position	Minimum K_B
Condition	External pressure distribution pattern	Internal pressure consideration				
Single tower	NDGJ5-88	No	0.382	0.453	±70°	7.153
Single tower	NDGJ5-88	Yes	0.518	0.454	±70°	6.458
Single tower	Experimental result	Yes	0.567	0.382	±60°	6.892
Two towers (second stage)	Experimental result	Yes	0.738	0.355	±70°	6.268
Four towers (third stage)	Experimental result	Yes	0.658	0.384	±80°	6.408

5 SOME KEY EFFECTS ON COOLING TOWERS' ULTIMATE LOAD-CARRYING CAPACITY BASED ON NONLINEAR FEM ANALYSES

Comparison studies of the cooling towers' ultimate load-carrying capacity under wind loads of different working conditions are conducted, which focus on comparisons of the failure shapes of shell and ultimate wind speeds. The static wind stability analysis is based on a general finite

element platform taking into account the dead weight, material and geometric nonlinear effects in analyzing process. The basic failure process of the cooling tower is simulated as follows. First, wind loads of design basic wind speed (set 10m/s on a height of 10 meters as the initial wind speed) are loaded using a step-by-step method (loading step length is around 2.5～10.0m/s). With the increase of wind loads, some local areas on the concrete shell are damaged under tensile stress (for C40 concrete, $f_{tk} \geqslant 2.39$MPa). As a result, the reinforcement bars withstand the whole tensile strength in those failed areas. Then, the shell concrete in the compressive region on the tower body comes to its ultimate compressive condition (for C40 concrete, $f_{ck} \geqslant 26.8$MPa). With the rapid increase of deformation, the structure soon reaches its ultimate condition which can easily be determined from the critical points on wind speed-deformation gradient curves.

5.1 Wind profile effect

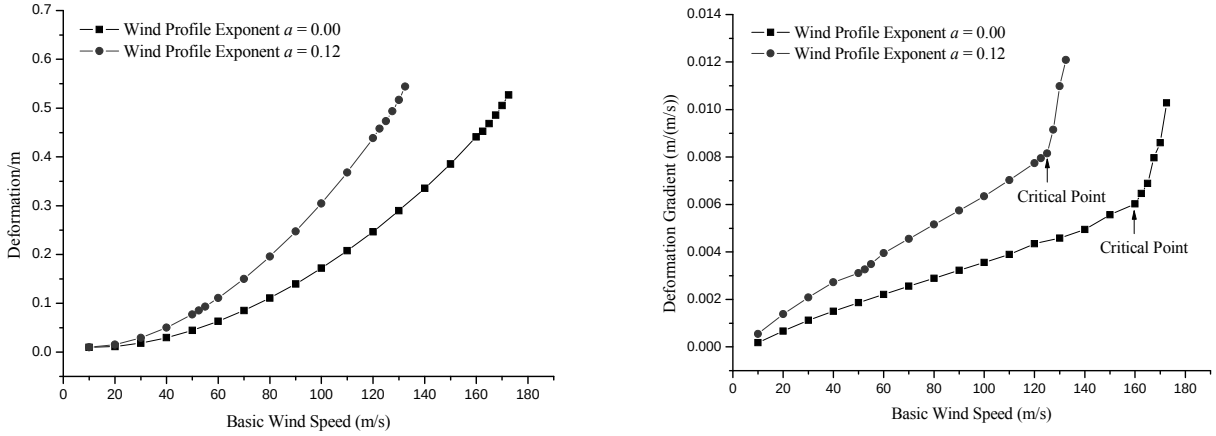

Fig.6 Displacements and their derivatives for different wind profiles

Table.9 Critical states for different wind profiles

Wind profile exponent	Occurrence position of maximum deformation		Critical state in tensile region			Instability critical state (Critical state in compressive region)			
			Occurrence position		Critical wind speed (m/s)	Occurrence position		Critical wind speed (m/s)	Primary compressive stress (MPa)
	Relative to tower height	Included angle from incoming flow	Relative to tower height	Included angle from incoming flow		Relative to tower height	Included angle from incoming flow		
α=0.00	0.782	0°	0.286	0°	72.5	0.209	±70°	160.0	24.2
α=0.12	0.782	0°	0.286	0°	52.5	0.286	±70°	125.0	25.2

Ignoring the internal pressure effect and applying the external wind pressure distribution curve of code NDGJ5-88, a comparison study of the cooling tower's ultimate load-carrying strength based on two different wind profiles (uniform profile and turbulent flow field profile) is conducted (see Fig.6 and Table.9). Results show that there exist noticeable wind profile effects. With the turbulent flow field profile, the vertical action center of the surface aerodynamic loads rises and the center of the maximum compressive stress region rises by 36% compared with that of the uniform flow condition. As the shell thickness at the position of the vertical action center decreases for the turbulent flow condition, the instability critical wind speed drops by 23.4%, causing structural buckling vulnerability.

5.2 Internal pressure effect

The study of the internal pressure effect on the cooling tower's ultimate load-carrying capacity is conducted. Results (Fig.7 and Table.10) show that there is no significant internal pressure effect,

for no notable changes of maximum total static wind-induced deformation have been observed. There is no change of the occurrence position of the maximum deformation, nor is there any change of the occurrence position of tensile stress or compressive stress at critical states according to Table.10. The instability critical wind speed drops by 4.0% after considering the internal pressure effect.

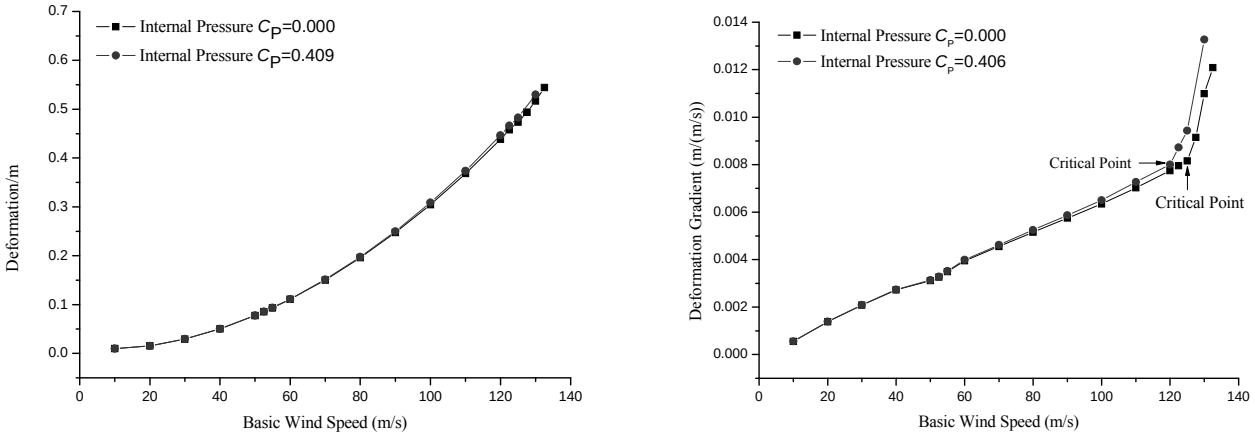

Fig.7 Displacements and its derivatives for different internal pressures

Table.10 Critical states for different internal pressures

Internal pressure	Occurrence positions of maximum deformation		Critical state in tensile region			Instability critical state (Critical state in compressive region)			
			Occurrence position		Critical wind speed (m/s)	Occurrence position		Critical wind speed (m/s)	Primary compressive stress (MPa)
	Relative to tower height	Included angle from incoming flow	Relative to tower height	Included angle from incoming flow		Relative to tower height	Included angle from incoming flow		
C_p=0.000	0.782	0°	0.286	0°	52.5	0.286	±70°	125.0	25.2
C_p=0.409	0.782	0°	0.286	0°	52.5	0.286	±70°	120.0	24.0

5.3 Boundary effect

After the Reynolds number effect modeling, the surface pressure mean value distribution of several intermediate sections coincide with the code results in this study. However, three dimensional effects (or boundary effect) in end regions (the top/bottom areas) of the tower surface can be demonstrated by the notable differences between experimental pressure distribution patterns and the surface pressure curve for sections of all heights given by the code NDGJ5-88, as shown in Fig.8.

Fig.9 and Table.11 both compare the boundary effect on the structural ultimate load-carrying capacity. It is shown that there is no significant boundary effect on the structural ultimate load-carrying capacity by comparison the static wind load deformation-wind speed curves, as well as the occurrence positions of maximum deformation and tensile or compressive stresses (see Fig.9 and Table.11). Since the critical wind speed of the total structural instability drops by 4.2% after considering the boundary effect, the overall boundary effect is mildly adverse.

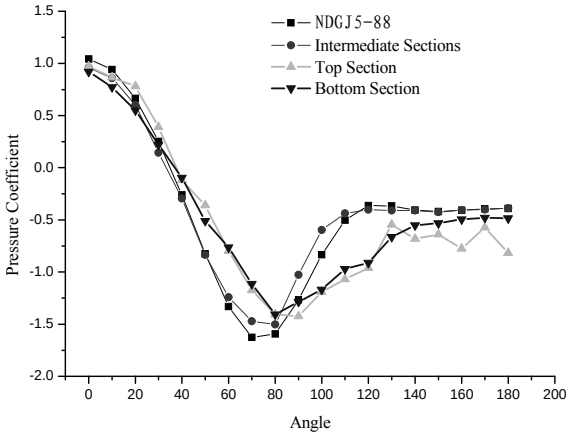

Fig. 8 Surface pressure curves of different heights

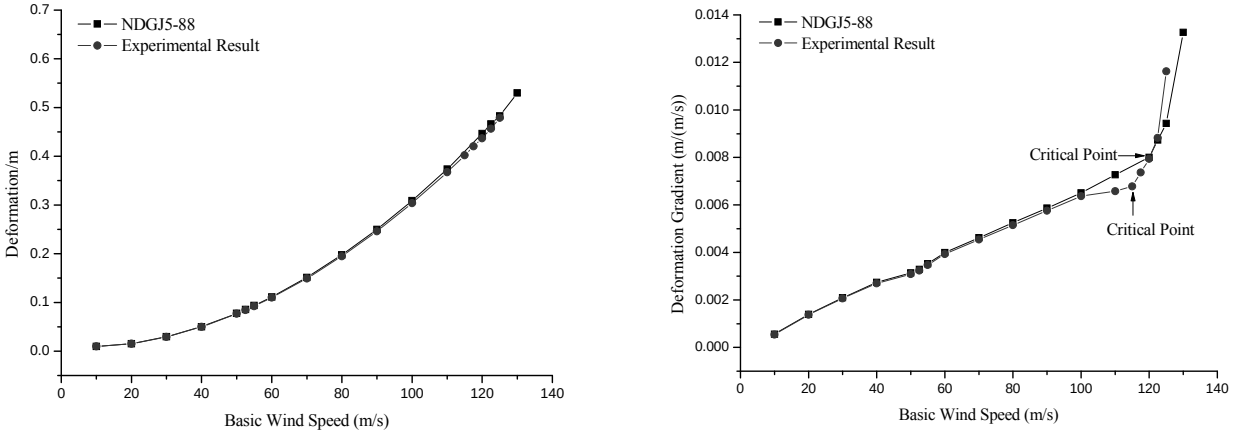

Fig.9 Displacements and its derivatives for different boundary conditions

Table.11 Critical stations for different boundary conditions

Surface pressure	Occurrence positions of maximum deformation		Critical state in tensile region			Instability critical state (Critical state in compressive region)			
			Occurrence position		Critical wind speed (m/s)	Occurrence position		Critical wind speed (m/s)	Primary compressive stress (MPa)
	Relative to tower height	Included angle from incoming flow	Relative to tower height	Included angle from incoming flow		Relative to tower height	Included angle from incoming flow		
NDGJ5-88	0.782	0°	0.286	0°	52.5	0.286	±70°	120.0	24.0
Experimenal results	0.782	0°	0.286	0°	52.5	0.286	±70°	115.0	23.7

5.4 Group tower interference effect

Fig.10 and Table.12 compare the cooling tower's ultimate load-carrying capacity with different group tower interference effects. For different group tower conditions, there is no significant change of the occurrence position of the maximum deformation or the occurrence positions of the maximum tensile/compressive stress at the critical states. Comparing the critical wind speed, it is shown in Fig.10 that: the critical wind speed for single tower > that for four tower group condition > that for two tower group condition. The results coincide with those of the local elastic stability study (see Section 4.4), proving the change of position of the vertical action center.

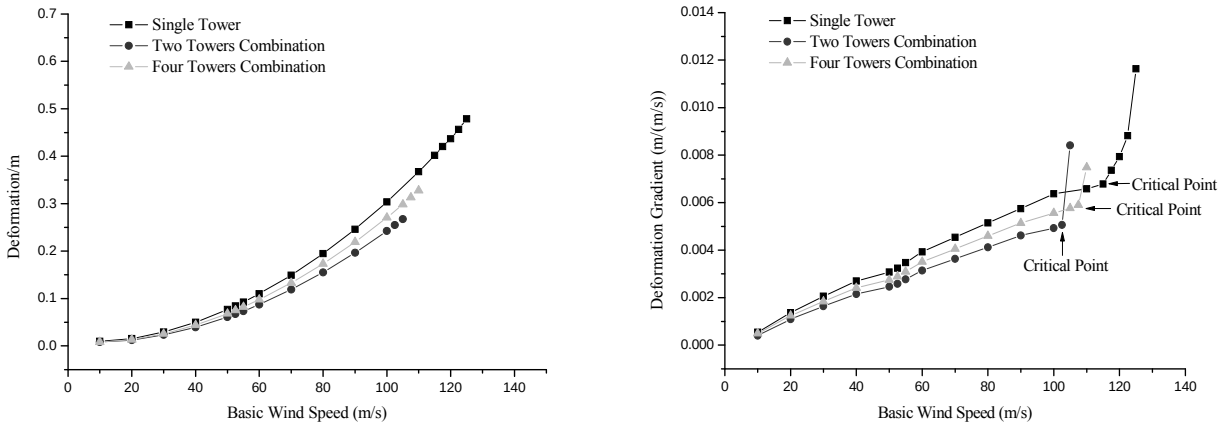

Fig.10 Displacements and its derivatives for different tower group combinations

Table.12 Critical states for different tower group combinations

Group combination	Occurrence position of maximum deformation		Critical state in tensile region			Instability critical state (Critical state in compressive region)			
			Occurrence position		Critical wind speed (m/s)	Occurrence position		Critical wind speed (m/s)	Primary compressive stress (MPa)
	Relative to tower height	Included angle from incoming flow	Relative to tower height	Included angle from incoming flow		Relative to tower height	Included angle from incoming flow		
Single tower	0.782	0°	0.286	0°	52.5	0.286	±70°	115.0	23.7
Two towers	0.782	0°	0.247	0°	50.0	0.286	±70°	102.5	17.5
Four towers	0.782	0°	0.247	0°	52.5	0.286	±70°	107.5	18.5

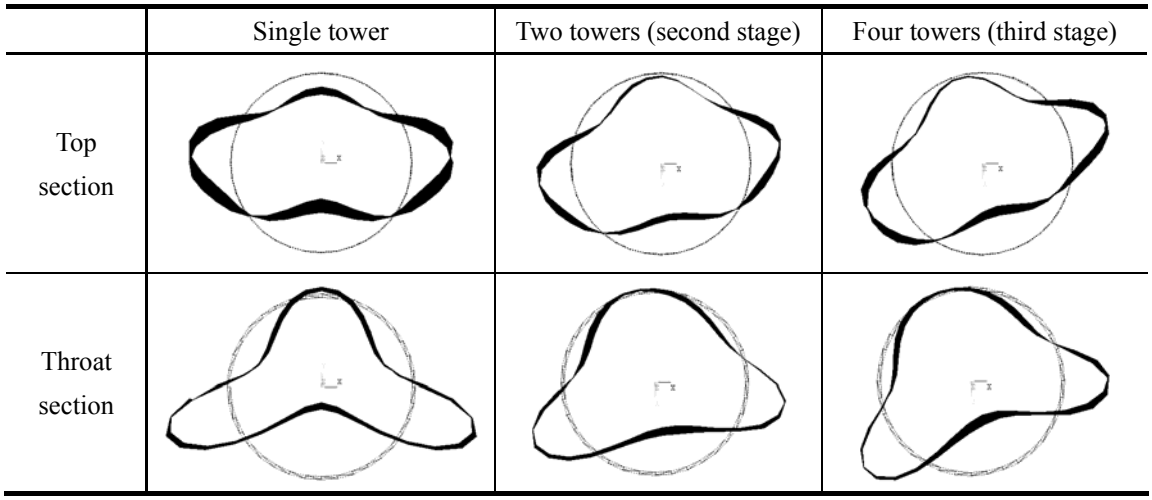

Fig.11 Structural failure shapes for different tower group combinations

Further study of structural failure (or buckling) shapes on both top and throat sections of different tower group combinations conditions are shown in Fig.11. It is demonstrated that the failure shapes of the second stage condition and the third stage condition are similar and there exist some differences in deformation symmetry properties as well as the occurrence position of maximum deformation between the single tower condition and the group tower conditions.

6 CONCLUSIONS

The conclusions drawn in this study are as follows:

(i) Generally, the extreme value wind load action is not taken as the control loading in cooling towers' structural design at present. The internal pressure effect on the tower's local elastic stability and overall structural ultimate load carrying capacity is mildly adverse. According to the

comparison study, the traditional methodology of considering extreme value wind pressure distribution patterns renders adverse structural performance compared with the methodology based on the wind tunnel tests for a single tower.

(ii) There exist notable group tower interference effects on the total extreme value wind loads, the structural responses (deformation and internal force), the local elastic stability, the ultimate load-carrying capacity and the instability shape of the cooling towers situated in the specific engineering site (described in Section 2). The variation trends of the tower group factor, the local elastic stability factor and the critical wind speed with different group tower conditions are different, demonstrating the complexity in considering the group tower interference effect. The methodology in considering group tower interference effect using the external pressure distribution obtained from codes, the tower group interference factor and the wind-vibration factor is conservative compared with the methodology based on the extreme value wind pressure distribution patterns obtained from wind tunnel tests.

(iii) The wind profile effect is obvious. Considering the wind profile of turbulent flow field, the critical wind speed of the instability critical state drops significantly, since the vertical center of the total surface aerodynamic wind action rises.

(iv) The boundary effect causes mildly adverse influence on the cooling tower's total structural stability.

(v) For most conditions referred to in this study, local areas on the concrete shell of cooling tower reach the allowable tensile stress under the action of the wind force with a wind speed of around 50m/s. The total structure's instability critical state generally appears before the crushing of the concrete in the compressive stress region, showing obvious geometric nonlinearity effects.

The FEM numerical simulation in this study applies a simplified way in considering the material nonlinearity effect of concrete. Our further works will lay more emphasis on the structural failure mode analyses applying more precise constitutive model of concrete.

Extreme value distribution of surface aerodynamic pressure of hyperbolic cooling tower

X. P. Liu, L. Zhao, Y. J. Ge

State Key Laboratory for Disaster Reduction in Civil Engineering, Tongji University, Shanghai 200092, China

Abstract

The simultaneous pressure-measuring tests of rigid model for a super large cooling tower were made in TJ-3 wind tunnel of Tongji University. In the process of external wind pressure measurement, by adjusting surface roughness and oncoming wind velocity, the actual aerodynamic characteristics of full-scale cooling towers were illustrated in the scale-reduced testing model with lower Reynolds number. By measuring tail flow of the cooling tower model using high-frequency anemometer, the mean estimating primary vortex shedding frequencies through frequency-spectrum transformation of aerodynamic time history for whole cooling tower was proved to be reasonable and simple. In this paper, the distribution rule about sectional drag force coefficients along the tower height is analyzed based on probability correlation technique, then the Fourier serious fitting curves of wind pressure extreme value distributions along the circumferential direction for each section are also proposed. For internal pressures of the cooling tower, some comparative tests about dependency of internal aerodynamic pressures and various ventilation ratios of stuffing layer located below the cooling tower are firstly carried out, then the internal wind pressure extreme value distributions for commonly-used ventilation ratio are suggested considering the correlation of aerodynamic pressures.

***Key words**:* cooling tower; Reynolds number effect; extreme value distribution

1 Introduction

As a typical high-rise and long-span flexible structure, the wind-induced performance of cooling tower under the dynamic action of wind loads has always been focused with more attention. By simultaneous pressure-measuring tests of cooling tower rigid model in wind tunnel, mean and fluctuating wind pressure distributions over its external and internal surfaces can be obtained. In the process of external wind pressure measurement, by adjusting surface roughness and oncoming wind velocity, the actual aerodynamic characteristics of full-scale cooling towers were illustrated in the scale-reduced testing model with lower Reynolds number. For the sake of simplicity, extreme aerodynamic pressure distribution can be formulated in such expression as below:

$$\mu_p = \mu_m + \sigma_\mu \times g \times \rho \tag{1}$$

in which, μ_p, μ_m and σ_μ are extreme value, mean value and RMS value of pressure shape coefficient, g is peak factor, ρ is correlation coefficient. The statistical estimation algorithm of g and ρ are discussed in details.

For internal pressures of the cooling tower, some comparative tests about dependency of internal aerodynamic pressures and various ventilation ratios of stuffing layer located below the cooling tower are carried out, then the internal pressure extreme value distributions under commonly-used ventilation ratio are suggested basing on the correlation of aerodynamic pressures.

2 Experimental arrangement

The test is carried out in the wind tunnel of TJ-3 atmospheric boundary layer in the State Key Laboratory of Disaster Reduction in Civil Engineering, Tongji University. The wind tunnel is a closed reflux rectangular cross-section wind tunnel, wherein the size of the test section is as follows: the width is 15m, the height is 2m, and the length is 14m. In the test, the engineering site belongs to the landform of Class A, the wind profile index α = 0.12, the surface turbulence intensity is 15%, the turbulence intensity on the top of the cooling tower is 10%. A rigid scale model of cooling tower is made of organic glass according to the scale ratio of 1: 200, in which the external pressure measuring model is a single-layer thin-walled tower drum, the internal pressure measuring model is a double-layer hollow tower drum, the internal and external pressure measuring points are arranged as Figure 1, and the congestion index of the cooling tower and other building models around the same is less than 7%.

The debugging and measurement for the simulated wind field of the atmospheric boundary layer are carried out through the Streamline hotline anemometer produced by DANTEC Company of Denmark, and the measurement for the average inner and outer surface pressure of the cooling tower and the fluctuating pressure is carried out by means of a DSM3000 electronic pressure scanning valve produced by Scanivalve scanning valve company of the United State. The signal sampling frequency is 312.5Hz, and the length for sampled data of a single sample measuring point is 6000 data.

The external pressure measuring model of the cooling tower is provided with 36 × 12 outer surface pressure measuring points along the circular and meridian direction. The internal pressure measuring model is provided with 36 × 6 inner surface pressure measuring points along the circular and meridian direction. The layout for the internal and external pressure measuring points is shown in Figure 2(unit: m).

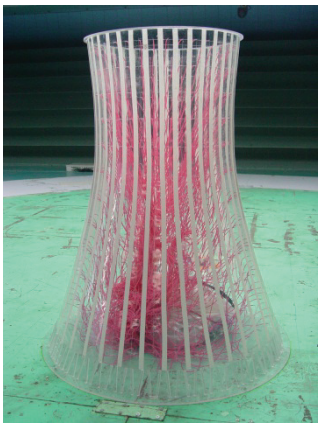

Fig.1a Model for external pressure

Fig.1b Model for internal pressure

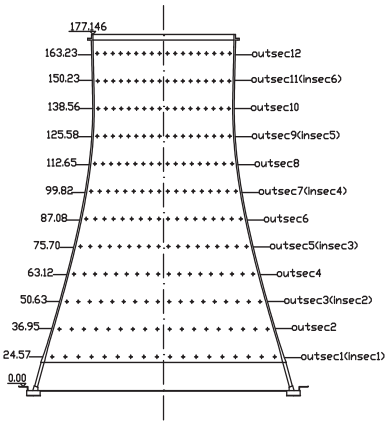

Fig.2 Arrangement for pressure points

The pressure coefficient C_{Pi} in the ith measuring point of surface of the cooling tower is expressed as:

$$C_{Pi} = \frac{P_i - P_\infty}{P_0 - P_\infty} \tag{2}$$

In which, P_i indicates the pressure applied to the ith measuring point, P_0 and P_∞ respectively indicate the total pressure and static pressure in the reference height point while

testing.

The Integral of the overall resistance coefficient (down wind) and the lift coefficient (cross-wind direction) measured in the external surface pressure measuring point of the cooling tower is defined as:

$$C_D = \frac{\sum_{i=1}^{n} C_{Pi} A_i \cos(\theta_i)}{A_T} \qquad C_L = \frac{\sum_{i=1}^{n} C_{Pi} A_i \sin(\theta_i)}{A_T} \tag{3}$$

In the formula, C_D and C_L respectively indicate the overall resistance and lift coefficient of the structure, A_i indicates the pressure of coverage area in the ith measuring point, θ_i indicates the included angle between the pressure and wind axis direction of the ith measuring point, and A_T indicates the projection area of the overall structure along the wind axis direction

The correlation coefficient between the measuring point, and the measuring point and the overall aerodynamic time history is defined as follows:

$$\rho_{xy} = \frac{E[(x - Ex)(y - Ey)]}{\sigma_x \sigma_y} \tag{4}$$

In the formula, Ex, Ey and σ_x, σ_y respectively indicate the expectation and variance for the stochastic sequences $x(t)$ and $y(t)$.

3 Reynolds number effect simulation

3.1Reynolds number effect simulation

The actual aerodynamic characteristics of full-scale cooling towers were well got by adjusting surface roughness for the scale-reduced testing model with lower Reynolds number, including scribed line and paper tape. And When oncoming wind velocity is 8m/s, the test curve of mean surface pressure shape coefficients were fitted well with the suggested curve from China Codes, as shown in Figure 3. In the paper, the range of the Reynolds number Re for the prototype structure of the ultra-large cooling tower under designed wind speed is 1.5×10^8 to 3.5×10^8.

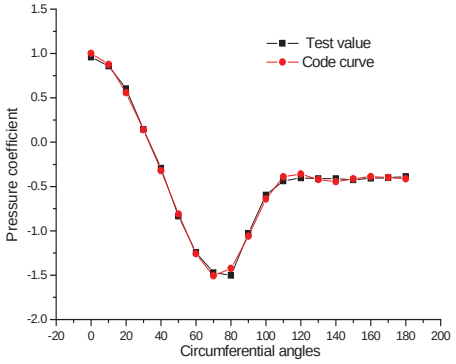

Fig.3 Pressure comparison of test and Codes

Due to the limitation of physical wind tunnel, the form of surface circumferential motion under a high Reynolds number is difficult to be simply reproduced by improving the test wind speed or increasing the geometric dimensions of the structure. The circumferential motion characteristics of the cylinder-like structure are not only related to the Reynolds number, but also closely related to surface roughness and other factors. As experience proves that the circumferential motion characteristics at a high Reynolds number can be approximately simulated by changing the surface roughness of the model. After comparing a variety of proposals of changing the surface roughness, the method for uniformly providing 36 vertical and continuous rough paper tapes (see Figure 1a) of 12mm

wide and 0.1mm thick and regulating test wind speed (4m/s to 12m/s) is finally used for simulating high Reynolds number effects, in which the simulation standard comprises the surface pressure distribution, overall resistance coefficient and value of St number and the like of cooling tower. The average wind pressure distribution coefficient of hyperbolic cooling tower, the simulation standard is a wind pressure distribution eight-item fitting curve measured on the site and recommended in the hydraulic specification, wherein the simulation process is focused on the maximum pressure coefficient, minimum pressure coefficient, wake flow pressure coefficient, zero-pressure coefficient angle, minimum pressure coefficient angle, and separation angle. Compared with Figure 7, it can be found that the average surface pressure distribution for the six middle sections of the cooling tower in case of surface groove + rough paper tape at the test wind speed of 8/s is in good agreement with the standard value, in which the resistance coefficient of the middle section is C_D=0.436, and the integral resistance coefficient of surface pressure specified in China is C_D=0.437.

3.2 *Effect of Weak Flow Vortex Shedding*

Strouhal number is a function of structure geometry and Reynolds number. When the Reynolds number Re is more than 3.5×10^6, the turbulent ingredients in the weak flow vortex shedding of the cylinder-like structure are more prominent; meanwhile, regular vortex shedding phenomenon also will be presented, and the St number at that time is slightly larger than 0.2. The St number is closely related to the dynamic response of the structure, which is also one of the Reynolds number effects to be simulated in the test. Due to the irregularity of turbulent ingredients in the weak flow, the direction measurement for the frequency of vortex shedding is more difficult, and therefore the paper attempts to indirectly determine the outstanding frequency of vortex shedding through the frequency spectrum function for time history of the while lift. In order to verify the validity of the method, the weak flow of the cooling tower is measured in several points by means of a hotline anemometer.

The hotline anemometer is arranged on the protected side of the cooling tower, the height for the probe of the anemometer and the distance to the cooling tower are changed, and a variety of points in the weak flow region of the cooling tower are measured under the condition of a test wind speed of 8m/s. The results show that the weak flow vortex shedding frequencies measured in the point of about 2/3 tower height above the ground and the point part from the protected side surface of the model with about 0.8 times of middle surface radius of the throat part are the most obvious, as shown in Figure 4a). The aerodynamic force time history of the whole cross-wind direction is obtained according to the time history integral of surface pressure coefficient of the cooling tower, and the spectrum function for the time history of lift coefficient is shown in Figure 4b).

The weak flow vortex shedding frequency (2.411Hz) is relatively close to the frequency (2.594Hz) obtained by changing the frequency spectrum of time history of the lift coefficient, in which the relative deviation is 7.5%. The St numbers respectively calculated according to the weak flow vortex shedding frequency and the frequency spectrum change for the time history of lift coefficient are 0.235 and 0.253 (the characteristic size is the diameter of 0.78m for the throat part of the cooling tower model, and the wind speed is

8m/s), both the numbers are greater than 0.2, so that it is further validated that the St number of the cooling tower is completely coincident with the target value simulated in the test.

b) Spectrum Function for Time History of Lift Coefficient

Figure 4: Spectrum Function for Fluctuation Vortex Shedding of Wake Flow and Time History of Circular Surface Aerodynamic Force of Tower Drum

4 Extreme pressure of external surface

4.1 *resistance coefficient for Sections*

The average resistance coefficient for the 12 meridian sections of the cooling tower model is arranged along the height and shown in the feature that the value of end part is large and value of middle part is small (as shown in Figure 5), both the resistance coefficients for the section of top and bottom of the cooling tower are significantly greater than the resistance coefficient of middle section, wherein the average

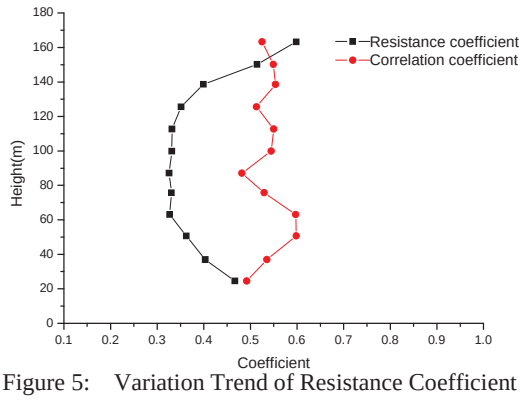

Figure 5: Variation Trend of Resistance Coefficient and Correlation Coefficient along the Height

resistance coefficients for the section of top and bottom of the cooling tower are 0.467 and 0.598, respectively; and the average resistance coefficients are respectively more than the minimum average resistance coefficients of the middle section with (0.326) 43% and 83%. The phenomenon is mainly due to the end effect of circumferential motion on the surface of the cooling tower, the stress of the bottom and top section of the cooling tower is more complicated, the local pressure coefficient is much larger than the designed value in the specification, and the local stability for the end part of the cooling tower shall be paid attention in the design process as the drum wall structure on the top of the cooling tower is relatively thin. In Figure 5, both the correlation coefficients for the time history of resistance coefficient of each section and the time history of resistance coefficient of whole cooling tower structure are about 0.55, which is between 0.48 and 0.60. Due to the impact for end part boundary effect of cooling tower, six representative middle sections (see Figure 2 Outsec4 to Outsec9) are selected as research objects in the simulation of Reynolds number effect and subsequent extreme value analysis for the pressure coefficient of external surface pressure.

4.2 *Extreme Pressure Distribution of External Surface*

4.2.1 *Extreme Pressure of Sections*

During the process for checking the local strength and local stability under the wind load effect of cooling tower, the result for the extreme value of pressure coefficient shall be adopted, but the specification just provides the average pressure coefficient distribution and stipulates the gust effect in the turbulent flow field of Class A is considered with the wind-induced vibration coefficient of 1.6. In order to compare with the extreme value of pressure coefficient specified in the specification, the measured extreme value for the pressure coefficient of each measuring point and the distribution rule thereof are analyzed. See Equation 1 for the definition of extreme value of the pressure coefficient, in which ρ_D and ρ_L are respectively used for the correlation coefficients for the time history of pressure coefficient of each measuring point and the time history of life, and the extreme value for the pressure coefficient related to the structure resistance and lift time history are respectively as follows:

$$\mu_{pD} = \mu_m + \sigma_\mu \times g \times \rho_D \tag{5}$$

$$\mu_{pL} = \mu_m + \sigma_\mu \times g \times \rho_L \tag{6}$$

Firstly, the correlation for the time history of pressure coefficient of each measuring point to the resistance and lift time history of the section is considered only, and it is assumed that all the sections are completely related to the stress time history of the whole cooling tower structure, the correlation coefficients for the average pressure coefficient, root variance and peak factor of each measuring point of the 6 middle sections of the cooling tower, the resistance of the section, and the lift time history in the turbulence flow field of Class A are shown in Figure 6. The distributions for the 6 section extreme values obtained from the Equations (5) and (6) and related to the resistance and lift time history are basically the same (as shown in Figure 7), and the average extreme values of the 6 sections are close to each other after averaging and comparing (as shown in Figure 8).

Taking into account the security of structure design, the envelope value for the two extreme values is compared with the extreme value of the specification (as shown in Figure 9), in which it can be seen that the distribution of pressure coefficient extreme value is slightly different from the result of the specification while considering the correlation of the measuring point to the resistance and lift of the section only, the difference between the corresponding angles of minimum values is about 10 degrees, and the absolute value for the pressure coefficient of the weak flow area of envelope value is greater than the extreme value of Xi'an Thermal Power.

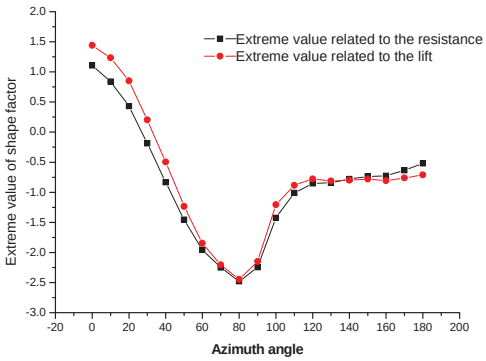

Figure 8: Comparison between Extreme Values of Two Pressure Coefficients

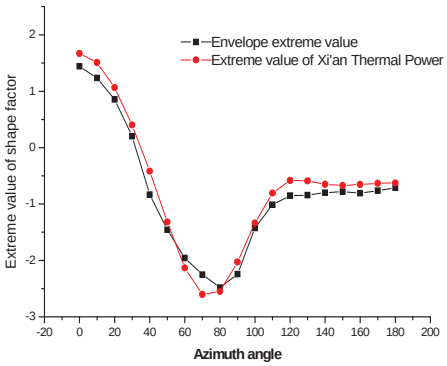

Figure 9 :Comparison between Aerodynamic Extreme Values of Section and Specification

4.2.2 *Extreme Pressure of the whole structure*

The correlation for the pressure coefficient of each measuring point to the resistance and lift time history of the whole structure shall be considered. The through for the calculation and analysis extreme value are the same with that above. Figure 10 and Table 1 compare the distribution of envelope extreme value and specified extreme value. In the process for the consideration of the correlation between the pressure coefficient of each measuring point and the stress time history of the structure, the distribution of pressure coefficient extreme value has a certain difference to the extreme value of the specification, the maximum (1.298) value and minimum (-2.307) value for the extreme value distribution of envelope pressure coefficient are 78% and 87% of the maximum (1.668) value and minimum (-2.603) value of specified extreme value respectively, the difference between the corresponding angles of the maximum negative pressure is 10 degrees, and the differences for the weak flow pressure and separation angle of the two extreme value distributions are small.

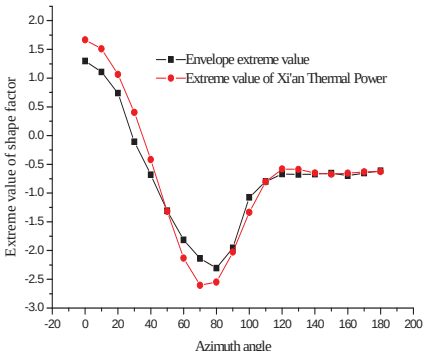

Fig.10 Test general envelope values and codes

Table 1 : Comparison for Characteristic Value of Extreme Value Distribution of Two Pressure Coefficient

Extreme Value Distribution	Maximum Value	Minimum Value	Average of Weak Flow Area	Angle of Minimum Value	Separation Angle
Envelope Extreme Value	1.298	-2.307	-0.661	80°	120°
Specified Extreme Value	1.668	-2.603	-0.629	70°	120°

The extreme value distribution curve of shape coefficient is fitted while considering the correlation to the structure by means of a Fourier series expansion equation $\mu_p(\theta) = \sum_{k=0}^{m} a_k \cos k\theta$ on the basis of least square method. When m is not less than 7, the fitting effect is good, when m is equal to 7, the value of the parameter a_k in the formula is as follows: a0=-0.7789, a1=0.3126, a2=1.0159, a3=0.7366, a4=0.0439, a5=-0.1429, a6=0.0742, and a7=0.0856.

5. Extreme pressure distribution of inner surface

5.1 *Impact of Ventilation Rate*

The ventilation rate of packing layer within the tower is simulated by placing an organic glass plate which is uniformly hollowed in the lower part of the cooling tower. The test results show that the ventilation rate of packing layer within the tower does not have obvious impact on the form of internal pressure distribution curve, closely related to the internal pressure, specifically the ventilation rate is inversely proportional to absolute value of the internal pressure. Table 2 shows the average of inner surface pressure coefficient of different ventilation rates in the turbulence flow field of Class A (taking the wind pressure of tower top as the reference pressure).

Table 2: Inner Surface Pressure Coefficient of Single Cooling Tower

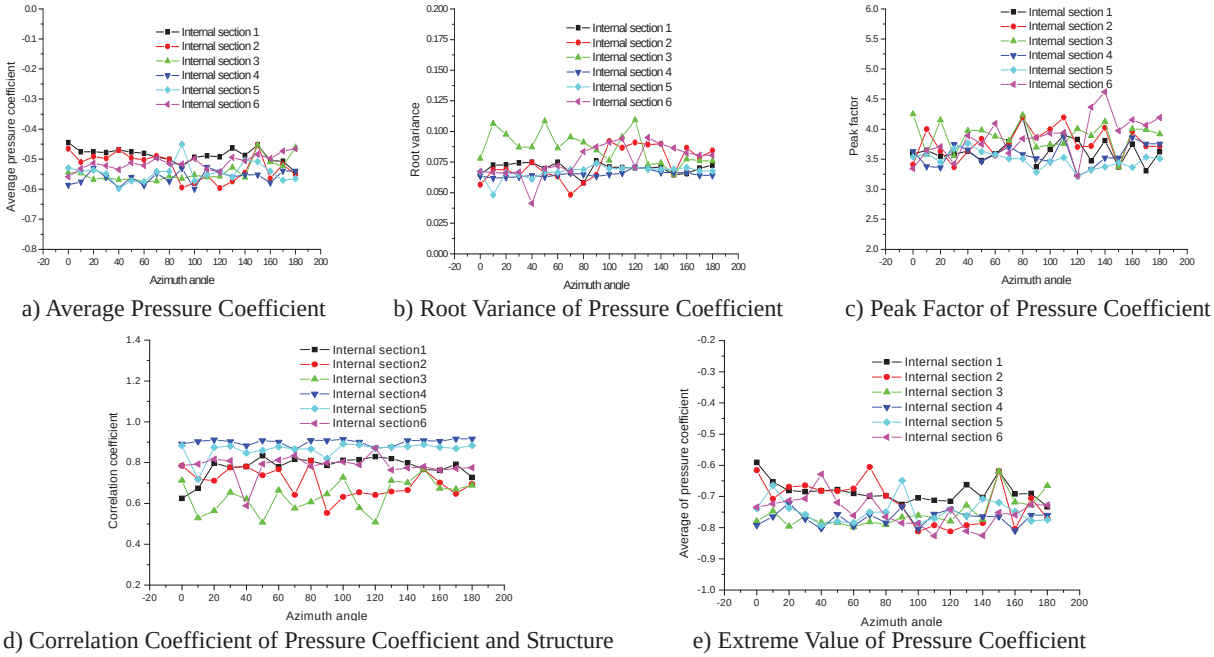
Ventilation Rate	100%	55%	30%	15%	3%	0%
Average Internal Pressure	-0.375	-0.382	-0.410	-0.524	-0.590	-0.761

5.2 *Distribution of Extreme Pressure*

Generally, the ventilation rate of natural draft cooling tower is more than 30%, but the temporary construction facilities will reduce the ventilation rate in the actual operation state, the paper takes the internal pressure with a ventilation rate of 15% as the wind pressure of actual structure due to the consideration of safety. Here, the distribution of extreme internal pressure is analyzed by taking the ventilation rate of 15% for example. The extreme value of pressure coefficient is defined as:

$$C_{pp} = C_{pm} - \sigma_{Cp} \times g \times \rho \tag{7}$$

In the formula, C_{pm} and indicate the average and root variance of pressure coefficient, g indicates a peak factor, and ρ indicates the correlation coefficient for the time history of pressure coefficient of each measuring point to lift time history for the pressure coefficient of each measuring point obtained in the while inner surface integral. Figure 11 shows the average, root variance, peak factor, correlation coefficient and extreme value of internal surface of the six sections. The circular distribution for the average, correlation coefficient and extreme value for the internal pressure coefficient along the inner surface is basically shown in the form of a straight line, and the values thereof are basically the same. The pressure coefficient of each section is average, and the changes for the average pressure coefficient of each section and the extreme value along the height of the cooling tower are compared; according to Figure 12, it can be seen that the pressure coefficient is not obviously changed with the height, but lasso uniformly distributed approximately. Thus, it can be indicated that the internal pressure coefficient of the cooling tower is uniform in the whole inner surface, the extreme internal pressure and average of all the measuring points are average respectively on the basis of the conclusion above, in which the average extreme value (-0.737) is 1.4 times of the mean average (-0.524), less than the wind-induced vibration factor 1.6 of turbulent flow field of Class A



a) Average Pressure Coefficient b) Root Variance of Pressure Coefficient c) Peak Factor of Pressure Coefficient

d) Correlation Coefficient of Pressure Coefficient and Structure e) Extreme Value of Pressure Coefficient

6 conclusion

The study to external and internal pressure distributions of the cooling tower is based on pressure measuring data of the rigid model. And the following summarizes the major findings and conclusions of this study:

1. The actual aerodynamic characteristics of full-scale cooling towers were well got by adjusting oncoming wind velocity and surface roughness for the scale-reduced testing model with lower Reynolds number.
2. In the process for the consideration of the correlation between the pressure coefficient of each measuring point and the stress time history of the structure, the distribution of pressure coefficient extreme value has a certain difference to the extreme value of the China Code which is slightly tends to conservative.
3. The extreme value distribution curve of shape coefficient is fitted while considering the correlation to the structure by means of a Fourier series expansion equation.
4. The ventilation rate is inversely proportional to absolute value of the internal pressure. And the pressure coefficient is not obviously changed with the height, but lasso uniformly distributed approximately.

Ventilation efficiency indices for evaluating ventilation performance of newly-built urban area

Tingting Hu [a], Ryuichiro Yoshie [b]

[a] *Tokyo Polytechnic University, Kanagawa, Japan, tingting@arch.t-kougei.ac.jp*
[b] *Tokyo Polytechnic University, Kanagawa, Japan, yoshie@arch.t-kougei.ac.jp*

ABSTRACT: This paper aims to numerically investigate relationship among ventilation indices which were adopted for estimating ventilation efficiency in newly-built residential areas at pedestrian level. A reference urban block model was designed according to a typical residential area in Shanghai. Urban parameters including building coverage ratio, passage width, building array and building height variation were considered. The ventilation efficiency was evaluated by spatial averaged wind speed ratio (VR_w), volume-averaged normalized concentration (C^*), and visitation frequency (VF). The results showed that, for most cases, a general relationship was found among the three indices: a large value of VR_w and a low value of VF resulted in a low value of C^*. However, a few exceptions were found in the densest case and these were explained by flow rate analysis.

KEYWORDS: urban ventilation; ventilation indices; CFD.

1 INTRODUCTION

Recently, urban ventilation performance is becoming an important concern because of urban heat island effects and air pollution. It is necessary to evaluate urban ventilation performance based on different design parameters in order to improve planning of new-built areas.

Volume-averaged wind speed ratio (VR_w) (Ng, 2009), volume-averaged normalized concentration (C^*), purging flow rate (PFR), residence time (TP) (Kato et al, 2003) and visitation frequency (VF) (Bady et al, 2008), have been successfully applied for evaluating ventilation performance in urban area. The authors have also used the above indices to investigate urban ventilation performance in newly-built area by numerical simulation (Hu and Yoshie, 2011). Based on this previous studies, C^* reflected the integrated effects of other indices such as VR_w and VF, so it can be served as the core index for evaluating ventilation performance. Generally, large VR_w values and small VF values resulted in low C^* values. However, some exceptions were found, for example, low C^* values were found with low VR_w values or large VF values. The reason of such discrepancy needs to be investigated in detail. Therefore, flow rate and mass of pollutant passing through each surface of target control volume were investigated and analyzed. A full-length paper should have a short introduction. This should state the reasons for the work, with brief reference to previous work on the subject.

2 ANALYSIS OUTLINE

2.1 *Analysis model*

A simplified urban block model (Fig. 1a) was designed according to a typical residential area in Shanghai (Fig. 1b). Figure 1c showed an enlarged view of a center block in Figure 1a. The com-

putational domain contained 8 blocks surrounding the central one. All 9 blocks had the same arrangement. Each block comprised a total of 72 residential buildings (48m (L) ×12m (W) ×18m (H)) with 6 stories. The building coverage ratio (BCR), which represents the ratio of ground floor area to lot area, was 40% and the floor area ratio (FAR), which represents the ratio of total floor area to lot area, was 230%.

To compare the ventilation efficiency of different urban patterns, other BCRs and arrays (Layouts 2-18) were considered, as shown in Table 1. The BCR was changed by increasing the building height while keeping the FAR constant. (The sum of building volumes was kept constant). The lengths and widths of buildings were not changed. The passage widths D_1 and D_2 between adjacent buildings (shown in Fig. 1f) changed with BCR and building array. The main road width in these models was 20m for all cases, as shown in Fig. 1a. The minimum distances from buildings to the main road side were designed according to the existing urban planning regulations in Shanghai.

2.2 *Computational condition*

The CFD technique with the standard k-ε model was used. Three wind directions 0°, 45° and 90°, shown in Figure 1a, were analyzed. The computational domain contained 8 blocks surrounding the central one. All 9 blocks had the same arrangement. The domain size was 1378 m (x) × 1378 m (y) × 198 m (z) for the reference case. A structured grid of 2,337,984 meshes was made. Table 2 shows the calculation conditions (AIJ guideline).

Size:326m (L_B) 326m (L_B) 2m (h) (Note: except building part)

Five surfaces of PSV

a. Front (Windward surface)

b. Back (Leeward surface)

c. Left, Right (side surfaces)

d. Top (upper surface)

Figure 2. Pollutant Source Volume (PSV)

Wind conditions at pedestrian level in an urban area play an important role in the dispersion of vehicle pollutants, diffusion of heat, and ventilation of buildings, as well as the comfort and safety of pedestrians. Therefore, it is necessary to understand the pedestrian wind environment around buildings 0-2m (z) and to take them into account in urban ventilation design. A uniform pollutant source assumed to be a passive scalar was generated throughout the pollutant source volume (PSV) (0-2m (z) volume of the center block), as shown in Figure 2, to simulate pollution from residence areas and vehicles. Six analysis indices were used to evaluate urban ventilation efficiency for all cases.

2.3 *Analysis indices*

2.3.1 *Spatial Wind Velocity Ratio (*VR_w*)*

Spatial wind velocity ratio (VR_w) is defined as the ratio of average wind velocity at pedestrian level to a reference wind velocity [Ng, 2009], and is calculated as:

$$VR_w = U_p / U_{ref} \quad (1)$$

where U_p is the volume-averaged wind speed in PSV (m/s) and U_{ref} is the inflow wind velocity at 10m height (m/s).

2.3.2 *Volume-averaged Normalized Concentration (*C^**)*

C^* is defined as the volume-averaged normalized concentration, and is calculated as:

$$C^* = (C \times U_{ref} \times W^2)/Q \quad (2)$$

where C is the calculated volume-averaged concentration (kg/kg), Q is the pollution emission rate (m^3/s) and W is the building width (m).

2.3.3 *Inflow rate of air (*$\Delta q_{air,in}$*)*

$\Delta q_{air,in}$ is the inflow rate of air passing through each surface of PSV (kg/s), and is calculated as:

$$\Delta q_{air,in} = \sum_{i=1}^{n} \left(\rho A_i \overline{u_{in,i}} \right) \quad (3)$$

where ρ is the air density (kg/m^3), A_i is the inflow area of cell face i (m^2), $\overline{u_{in,i}}$ is the time-averaged normal inflow wind velocity of cell face i (m/s), and n is the cell number at boundary surface of PSV.

2.3.4 *Inflow rate of pollutants* ($\Delta q_{P,in}$)

$\Delta q_{P,in}$ is the inflow rate of pollutants passing through each surface of PSV (kg/s), and is calculated as:

$$\Delta q_{P,in} = \sum_{i=1}^{n} \left(\rho A_i \overline{c_i} \overline{u_{in,i}} + \rho A_i \overline{c_i' u_{in,i}'} \right) \quad (4)$$

where $\overline{c_i}$ is time-averaged pollutant concentration at the boundary of cell face i (kg/kg), c_i' is the concentration fluctuation (kg/kg), and $u_{in,i}'$ is the inflow velocity fluctuation (m/s).

2.3.5 *Outflow rate of pollutants* ($\Delta q_{P,out}$)

$\Delta q_{P,out}$ is the outflow rate of pollutants passing through each surface of PSV (kg/s), and is calculated as:

$$\Delta q_{P,out} = \sum_{i=1}^{n} \left(\rho A_i \overline{c_i} \overline{u_{out,i}} + \rho A_i \overline{c_i' u_{out,i}'} \right) \quad (5)$$

where $\overline{u_{out,i}}$ is the time averaged normal outflow wind velocity of cell face i (m/s) and $u_{out,i}'$ is the outflow velocity fluctuation (m/s).

2.3.6 *Visitation Frequency (*VF*)*

VF represents the number of times a particle enters the domain and passes through it (Bady et al, 2008). To calculate VF, the following equation was applied:

$$VF = 1 + \Delta q_{P,in} / q_P \quad (6)$$

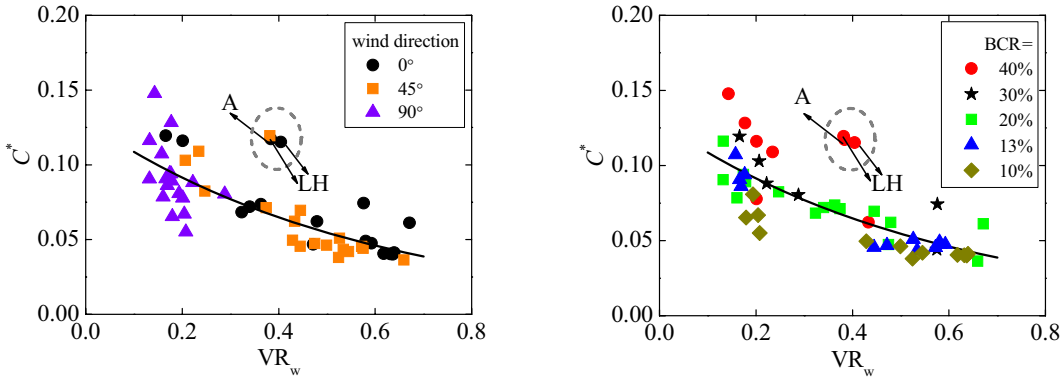
where q_P is the pollutant generation rate $q_P = PSV \times S$ (kg/s), PSV is the Pollutant Source Volume (m^3), and S is the uniform generation source strength ($kg/m^3 \cdot s$).

3 RESULT AND DISCUSSION

Based on previous studies (Hu and Yoshie, 2011), C^* reflected the integrated effects of other indices such as VR_w and VF, so it can be served as the core index for evaluating ventilation performance. Generally, large VR_w values and small VF values resulted in low C^* values. However, some exceptions were found, for example, low C^* values were found with low VR_w values or large VF values. In order to investigate such discrepancy in detail, flow rate and mass of pollutant which reflected by inflow rate of air ($\Delta q_{air,in}$); inflow rate of pollutants ($\Delta q_{P,in}$) and outflow rate of pollutants ($\Delta q_{P,out}$) passing through each surface of target control volume were studied and analyzed.

3.1 *Relationship between VR_w and C^**

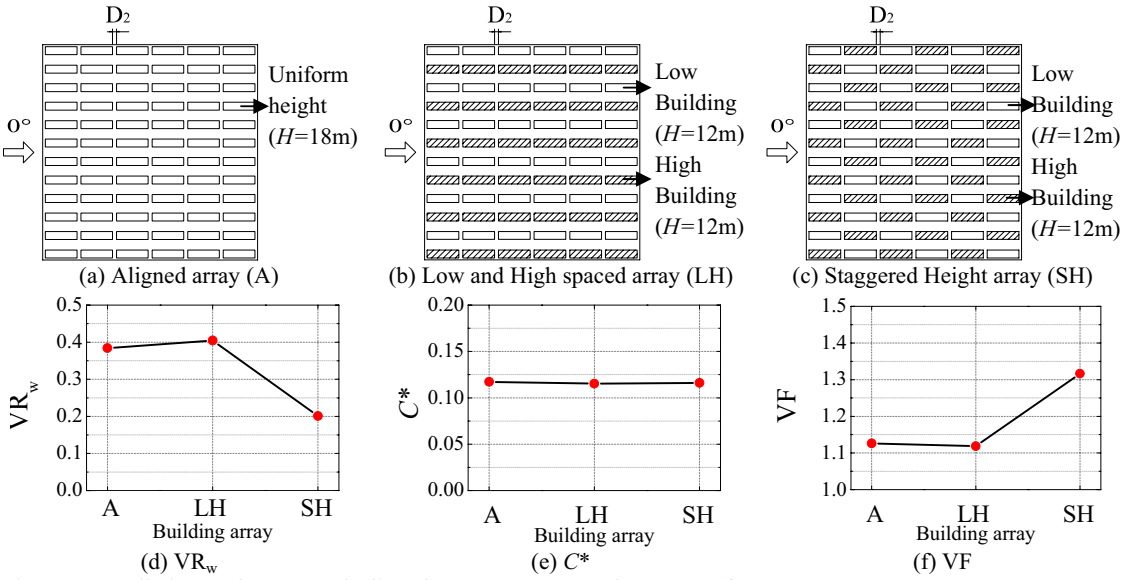
All the cases were classified by three wind directions (Fig. 3a) and four BCRs (Fig. 3b). As expected, VR_w and C^* were negatively correlated for most cases. Several exceptions were indicated by gray dotted circles in both figures.



(a) Classified by wind direction θ (b) Classified by BCR

Figure 3. Relationship between VR_w and C^*

For θ=0°, 45°, C^* decreased as VR_w increased except at three points with both high C^* values and VR_w values, which were enclosed by the gray dotted circle. From Figure 3b, the three exceptions share the same BCR (40%) which were the densest situations. The three cases were A and LH arrays. Figures 4a and 4b showed the view of center block of those two arrays and Figure 4c showed that of SH array with BCR (40%) for reference.



(a) Aligned array (A) (b) Low and High spaced array (LH) (c) Staggered Height array (SH)

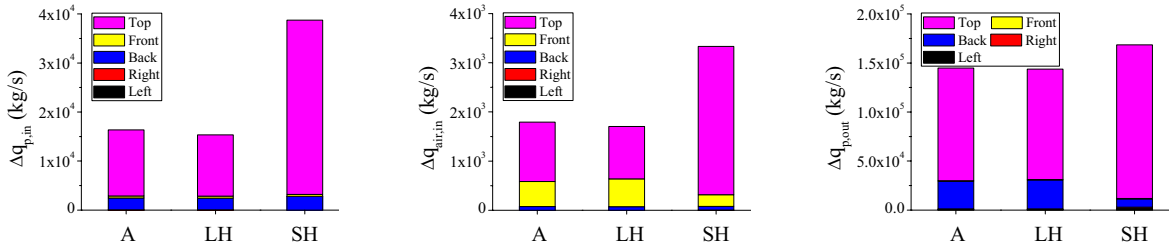
(d) VR_w (e) C^* (f) VF

Figure 4. Ventilation performance of Aligned array, LH array and SH array (θ = 0°, BCR = 40%)

As displayed in Figure 4d, VR_w values of A and LH array were higher than that of SH array. It was because in dense area, small passage width D_2 made the passage parallel to the wind direction like a pipe in the A and LH arrays. This pipe-like flow can speed up the wind in stream-wise direction and cause large value of VR_w. Although VR_w values were different between A, LH and SH array, C^* values were almost the same (Fig. 4e). Therefore, the discrepancy that large VR_w values and high C^* values occurred for A and LH arrays. It can be interpreted by flow rate analysis depicted in Figure 5.

According to Figure 5b, on one hand, an even larger amount air entered PSV via the front surface of the A and LH arrays, and much less air entered through the top surface than for the SH array. One the other hand, as displayed in Figure 5c, even larger amount pollutant was ex-

hausted PSV via the back surface of the A and LH arrays, and much less pollutant was exhausted through the top surface than for the SH array. These two reasons resulted in a large value of C^*.It explained the apparent contradictions between the large VR_w and C^* values. It is noted that the contributions of each surface were different in terms of outflow rate of pollutant (Fig. 5c). For A and LH arrays, larger outflows of pollutant discharged from the back surface than for SH array. This was detrimental to downstream regions. Therefore, although C^* was nearly the same in PSV for the three arrays, SH array was more favorable for downstream regions.



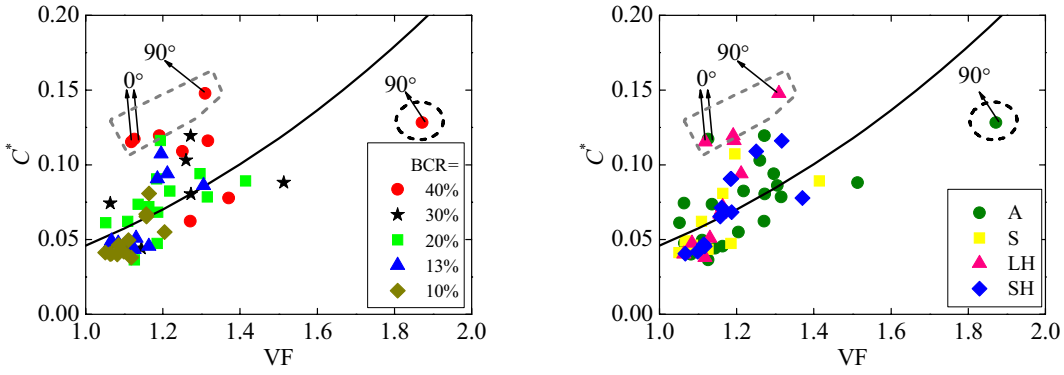
(a) Inflow rate of pollutants (b) Inflow rate of air (c) Outflow rate of pollutants

Figure 5. Flow rate of Aligned array, LH array and SH array (θ = 0°, BCR = 40%)

For θ=90°, the relationship between VR_w and C^* was not clear. VR_w was low and showed little difference while C^* showed large variations for all the cases.

3.2 *Relationship between VF and C^**

The relationship between VF and C^* was classified by BCRs (Fig. 6a) and building arrays (Fig. 6b) respectively. It was shown that C^* generally increased with the increase of VF. However, there were two exceptions.



(a) Classified by BCR (b) Classified by building array

Figure 6. Relationship between VF and C^*

One was large values of C^* and small values of VF (pointed out by the gray dotted polygon). It is noted that most of those exceptions were for A and LH arrays with BCR=40% for θ=0°, 90°.

For θ=0°, as displayed in Figures 4e and 4f, for A and LH array, C^* values were high while VF values were small. The explanation was given in Figure 5. According to Figure 5a, a small amount of pollutant re-entered PSV, resulting in a small value of VF for A and LH array. However, the amount of inflow air and outflow of pollutant to PSV were also small for those cases (Figs. 5b and 5c). Therefore, the pollutant couldn't be diluted and removed and led to a high val-

ue of C^*. For LH array in the case of θ=90° (Fig. 7b), C^* values were high (Fig. 7e) while VF values were small (Fig. 7f). The reason was shown in Figure 8. A small amount of pollutant re-entered PSV, lead to small VF value for LH array (Fig. 8a). Meanwhile, the outflow of pollutant (Fig. 8b) and amount of inflow air (Fig. 8c) to PSV were also small and caused large C^* values. This explained the contradiction that small VF value and large C^* value.

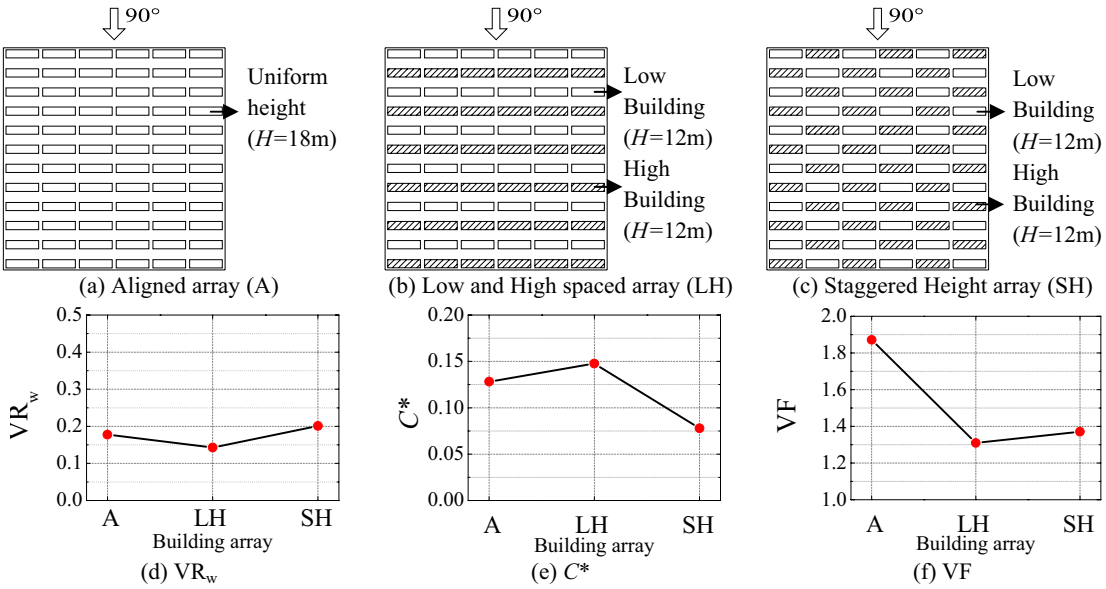


Figure 7. Ventilation performance of Aligned array, LH array and SH array (θ = 90°, BCR = 40%)

Another exception was the A array with BCR=40% for θ=90° (indicated by a black dotted circle in Fig. 6). As depicted in Figures 7e-7f, VF value was very large while the C^* value was not so high. According to Figure 8a, a large amount of inflow pollutant re-entered PSV through the top surface, resulting in a large value of VF. However, the outflow of pollutant and inflow of air were also very large and promoted exhausting and diluting of pollutant (Figs. 8b and 8c). Thus, the value of C^* was not so high.

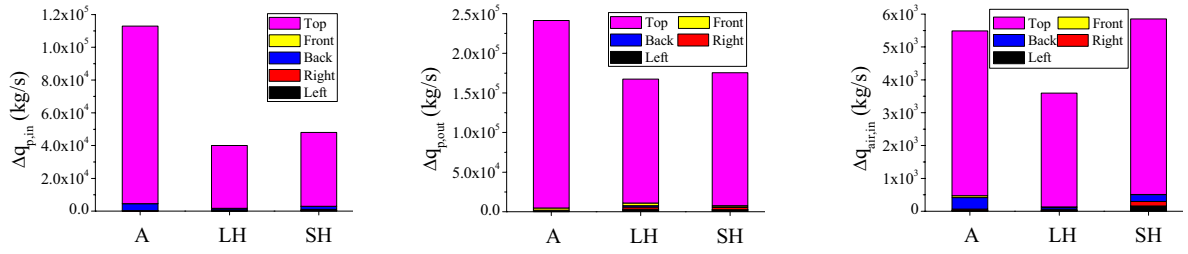

Figure 8. Flow rate of Aligned array, LH array and SH array (θ = 90°, BCR = 40%)

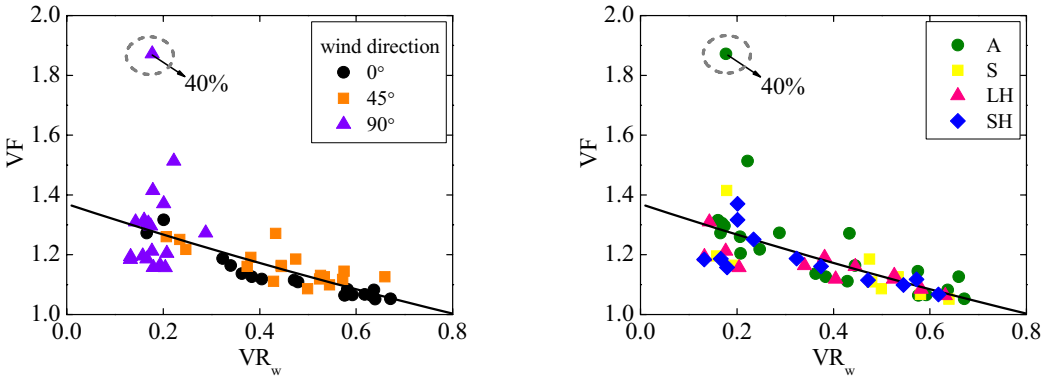
3.3 *Relationship between VR_w and VF*

Figures 9a and 9b showed that VR_w and VF were negatively correlated. As displayed in Figure 9a, for θ=0°, 45°, VF decreased as VR_w increased, and for θ=90°, correlation between VR_w and VF was not clear. VR_w was low and showed few changes while VF showed large differences among all the cases. The A array with BCR=40% for θ=90° showed the largest value of VF. As

discussed in Figure 8a, the largest amount of pollutant re-entered PSV through the top surface, so the value of VF was largest for this case.



(a) Classified by wind direction θ

(b) Classified by building array

Figure 9. Relationship between VR_w and VF

4 CONCLUDING REMARKS

In order to investigate the ventilation efficiency of newly-planned residential areas, CFD simulations were carried out for various building arrangements. A reference urban model was designed according to a typical existing residential area in Shanghai. Keeping FAR constant, other urban models were designed by changing urban parameters (building coverage ratio, passage width, building array and building height variation).

The ventilation efficiency of the different cases were evaluated by spatially averaged VR_w, C^*, and VF. The detailed ventilation information reflected by inflow rate of pollutants ($\Delta q_{P,in}$), outflow rate of pollutants ($\Delta q_{P,out}$) and inflow rate of air ($\Delta q_{air,in}$) were used to explain the relationship among three indices (VR_w, C^*, and VF).

Relationships among ventilation indices (VR_w, C^*, and VF) were summarized for most cases. In general, large VR_w and small VF resulted in low C^*. However, a few exceptions were found in the dentist cases (BCR=40%). They were explained by flow rate analysis. In detail, with the increase of VR_w value, C^* and VF values decreased respectively for θ=0°, 45° except for A and LH array with BCR=40%. And for θ=90°, relationship between VR_w value and C^*, VF values were not clear, VR_w was low and showed few changes while C^* and VF showed large differences among all the cases. With the increase of VF value, C^* value increased for all wind directions.

ABSTRACT: Street canyon phenomenon, in which waste heat and exhaust gases stagnate in the space between multi-story buildings, is contributed for urban air quality deteriorating. The flow field, temperature field, and concentration field of a pollutant in a street canyon are complex. Much research has focused on the flow field, gas concentration field, and their numerical simulations. However, the temperature distribution of the flow field on the street surface has not been investigated experimentally. Therefore, the purpose of this study is to experimentally characterize the effects of building arrangements on the street surface temperature distribution and flow pattern along a heated street canyon. In addition, numerical simulation was used for comparing the experimental results. As a result of this research, contribution factors of cooling effect along the heated street canyon were become clear.

KEYWORDS: Street canyon, wind tunnel, numerical simulation, flow field, temperature field.

1 INTRODUCTION

In recent years, urban air quality has deteriorated due to an increase in the number and density of multi-story buildings. One contributing factor is the street canyon phenomenon, in which waste heat and exhaust gases stagnate in the space which is canopy, above the streets and between high-rise buildings. The flow field, temperature field, and concentration field of a pollutant in a street canyon are complex; highly reliable experimental data is required for the evaluation, prediction and improvement of each field. Much research has focused on the flow field [1], gas concentration field [2-4], and their numerical simulations [3-7]. However, the temperature distribution of the flow field on the street surface has not been investigated experimentally. Therefore, the purpose of this study is to experimentally characterize the effects of building arrangements on the street surface temperature distribution and flow pattern along a heated street canyon. The experiments were performed by actively controlled multiple-fan wind tunnel in our campus; Oita National College of Technology (ONCT). In the ONCT wind tunnel, any kind of turbulent fluctuating flow was generated by actively controlled multiple-fans. This study was carried out under the collaborative work with Toyohashi University of Technology (TUT). TUT wind tunnel has different type of generating turbulence. Compared to our work with different types of turbulent wind properties, it is expected that new knowledge could be obtained. In this paper, as the first step, the effects of building arrangements on street surface temperature and flow patterns with using our multiple-fan wind tunnel are reported. In addition, numerical simulation was used for comparing the experimental results.

2 EXPERIMENTAL SETUP

2.1 *Multiple-fan Wind Tunnel*

The turbulence wind tunnel is an actively controlled multiple-fan-type generator with 66 small, independently computer controlled inlet fans. Each fan duct has separately channels the air from the inlet to the measurement section, at which point the air streams are mixed to create turbulent flow. Any natural turbulent wind condition can be generated by the actively controlled fans. The measurement section has a height of 1015 mm, a width of 1095 mm, and a length of 3600 mm. The wind tunnel apparatus is shown in Figure 1. To generate imitated natural wind in this tunnel, Kármán type spectrum[8-9] was used. This spectrum was shown well the natural wind to set several parameters in the equation (1). To create a time series wind velocity fluctuating data for controlling fans of wind tunnel, inverse FFT method was used.

$$S_u(f) = 4I_u^2 L_u U \frac{1}{\{1+70.8(\frac{fL_u}{U})^2\}^{\frac{5}{6}}} \quad (1)$$

2.2 *Experimental Method*

The street canyon model was built comprising a heated street model and building models. To heat the street model, electrical current was impressed to a thin metal plate directly set in the bottom of the street floor. The building models were made of plastic blocks in three-dimensional configurations. Two normalized sizes were used: 1:1:1 and 2:1:1, where the model size is normalized to the street canyon width. The building models were arranged in several configurations along the heated street, as shown in Table 1. The building models had various combinations of upstream and downstream building heights in both linear and staggered arrangements. Thermography which is infrared imaging camera, was used to observe the temperature distribution of the heated street. In addition, the flow field in the canopy was observed using the smoke-wire method. The wind tunnel was used to test in steady flow and fluctuating turbulent flow.

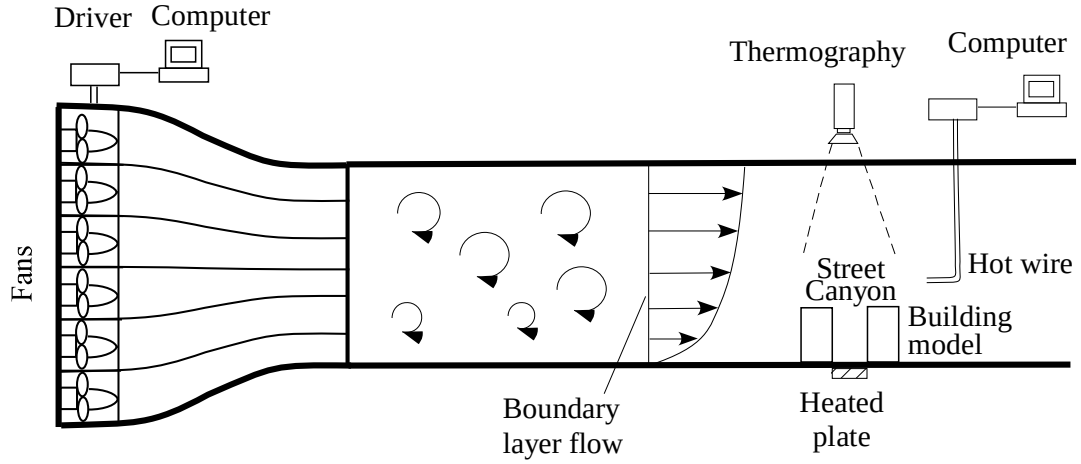

Figure 1. Wind tunnel experimental setup.

Table 1. Configurations of three-dimensional models.

Case	Upstream model	Downstream model	Arrangement
Case 1	1:1:1	1:1:1	Linear
Case 2	2:1:1	2:1:1	Linear
Case 3	1:1:1	2:1:1	Linear
Case 4	2:1:1	1:1:1	Linear
Case 5	Alternating (Symmetrical)		Linear
Case 6	Alternating (Asymmetrical)		Linear
Case 7	1:1:1	1:1:1	Staggered
Case 8	2:1:1	2:1:1	Staggered
Case 9	1:1:1	2:1:1	Staggered
Case 10	2:1:1	1:1:1	Staggered
Case 11	Alternating (Left diagonal)		Staggered
Case 12	Alternating (Right diagonal)		Staggered

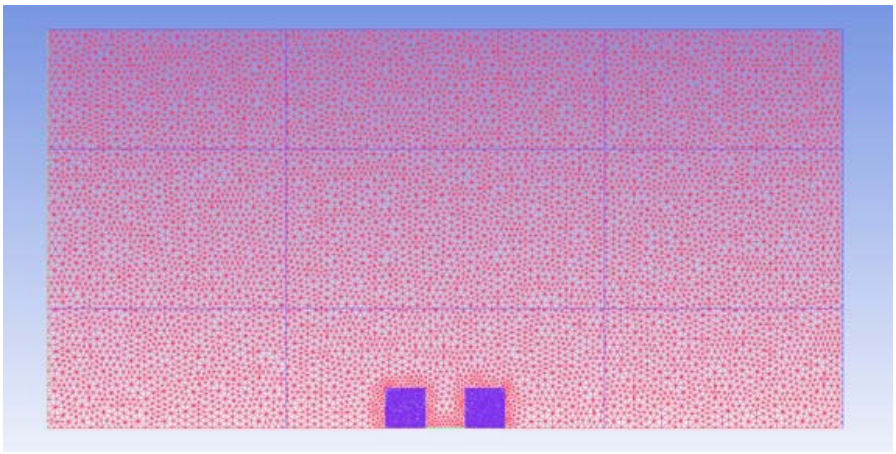

Figure 2. Mesh setup for numerical simulation.

2.3 *Numerical simulation setup*

To comparing the numerical results with the experimental results of temperature field and flow field of wind tunnel experiments, the validity of the numerical analysis methods and results of numerical analysis has been verified. It seems to be able to establish a quantitative approach by creating of numerical calculation of heated street canyon phenomenon. In this study, to investigate for the numerical analysis of temperature field and flow field in the street canyon, general-purpose thermal and fluid analysis software; ANSYS CFX ver.13, was used for steady state flow condition. This software consist of three steps individual software, CFX-Pre which is to set the boundary conditions, CFX-Solver which is to perform the analytical calculations and CFX-Post which is to display the analysis results. Computational domain was set 0.15m for Y-axis, 0.5m for Z-axis, 1m for Z-axis in the direction of the rectangular parallelepiped, which was placed two pitch sizes of imitated buildings toward the street for the original position. Type of mesh was automatically created by Tetra Mixed as shown in Figure 2, which is commonly used in fluid analysis. Mesh points of the analysis model is about 1.6 million. The solver was set by standard k-ε model for turbulent condition.

3 RESULTS AND DISCUSSION

3.1 *Wind tunnel experimental results*

The temperature distributions in low-turbulence steady flow are shown in Figure 3. The Case 1 configuration, per Table 1 (i.e., WS /Hb=1 with 1:1:1 upstream and downstream building models in a linear arrangement), in which the areas in the middle of the street and in front of the downstream buildings were well cooled due to the frontal eddy generated at separation flow reattachment, is shown in Figure 3 (a). The Case 2 configuration, (i.e., 2:1:1 upstream and downstream building models in a linear arrangement), in which the street areas in line with the building gaps were remarkably cooled due to flow acceleration, are shown in Figure 3 (b). However, the areas just behind the upstream buildings were not well cooled due to flow stagnation. Cavity flow was also observed in the street by flow visualization.

The temperature distributions of the Case 3 and Case 4 models are shown in Figure 4. Per Table 1, the Case 3 configuration has taller downstream buildings, whereas the Case 4 configuration has taller upstream buildings. Horseshoe vortices formed in the gaps between the upstream buildings in both configurations. In Case 3, the separation flow from the upstream buildings collided with the downstream buildings and formed a frontal eddy, resulting in effective cooling of the street surface in front of the downstream buildings. Because the upstream buildings in Case 4 are taller, the air flowing between the buildings was accelerated and a lee eddy was formed over the street.

The temperature distributions of the Case 5 and Case 6 model configurations, both of which feature a linear arrangement of alternating building heights, are shown in Figure 5. The Case 5 model is arranged symmetrically, where both upstream and downstream buildings have the same height. The Case 6 model is arranged asymmetrically, where the upstream and downstream buildings have different heights. In Case 5, the street areas in line with the building gaps were well cooled, however, the areas just behind the upstream buildings were not well cooled due to flow stagnation, and the separation flow from the upstream model skimmed over the downstream model. Case 6 exhibited a considerable cooling effect over the street in front of the downstream model, specifically when the air flow collided with the taller downstream buildings and formed a frontal eddy.

The temperature distributions of the Case 4 and Case 10 model configurations are shown in Figure 6. Both configurations feature taller upstream buildings, but Case 4 features a linear arrangement whereas Case 10 features a staggered arrangement. The areas behind the upstream buildings nearest to the gaps were well cooled by the trailing vortices that were generated from the upstream side walls. In Case 10, the trailing vortices collided with the downstream buildings and formed a horizontal frontal eddy. Therefore, the cooling effect of the Case 10 model configuration is slightly higher than that of Case 4. However, if the upstream model were taller than the downstream model, it is clear that the cooling effect would decrease due to flow stagnation behind the upstream model.

The data in Figures 3 through 6 reveal a significant correlation between the formation of an eddy and the cooling effect on the street; how the eddy forms on the street surface determines the cooling effect.

3.2 *Numerical simulation results*

Results of numerical analysis are described below in different configurations of building models located in a uniform steady flow as shown in Figure 7. For each case, these figures show the temperature distribution and stream lines.

The temperature distributions and stream lines of the Case 1 model configuration are shown in Figure 7 (a). Some part of airflow at the top of the model which separated the upstream side was reattached to the downstream model on the front surface, and the heated street canyon was cooled by the airflow as the downdraft. In addition, the downdraft would be part of the circulating flow of the entire street, to excite the circulation.

The temperature distributions and stream lines of the Case 2 model configuration are shown in Figure 7 (b). Airflow separated on the leading edge of the front model was increased speed in the gap between the buildings, and the street of the gap between the models surface was cooled well. Circulating flow which was stable in street canyon has been formed, and the separated flow from the upstream model was difficult to approach in the street canyon. It became clear that the cooling range for the backward of the upstream model was narrow compared with the Case 1 configuration.

The temperature distributions and stream lines of the Case 3 model configuration are shown in Figure 7 (c). The most of the separated flow from the upstream side model reattached to the front surface of the downstream side as a downdraft. The downdraft become part of the circulating flow of circulating whole street canyon, and the flow which were passing through above the street made the circulating flow excite furthermore. Therefore, the airflow which reattached to the downstream side model is easy to influx from the top, a large amount of cold air flowed into street, the entire street has been efficiently cooled.

The temperature distributions and stream lines of the Case 4 model configuration are shown in Figure 7 (d). As with Case2, airflow separating on the leading edge of the front model was increased speed in the gap between the buildings, and the street of the gap between the models surface was cooled well. Airflow which separated from the top of the upstream side were passed through downward without reattach on the downstream model, the airflow is difficult to approach from the top to the street surface, stable circulating flow was formed above the street.

Figure 8 shows the temperature distribution and wind velocity vectors of the street surface for the Case1 configuration. Central part of the upstream side behind the model is cooled well by a cold downdraft from the top. Airflow which flows to the rear of the model was reattached to the street surface, high-temperature part formed arched shape. This is because cold air which has flowed into the street from the top, with exchanging heat on the street, spread radially with weakening the cooling capacity. Even though the street surface of the gap between the models were easily cooling, arched shaped high-temperature part were distributed on the street surface. This is because the airflow of the cooling capacity was weakened by heat exchange along the high-temperature part on the street surface.

The data in Figures 7 through 8 reveal a correlation between the temperature distribution and stream structure for the cooling effect on the street; how the downdraft forms in the street for the circulating flow determines the excitation of the cooling.

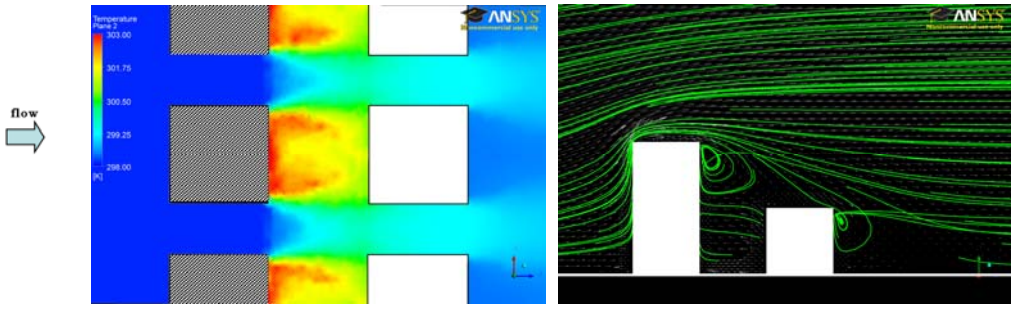
(c) Case 3



(d) Case 4

Figure 7. Temperature distribution and stream line.

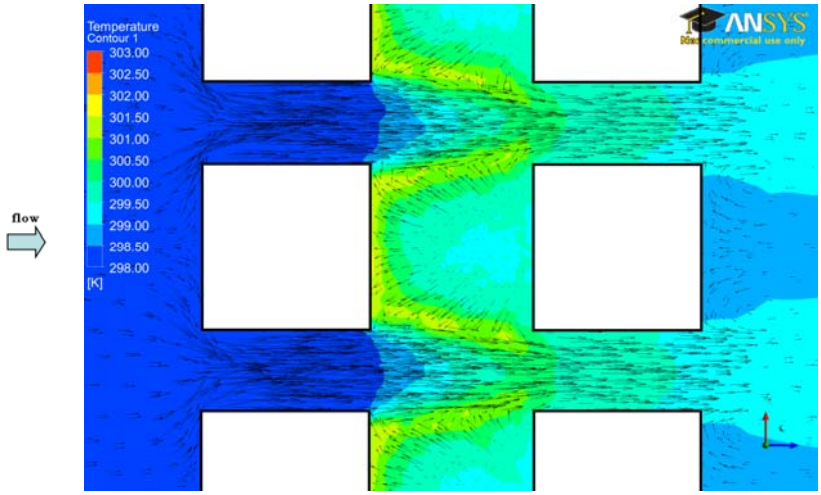


Figure 8. Temperature distribution and flow vector of Case 1.

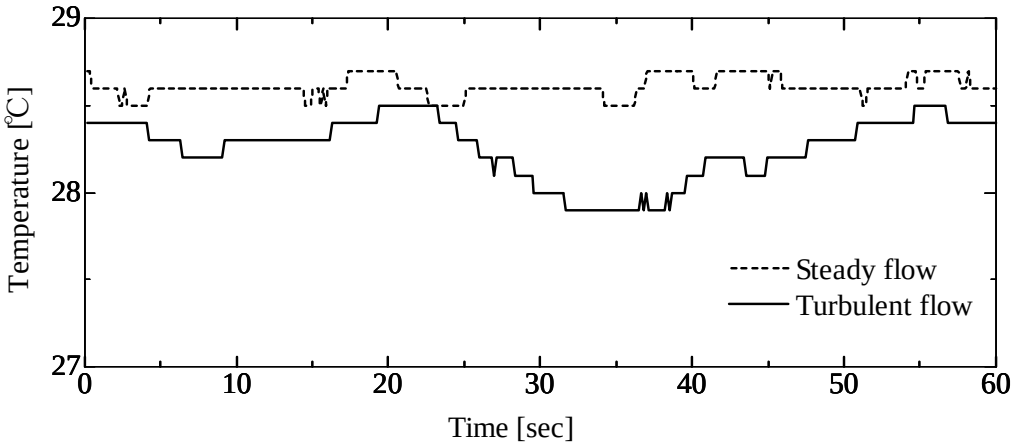

Figure 9. Temperature fluctuation in turbulent flow.

3.3 *Turbulent effects*

The temperature fluctuation in turbulent flow produced by actively controlled multiple-fan is shown in Figure 9. It is clear that the cooling effect of the turbulent flow is greater than steady flow; how well the street is cooled depends on the fluctuation of the turbulence and the downdraft. It is also evident that a turbulent eddy contributes to the cooling of a heated street surface. The average temperature is significantly low in the turbulence flow compared to the steady flow. The maximum and minimum temperature is fluctuating in the turbulent flow depends on the wind velocity. Because a significant velocity fluctuation exists when the actively controlled multiple-fans, the street temperature varies to the steady flow and the temperature distribution never reaches steady-state.

4 CONCLUSIONS

In this research, building models were arranged at the upstream and downstream sides of a heated street canyon, and the temperature distributions of the street were investigated. Several results were observed:

(1) For the wind tunnel experimental results, temperature distribution and flow visualization reveal a significant correlation between the formation of an eddy and the cooling effect on the street; how the eddy forms on the street surface determines the cooling effect.
(2) The numerical simulation results reveal a correlation between the temperature distribution and stream structure for the cooling effect on the street; how the downdraft forms in the street for the circulating flow determines the excitation of cooling.
(3) For the turbulent effects, a significant temperature fluctuation exists when the actively controlled multiple-fans; how the velocity fluctuation varies the street temperature and the temperature distribution never reaches steady-state.

For future work, a database will be created for heated street canyons based on additional experiments in simulated natural wind flow using different types of turbulent wind tunnels.

[b]*Tokyo Polytechnic University, Kanagawa, Japan*

ABSTRACT: The traditional method (body-fitted method) of simulating flows around obstacle arrays is usually used to simulate urban environments. However, with increasing numbers of simulated buildings, a great deal of time and labor are required to generate body-fitted grids. In order to solve this problem, the drag force method using gas-solid two-phase flow was applied to simulate an urban environment. At first, it was important to assess the precision of the drag force method compared with that of the traditional method. Thus, numerical tests were carried out on a high-rise building and building arrays. The results obtained from the traditional method and the drag force method were in good agreement with experimental data. The grids for the drag force method didn't need to be body-fitted, so it required much less time to generate them.

KEYWORDS: Large eddy simulation; subgrid-scale model; drag force.

1 INTRODUCTION

With the increase of urban populations, urban environments have become an important research subject. Increasing numbers of researchers are using CFD to study urban environments. Because of the increase of the computational domain of urban environments and simulated buildings, huge number of grids is needed and a great deal of time and labor are required to generate body-fitted grids. In order to solve this problem, it is not enough to simply improve computer performance. A better method for simulating an urban environment needs be developed.

In the early development stage, restrictions of computer performance enabled flow fields around only simple geometry to be simulated using the traditional method. For example, the flow field around a square cylinder (or other simple geometry building) could be simulated using large eddy simulation. Kelkar and Patankar (1992)[1] predicted vortex shedding behind a square cylinder. Mukhopadhyay et al. (1992)[2] researched wakes behind a square cylinder in a channel. Rodi et al. (1997) [3] simulated the flow field around a square cylinder and a wall-mounted cube flow in a channel. Bouris and Bergeles (1998)[4] predicted vortex shedding from a square cylinder in 2D.

With development of computers, flow fields around building arrays could be simulated by the traditional method. Hanna et al. (2002)[5] used the Smagorinsky model to simulate the flow field around simple obstacle arrays. Tseng (2006)[6] predicted urban dispersion using large eddy simulation. Xie and Castro (2009)[7] applied LES to simulate flow and dispersion in urban streets. Gousseau et al. (2011)[8] adopted RANS and LES to simulate the wind field and pollution dispersion around a group of buildings in a downtown area.

With the increasing numbers of simulated buildings, a great deal of time is required to generate body-fitted grids. To overcome this problem, a drag force method of gas-solid two-phase flow is used to simulate urban environments. This method is introduced in Section 2. Section 3 compares numerical results obtained by this method for wind fields around a high-rise building and building arrays with those obtained by the traditional method and experiment data. Conclusions are given in Section 4.

2 DRAG FORCE METHOD

In our drag force method, the buildings are firstly discretized by a first set of grids, as shown in Fig. 1(a). This first set of grids is a body-fitted one, in which each grid in the building is assumed to be filled with a sphere, as shown in Fig. 1(b). The volume of the sphere is determined such that the air void fraction rate (= $(V_r-V_s)/V_r$) becomes very small (for example 0.001), where V_r=volume of rectangular cell and V_s= volume of sphere.

Secondly, a second set of grids is generated, as shown in Fig. 1(c), in which black and red lines show the second and first set of grids, respectively. The second set of grids is not a body-fitted one and is used for flow calculations. Cells that contain solid parts of a building in the second set of grids are expressed by solid void fractions as:

$$\varepsilon_p = \sum_{k=1}^{N^*} V_k / (\Delta x \Delta y \Delta z) \tag{1}$$

where Δx, Δy, Δz are grid lengths of the second set of grids that contain solid parts of a building, N is the number of spheres in the second set of grids and V_k is the volume of the k^{th} sphere in the second set of grids.

The air void fraction is expressed as:

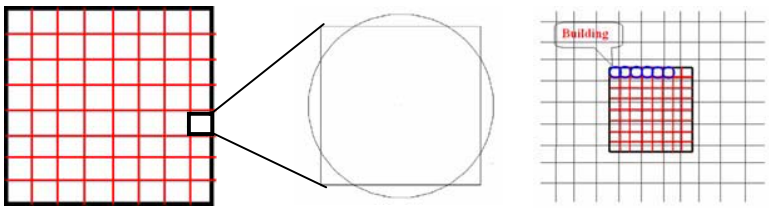
$$\varepsilon_g = 1-\varepsilon_p \tag{2}$$

The drag force coefficient determined by Ergun/Wen and Yu (1952; 1966)[9, 10] was used, and is expressed as:

$$\beta = \frac{3}{4}\frac{(1-\varepsilon_g)\varepsilon_g}{d_p}\rho_g\left|u_g-u_p\right|C_{D0}\varepsilon_g^{-2.7}, \varepsilon_g > 0.8;\ 150\frac{(1-\varepsilon_g)^2\mu_g}{\varepsilon_g d_p^2}+1.75\frac{(1-\varepsilon_g)\rho_g\left|u_g-u_p\right|}{d_p}, \varepsilon_g \le 0.8 \tag{3}$$

$$C_{D0} = \begin{cases} 24(1+0.15\,\mathrm{Re}^{0.687})/\mathrm{Re}, \mathrm{Re} \le 1000 \\ 0.43, \mathrm{Re} > 1000 \end{cases}, \quad \mathrm{Re} = \rho_g d_p \varepsilon_g \left|u_g-u_p\right|/\mu_g \tag{4}$$

where u_g, u_p, ρ_g and μ_g are gas velocity, solid velocity, gas density and gas viscosity coefficient, respectively. u_p is zero in this method.



(a) Discretization of building by first set of grids (Body-fitted grids)

(b) A sphere for a grid

(c) First and second sets of grids

Fig.1 Discretization of building for drag force method

The filter (LES) momentum equation is expressed as:

$$\nabla\cdot[(\varepsilon_g)\bar{u}_g] = 0$$
$$\varepsilon_g\left(\frac{\partial\bar{u}_g}{\partial t}+\bar{u}_g\cdot\nabla\bar{u}_g\right) = -\frac{\varepsilon_g\nabla\bar{p}}{\rho_g}+\varepsilon_g\nu_g\nabla\cdot(\nabla\bar{u}_g+\nabla\bar{u}_g^{T})-\frac{\beta\bar{u}_g}{\rho_g} \tag{5}$$

Even if the cells are totally inside the building (even the cells are totally solid), they are treated as fluid cells with very small ε_g (for example, ε_g= 0.001). Thus, it becomes possible to universally apply equations (3) for every cell regardless of its phase (fluid or solid).
With regard to the numerical tests in this paper, the new subgrid-scale model (Gu and Jiao 2011)[11] was used.

3 NUMERICAL TEST

3.1 *HIGH-RISE BUILDING*

Fig. 2 shows a high-rise building with the same geometry as that of the wind-tunnel experiment of Meng and Hibi (1998)[12]. The Reynolds number based on H (building height) and U_H (inflow velocity at $z = H$) was 24,000. H, L and W were 0.16m, 0.08m and 0.08m. The flow field around the high-rise building was simulated by using the traditional method (body-fitted method) and the drag force method. The results by the two methods were compared with experiment data (Meng and Hibi 1998).

The grids and boundary conditions of the numerical test were the same as those of Tominaga et al.[13] (2008). The non-uniform grid and the inflow condition of Kataoka (2002, 2008)[14, 15] were used. The grid numbers using the two methods were almost the same: 60×45×39. The velocity components at the inflow boundary (Kataoka 2008) are given by:

$$\begin{aligned} u_{inlet}(y,z,t) &= < u >_{inlet}(z) + \phi(\theta) \times \{u(y,z,t) - < u > (y,z)\}_{recy} \\ v_{inlet} &= \phi(\theta) \times \{v(y,z,t) - < v > (y,z)\}_{recy} \\ w_{inlet} &= \phi(\theta) \times \{w(y,z,t) - < w > (y,z)\}_{recy} \end{aligned} \tag{6}$$

where subscripts denote the values at the inlet and the downstream (recy) planes and <> is a time-averaged value. $\phi(\theta)$ is the damping function (Kataoka 2008).

Air void fraction in the high-rise building was set to 0.05 in the drag force method.

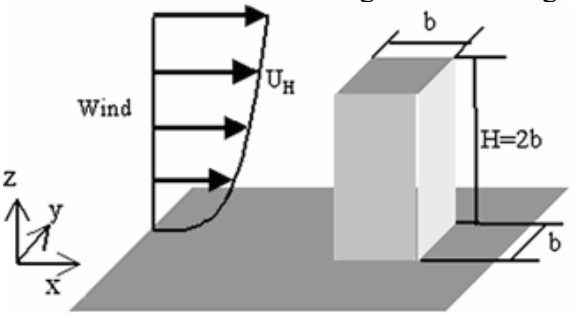


Fig. 2 Geometry of high-rise building

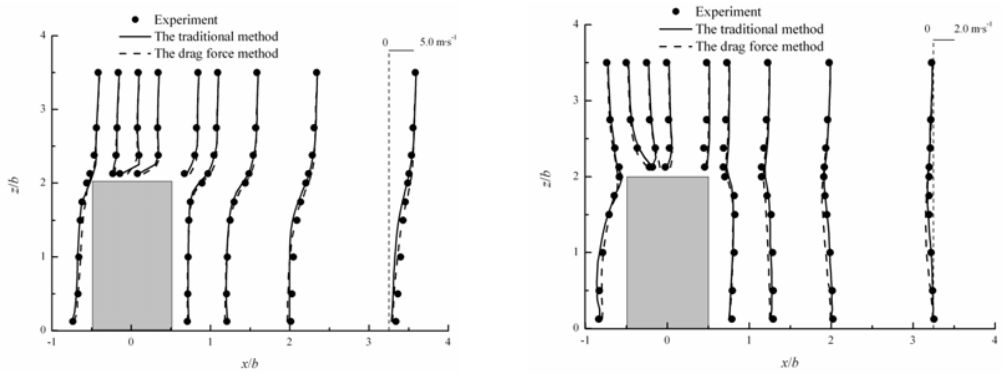
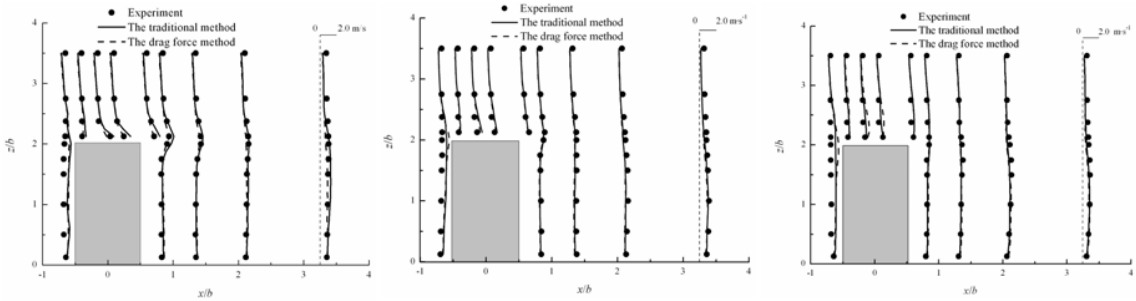
Figs. 3 and 4 show the mean velocity profiles and the r.m.s. value profiles at the y/b = 0 plane. There were nine profiles: at x/b=-0.75, x/b=-0.5, x/b=-0.25, x/b=0, x/b=0.5, x/b=0.75, x/b=1.25, x/b=2 and x/b=3.25. The mean velocities by the drag force method were a little closer to the experiment data than those by the traditional method, as shown in Fig. 3. The r.m.s. values by the traditional method and the drag force method were in agreement with the experiment data, as shown in Fig. 4.



(a) Mean velocity profiles in streamwise direction U ($y/b = 0$)

(b) Mean velocity profiles in normal direction W ($y/b = 0$)

Fig. 3. Mean velocity



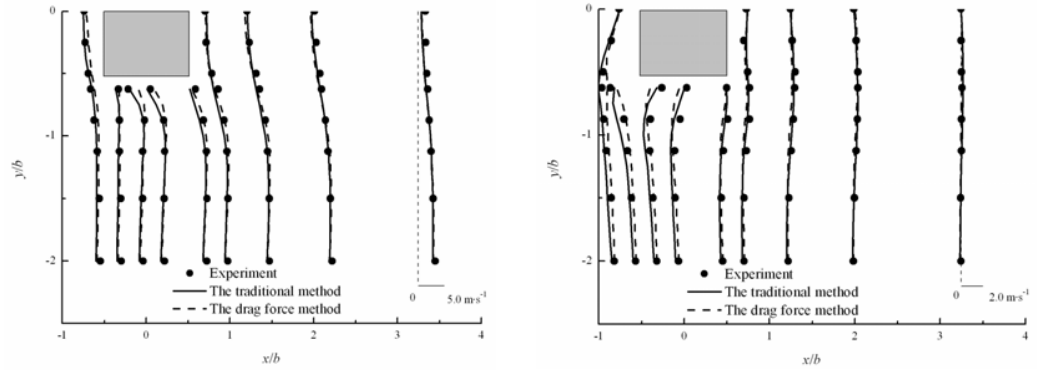
(a) r.m.s. value profiles in stream-wise direction u_{rms} ($y/b = 0$)

(b) r.m.s. value profiles in spanwise direction v_{rms} ($y/b = 0$)

(c) r.m.s. value profiles in normal direction w_{rms} ($y/b = 0$)

Fig.4. r.m.s. value profiles

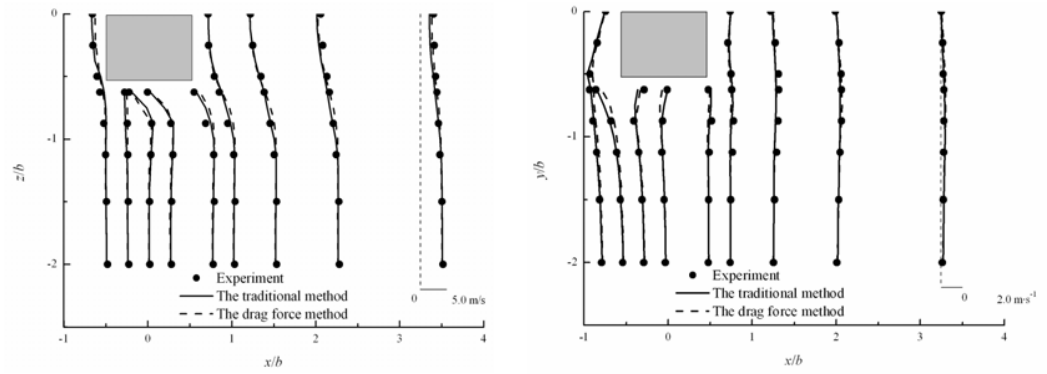
Figs. 5 and 6 show the mean velocity profiles at $z/b = 0.125$ and 1.25 plane, respectively. The numerical results in Figs. 5 and 6 are in agreement with the experimental data. The results by the drag force method are closer to experimental data than those by the traditional method.



(a) Mean velocity profiles in streamwise direction U ($z/b = 0.125$)

(b) Mean velocity profiles in spanwise direction V ($z/b = 0.125$)

Fig. 5. Mean velocity



(a) Mean velocity profiles in streamwise direction (b) Mean velocity profiles in spanwise direction V
U (z/b = 1.25) (z/b = 1.25)

Fig. 5. Mean velocity

The major purpose for the numerical simulation of the high-rise building was to validate the precision of the drag force method. It was found that the results by the drag force method were closer to experimental data than those by the traditional method. The numerical results verify that the drag force method can be used to a simulate flow field around a high-rise building.

3.2 *BUILDING ARRAYS*

The flow field around the building arrays was simulated using the traditional method and the drag force method. The geometries of the building arrays, as shown in Fig. 6, were the same as those in the wind-tunnel experiment of Davidson et al. (1996)[16]. The height H, length B and width W were 0.12m. The grid number and boundary conditions were the same those of Gu and Jiao (2011)[17]. The non-uniform grids in the computational domain were used for the simulations of the turbulent flows around staggered and aligned obstacle arrays. The grid numbers of the traditional method and the drag force method were almost the same. The staggered obstacle array had about 816,000 grids and the aligned obstacle array had about 672,000 grids. The velocity formulation at the inflow boundary of Kataoka (2002, 2008) (equation (6)) was used. In the drag force method, the air void fraction in the obstacles was set to 0.05.

Figs. 7 and 8 show the numerical streamwise mean velocity profiles of the staggered obstacle array and the aligned obstacle array, which were compared with experimental data. It was found that the results of the traditional method and the drag force method were in agreement with experimental data.

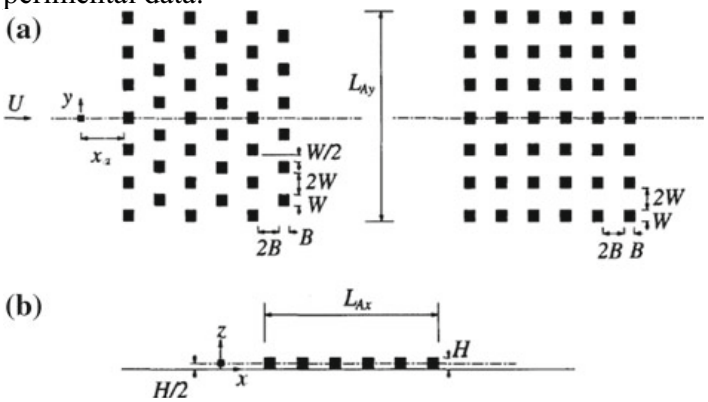


Fig. 6 Geometries of building arrays: (a) Plan view of staggered array configuration (left) and aligned array configuration (right); (b) Side view of aligned array configuration

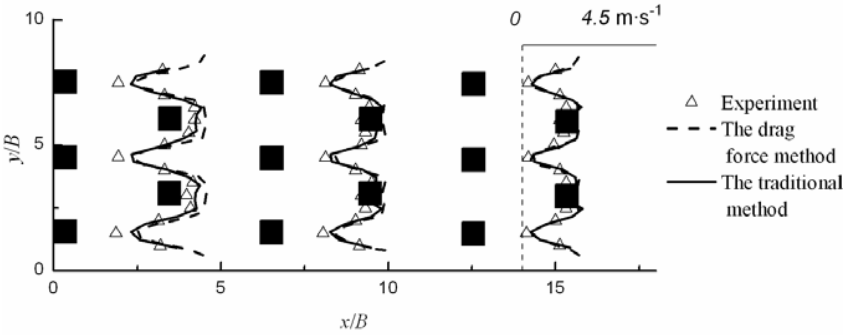

Fig. 7 Lateral profiles of streamwise mean velocity at z = H/2 along x-axis of staggered obstacle array

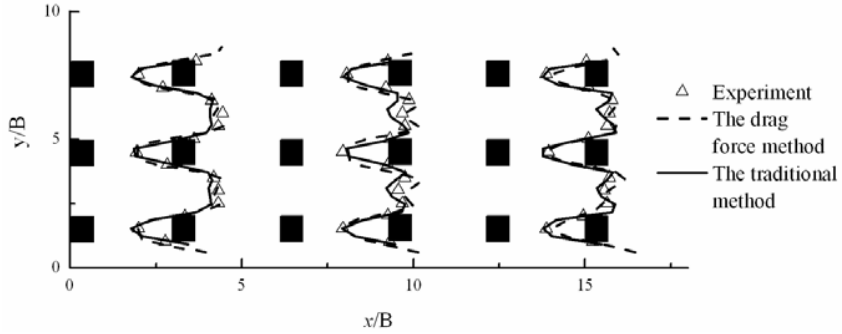

Fig. 8 Lateral profiles of streamwise mean velocity at z = H/2 along x-axis of aligned obstacle array

The numerical simulation results by the drag force method and the traditional method of the staggered obstacle array and the aligned obstacle array were in agreement with experimental data. Thus, the drag force method could be applied to simulate an urban environment. The drag force method doesn't need body-fitted grids and can thus reduce the time required to generate grids.

4 CONCLUSION

With the increasing numbers of simulated buildings required to research urban environments, preprocessing for grids takes a great deal of time and labor, especially when generating hexahedron body-fitted grids. To simplify the generation of grids, a drag force method of gas-solid two-phase flow was proposed. Numerical tests have shown that the results by the traditional method and the drag force method were in agreement with experimental data. The advantages of the drag force method are that it doesn't need body-fitted grids and thus greatly simplifies grid generation, and that it also simplifies simulation of obstacle arrays.

ABSTRACT: The main objective of the present study is to assess the influence of urban geometry to the wind environment of pedestrian space based on numerical simulation on airflow over urban-like obstacle. Large-eddy simulation (LES) is use to simulate the airflow over staggered uniform arrays with various plan area density and various aspect ratios. The spatially averaged profiles of mean wind speed and pedestrian wind environment were determine and compared. The result indicates that (1) the spatially-averaged mean wind speed monotonically decreases with the increases of packing density and aspect ratio and (2) the pedestrian mean wind shows the power law relationship to the frontal area ratio of building. In addition simple power law equation presents to explain the relationship.

KEYWORDS: LES, mean wind speed, aspect ratio, plan area ratio, frontal area ratio, pedestrian wind environment

1 INTRODUCTION

The urban wind environment is one of important factors determining the quality of life of urban habitants. Actually, the airflow within urban canopy layer is a driving force of wind-induced ventilation of room air of urban buildings, thus, urban wind condition affects the efficiency of passive control of room air quality. In addition, the transfer phenomena of heat, vapor, and other various types of scalar around urban buildings are deeply related with urban micro-climate and Thermal comfort of pedestrian space [1].

Therefore the physical relation between urban geometry and pedestrian wind environment has been studied aiming for application in urban planning and building design toward more comfort and healthy city. For example, Kubota et al. [2] performed multi-point measurement of mean wind speed using scaled models of real urban districts in a wind tunnel, and revealed that pedestrian mean wind speed decreases linearly with building coverage. Studies focusing on airflow around idealized block arrays have also done [3-4]. Using such idealized block arrays allows them to identify significant and insignificant parameters on urban configuration efficiently. For example, Hang & Li [3] conducted CFD simulation on the effect of geometry on the air exchange rate inside the canyon and revealed that the air exchange rate depends on height of building and λ_p. Next, Zhang et al. [3] concluded that wind environment around the building strongly depends on the building layout and the wind direction.

In general, pedestrian wind environment is associated with the the scalar dispersion which is strongly affected by the process of buoyancy and advection. Li X-X et al. [5] performed Large-Eddy Simulation (LES) on airflow of 2D street canyon with various conditions of building-heights to street-width ratio and reported that the low aspect ratio enhances effectively pollutant

removal. Boppana et al.[6] performed LES of scalar dispersion of 3D block arrays and investigated the influence of heterogeneous block height. They found that tall blocks located in a non-uniform height array generate a larger vertical flux above mean canopy height and weaker streamwise advection.

In the present work, we investigate the relationship between mean wind speed at pedestrian level of uniform urban block arrays and urban geometry parameters, such as plan area ratio (ratio of building roof to ground surface area, λ_p), frontal area ratio (ratio of building frontal area to ground surface area, λ_f) and building aspect ratio (ratio of building roof to frontal area, α_p).Large-Eddy Simulation (LES) with fine Cartesian grid size is done to estimate the spatially distribution of scalar velocity and turbulent statistic within urban canopy layer. The accuracy of the calculated profiles is confirmed by comparing the data with numerical result of Kono et al. [7] and experimental data by Cheng & Castro [8]. Subsequently, mean wind speed at pedestrian derived from the present data of LES is presented under various conditions of urban geometry with a comparison against the experimental result by Kubota [2].

2 NUMERICAL SIMULATON

2.1 *PALM*

Detailed distributions of velocity over idealized urban arrays comprising uniform blocks are simulated using urban version of Parallelized LES Model (PALM) code firstly developed at Institute of Meteorology and Climatology, University of Hannover [9]. PALM can simulate the convective atmospheric boundary layer with explicitly resolved solid obstacles within three-dimensional domain on Cartesian grid. This code solves filtered Navier–Stokes equations with non-hydrostatic incompressible Boussinesq approximation. Finite difference method is used for the discretisation of the differential equation and 3rd order Runge-Kutta scheme is applied for time integration. Massive passing interface (MPI) is use for parallel communication. The further details of urban version of PALM code are described in [10].

Table 1: Geometry of arrays set-up for simulation

Arrays	Case	λ_p (%)	α_p	Block base size	Block height h	Computational domain size $L_x \times L_y \times L_z$
RB1	RB1-4	4.4	1	L	L	$9.5L \times 9.5L \times 4L$
	RB1-8	8.2				$7L \times 7L \times 4L$
	RB1-16	16				$5L \times 5L \times 4L$
	RB1-25	25				$4L \times 4L \times 4L$
	RB1-33	32.7				$3.5L \times 3.5L \times 4L$
	RB1-44	44.4				$3L \times 3L \times 4L$
RB1.5	RB1.5-16	16	1.5	L	$1.5L$	$5L \times 5L \times 6L$
	RB1.5-33	32.7				$3.5L \times 3.5L \times 6L$
	RB1.5-44	44.4				$3L \times 3L \times 6L$
RB0.5	RB0.5-44	44.4	0.5	$2L$	L	$6L \times 6L \times 4L$
RB0.33	RB0.33-44	44.4	0.33	$3L$	L	$9L \times 9L \times 4L$

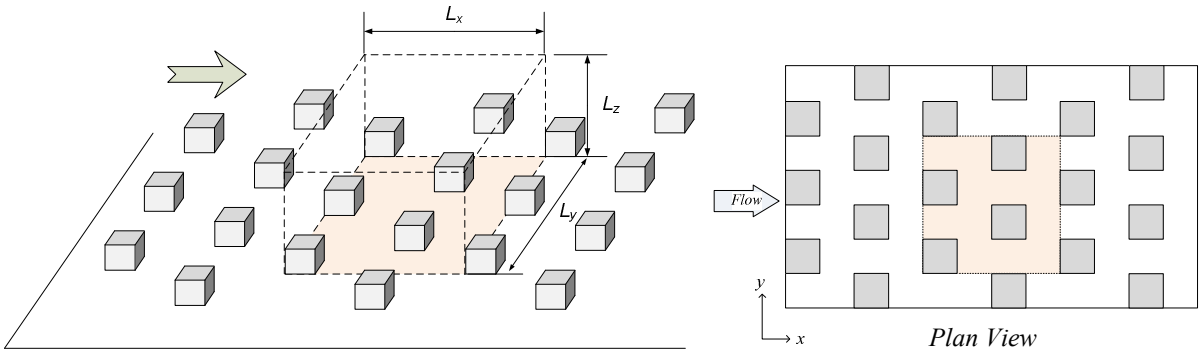

Figure 2. Schematic diagram of computational domain and block arrangement.

2.2 *Simulation set-up*

Table 1 shows the geometry of the arrays analyzed in this study. All arrays consist of uniform rectangular blocks with square base are arranged in staggered layout; the geometry of them were decided based on our previous wind tunnel experiment [11]. A basic length scale of blocks defined as 25m (hereafter L = 25m) in all cases of this simulation which is 1000 times of basic length scale of the wind tunnel experiment [11]. Figure 1 shows the shape of the elements that constitute the arrays.

Periodic boundary conditions are imposed for both spanwise and streamwise boundaries to simulate a horizontal infinite block array. At the bottom of the domain, non-slip condition with Dirichlet type is imposed, and free-slip condition with Neumann type is used at the top of the domain. Because of periodicity, the domain consists of only four unit blocks in staggered arrangement (*see* Figure 2). The computational domain height (L_z) is 4 times of canopy height. The grid size for all cases is fixed to L/64 (0.39m).

The fully developed flow inside computational domain was driven by height-independent constant pressure gradient using the following expression:

$$\frac{\partial P}{\partial x} = -\frac{\rho u_*^2}{L_z} \tag{1}$$

where u_* = friction velocity and L_z = computational domain height.

The u_* is based on the friction velocity calculated by wind tunnel experiment [11]. It refers to the condition of roughness Reynolds number, Re_* ranging from 1.1×10^5 to 4.0×10^5, based on the friction velocity (u_*) and roughness length (z_0) with the assumption that roughness length is about 10% of canopy height. According to Snyder and Castro [12], the fully rough turbulent flow is supposed to develop for condition of Re_* exceeds $O(1)$. In addition, Uehara [13] mentioned that critical Reynolds number for canopy flow to be independent of viscous effect ranging be-

tween 2100 and 15000. Since the current simulation setting satisfies these criteria of Re_*, the viscous effect is supposed to be negligible for all cases. A sequence of $200T$ ($T = h/u_*$, h indicates block height) of the time series calculation data after initial duration about $200T$ is analyzed as data converge statistically to steady state. Although the duration $200T$ is shorter than that proposed by Coceal et al.[14], we confirmed the validity of the duration by comparing mean wind profiles within canopy derived from data of several durations.

2.3 *Validation*

Figure 3 shows vertical profiles of normalized streamwise mean velocity over a cubical array ST1 (λ_p = 0.25) derived from the current simulation, LES result by Kono et al. [7] and a wind tunnel measurement by Cheng & Castro [8] at four locations. The plots for all four measurement points show good agreement with the former data for $z/h < 2$. However the present result underestimates the streamwise mean velocity for $z/h > 2$ as compared to Kono et al.[7]. It is probably due to the different domain height. In their study, the domain height is about $7.5h$ which is greater than that of our simulation. In contrast, the present data qualitatively well agree with the measurement data by Cheng & Castro [8].

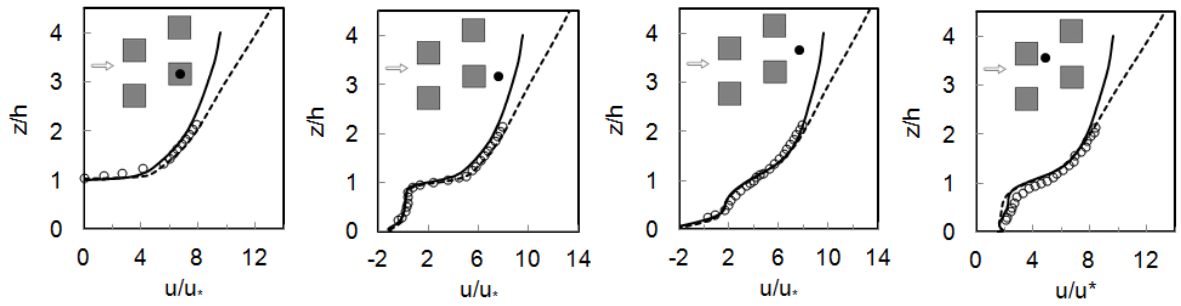

Figure 3. Profile of mean streamwise velocity u, normalize by friction velocity u_* at four different location of a cubical staggered arrays with λp = 25%. (a) above a cube, (b) behind a cube, (c) in front of a cube and (d) in gap. Solid line: RB1-25; dashed line: LES data by Kono et al. [9]; symbol: wind tunnel data from Cheng & Castro [10].

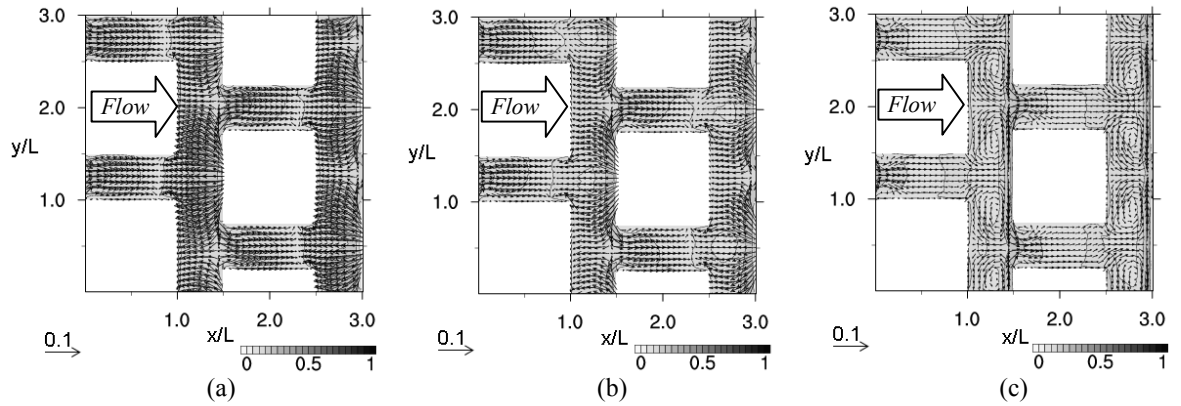

Figure 4. Vector and contour plot of normalized mean wind speed V/V_{ref} of RB1-44 arrays at different horizontal plane height. The data at (a) $z = 0.05h$, (b) $z = 0.1h$, and (c) $z = 0.25h$.

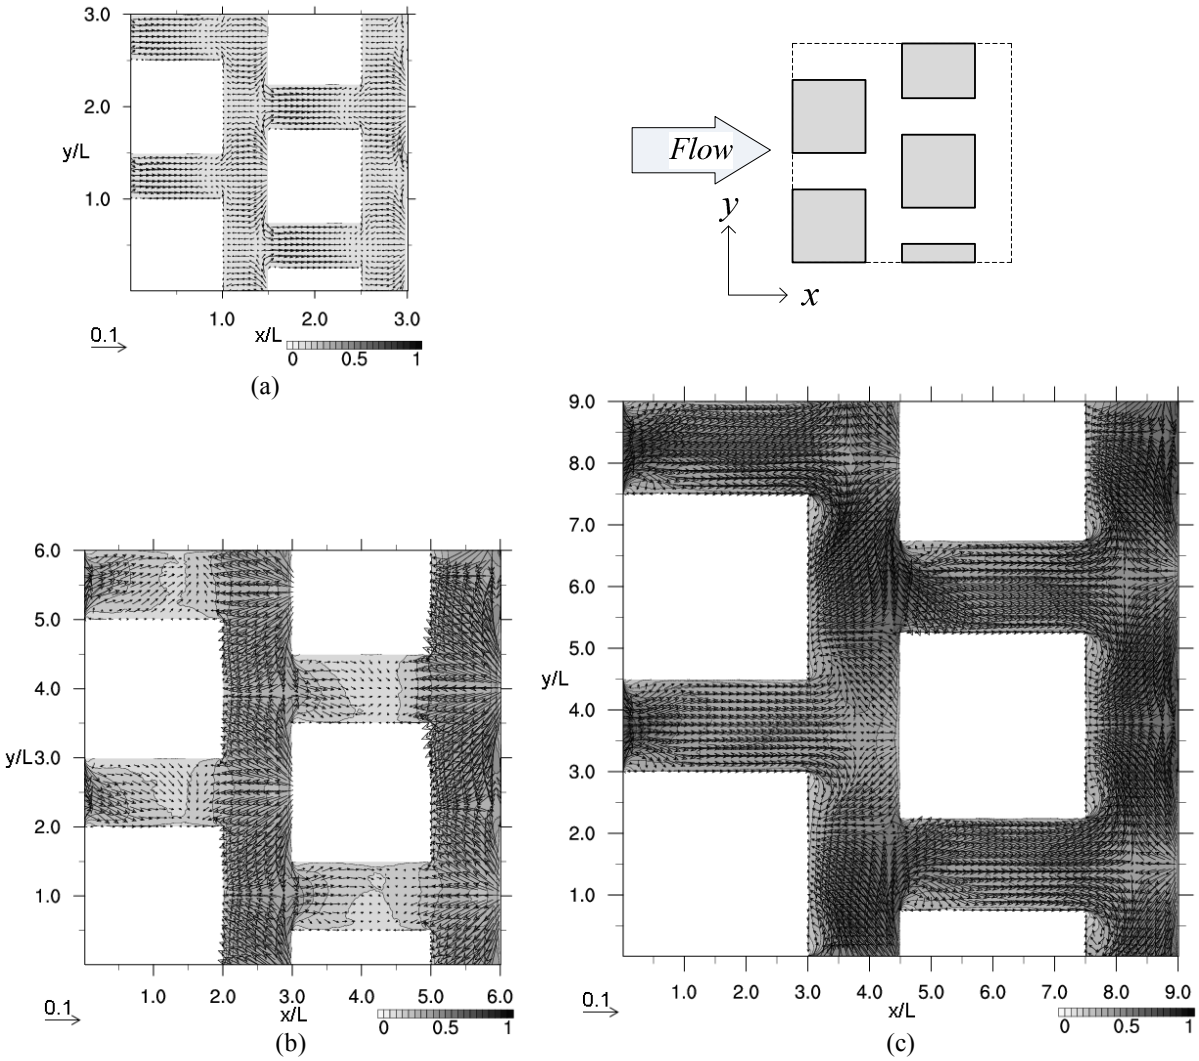

Figure 5. Vector and contour plots of normalized mean wind speed V/V_{ref} at $z = 0.1h$ for $\lambda_p = 44\%$ under various α_p conditions, (a) $\alpha_p = 1.5$, (b) $\alpha_p = 0.5$ and (c) $\alpha_p = 0.33$.

3 RESULT AND DISCUSSION

3.1 *Flow structure*

Mean wind speed within canopy is effective information to assess the thermal comfort of pedestrians. It is consists of mean part ant turbulent part as follows,

$$V = \sqrt{\overline{u}_i^2 + \overline{u_i'^2} + 2\overline{u}_i\overline{u_i'}} \tag{2}$$

where i = indices (1,2, and 3).

A height of 1.5m from the ground surface can be translated into $0.05h$, $0.1h$ and $0.25h$ with the assumption that buildings have 10, 5 and 2 stories respectively and a floor height is 3 m. Since the Reynolds number effect is supposed to be negligible for the current simulation condi-

tion as mention before, the spatio-temporal average of mean wind speed at 0.05*h*, 0.1*h* and 0.25*h* derived from the current simulation can be treated as the pedestrian wind speed in an urban building array with a building storey of 10, 5 and 2, respectively.

We first present the normalized flow pattern of horizontal plane of RB1-44 to show the different trend of pedestrian airflow according to height in Figure 4. The vector plots indicate that reverse flow occurs in front of the block at z = 0.05*h* and 0.1*h* (*see* Figure 4a and b). Figure 4a shows a stronger reverse flow compared to Figure 4b. It might be due to the effects of both shear stress at the ground surface and strong downdraft occurs close to the ground surface. Unlike the similar vector plots for at z = 0.05*h* and z = 0.1*h*, the result of z = 0.25*h* shown in Figure 4c shows different tendency. In this figure, a recirculating vortex pair occurs behind a block has high velocity in front of the block. These three figures indicate that the flow pattern systematically varies depending on the height. In addition, the wind speed decreases with the increase of the height especially at a height z = 0.25*h*.

Next Figure 5 shows the effect of different block aspect ratio α_p on flow pattern under the condition of λ_p = 44%. Comparison between Figures 5a and 5c, both contour and vector plot shows that the normalized wind speed increases especially between adjacent blocks for lower aspect ratio conditions. The reason why the array (RB1.5) shows very low mean wind speed near a street might be caused by the fact that the flow around an array consists of slender blocks is less affected by the longitudinal vortices generated in upward of blocks compared with the flow around a block array with low aspect ratio.

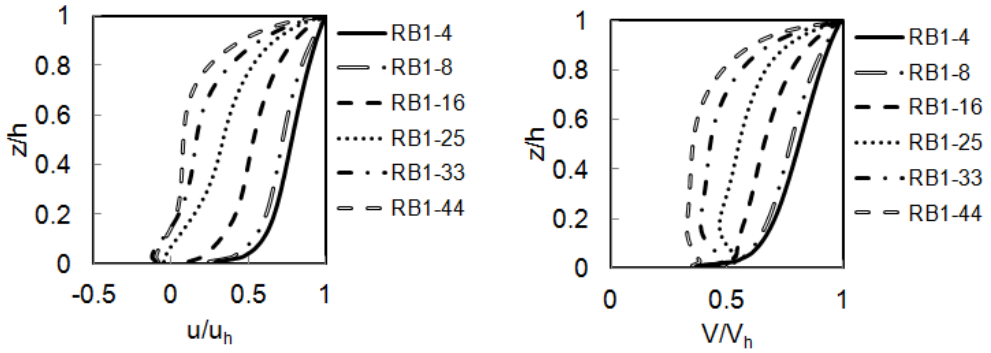

Figure 6. Wind profiles inside canopy normalized by values at canopy height against λ_p. (a) mean streamwise velocity (b) mean wind speed.

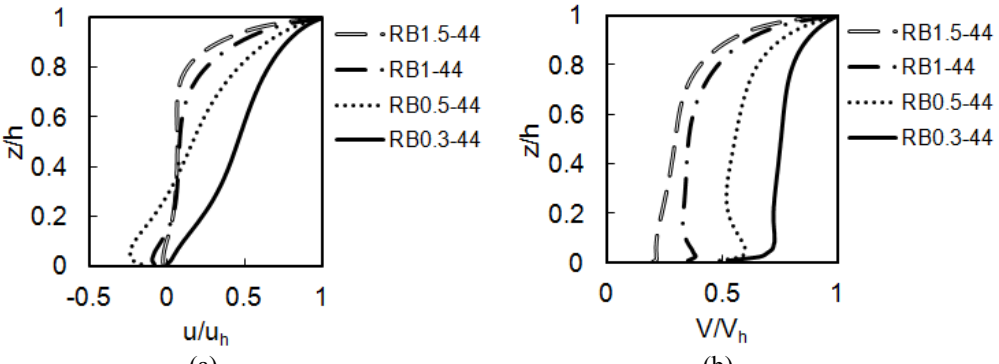

Figure 7. Wind profiles inside canopy normalized by values at canopy height against α_p. (a) mean streamwise velocity (b) mean wind speed.

3.2 *Spatially-average mean flow profile*

Figure 6 indicates the vertical profiles of spatio-temporal average of velocity over cubical arrays (ST1) under various λ_p conditions for streamwise velocity and mean wind speed V. The values are normalized by those at canopy height. The result of normalized streamwise velocity (*see* Figure 6a) indicates that the values of arrays with higher λ_p are approximately lower, but the difference of velocity among arrays varies according to the height. In addition, the spatially averaged velocity of arrays with λ_p over 33% show strong reverse flow below $0.16h$ due to skimming flow regime. As a natural consequence, the mean wind speed profile is dependent with λ_p similar to streamwise velocity, however, the values of arrays with λ_p condition over 25% have an inflection point at a height of around $0.02h$ because of the reverse flow near the street surface as we discussed in section 3.1.

Next, Figure 7 shows the profiles of spatially averaged streamwise velocity and mean wind speed of arrays with different block aspect ratio under the condition of λ_p = 44%. From Figure 7(a), it is clearly found that the streamwise velocity of array RB0.5-44 is significantly negative below $z = 0.35h$, and has the strongest reverse flow within canopy layer among four arrays, despite array block aspect ratio of RB0.5-44 is neither largest nor smallest. In contrast, the streamwise velocity of arrays RB1-44 and RB1.5-44 are nearly constant and zero within lower half of the canopy, and the mean wind speed of the arrays show small compared with the others. Since an array with high block aspect ratio refers to deep street canyon, it is supposed to be reasonable tendency. The mean wind profiles of all arrays are different from the curves of streamwise velocity profiles, and it suggests that the contribution of turbulence part to total kinetic energy is large in pedestrian space. In addition, wind speed profiles of arrays with block aspect ratio below 1.0 have inflection points.

3.3 *Effect of building geometry on pedestrian wind speed*

3.3.1 *Dependencies of plan area ratio and block aspect ratio*

Kubota et al. [2] reported that the plan area ratio strongly affects mean wind speed ratio (the wind speed around the models measure at 5 mm height in the wind tunnel divide by the wind speed at the same height without models) of scaled models of real urban districts consist of various building types. In the present study, mean wind speed ratio was computed by the scalar velocity at pedestrian level normalized by the value at half of computational domain height ($2h_{max}$). Figure 8 shows the relationship between the mean wind speed ratio and the plan area ratio for 3 types of building height, 10, 5, and 2 stories. The wind tunnel data of Kubota et al. [2] are used for comparison. The data of the present experiment shown in Figure 8 (a), (b) and (c) are calculated based on assumption that buildings are 10, 5 and 2 storey respectively.

The mean wind speed of each array monotonically decreases as plan area ratio increases. Such decreasing tendency is consistent with that of the experiment using scaled real urban districts by Kubota. However, the scattering data of mean wind speed due to different block aspect ratio (α_p) at λ_p = 44.4% suggests that plan area ratio is not a parameter to assess universally the pedestrian wind speed. The mean wind speed for arrays with low α_p is higher than that for arrays with high α_p. It is reasonable tendency; because arrays with low α_p refer to shallow street canyon.

3.3.2 *Dependencies of frontal area ratio*

Frontal area ratio λ_f is another important building parameter to evaluate the urban effect on wind environment, because the frontal area of the block is a factor were the pressure drag exerting on the flow [16]. Figure 9 shows the relationship between λ_f. and mean wind speed ratio, in which the data derived based on three different assumptions of building height as mentioned before are illustrated. Figures 9a, b and c indicate that the relationship between λ_f and V/V_{2h} is similar to that between λ_p and V/V_{2h}, but the former one is more universal.

3.4 *Simple estimation of pedestrian wind environment*

A simple mathematical equation can be derived from the present result to estimate the effect of urban geometry on pedestrian wind speed. Based on the non-linear least square method, the mean wind speed velocity ratio can be expressed by simple power law equation as a function of λ_f as below,

$$V/V_{2h} = 2.5\lambda_f^{-4/5} \tag{3}$$

Figures 9a, b and c include the estimates based on equation (3), which agree well with the LES result for all conditions especially in higher frontal area ratio. Thus it is supposed that the equation can be used for assessment of the effect of urban building density on pedestrian wind environment especially in densely packed cities like Tokyo or Hong Kong.

Figure 8. Relationship between λ_p and mean wind speed ratio of cases. (a) z =0.05h; (b) z =0.1h; (c) z =0.25h.

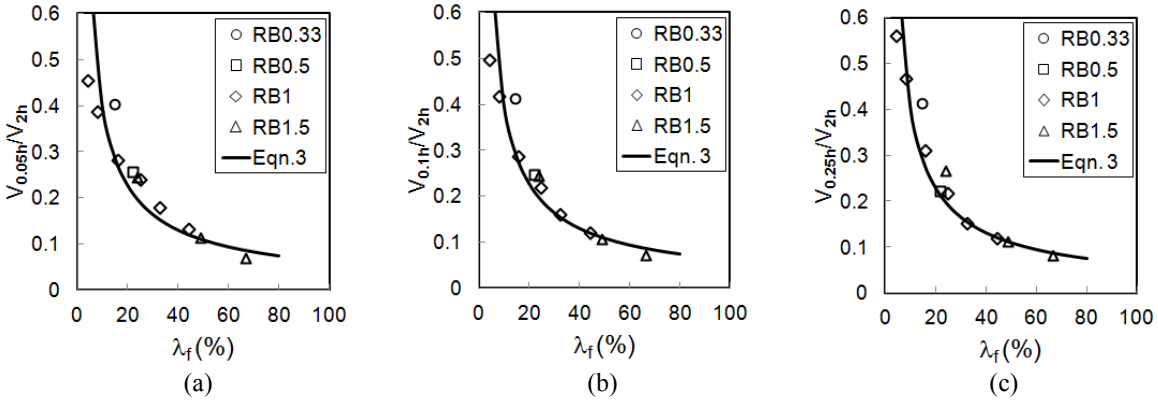

Figure 9. Relationship between λ_f and mean wind speed ratio of cases. (a) z =0.05h; (b) z =0.1h; (c) z =0.25h.

4 CONCLUSION

We have performed Large-eddy simulation of flow over block arrays with various conditions of λ_p and α_p, and the following conclusions are reached. First, the flow patterns clearly indicate the effect of both λ_p and α_p. Different distribution of the wind speed at different horizontal plane height can be translated the pedestrian wind distribution of urban street with different building height. Secondly, the mean wind speed within canopy region is strongly influenced by λ_p and α_p. The mean wind speed increases with decreasing λ_p and α_p within the canopy, and it indicates that the porosity of the building arrays affect the efficiency of ventilation in pedestrian space. Thirdly, the wind speed at pedestrian level show a relatively universal relationship with the frontal area ratio regardless of block aspect ratio and building height, and the tendency can be expressed by a simple power law equation.

5 ACKNOWLEDGEMENTS

The authors wish to express our gratitude to Dr Kono and Professor Kubota, for providing data sets that have been valuable in the validation of our work. This research was financially supported by grant-in aid for scientific research (22360238) from the Ministry of Education, Science and Culture of Japan, and Asahi glass foundation. These simulations were performance on the Kyushu University IBM supercomputing centre.

ABSTRACT: This paper presents a numerical study of the interference drag of two cyclists in dropped position and in time-trial position. The study is based on 3D laser scanning of the cyclist geometry and on high-resolution grid generation, where the centre of the wall-adjacent cell is at about 15 micrometer from the body surface, resulting in y* values well below 5. The cell size in the wake is about 0.03 m. Both the Reynolds-averaged Navier-Stokes (RANS) approach with closure provided by the standard k-ε model and Large Eddy Simulations (LES) are performed. For LES, the time step is $3x10^{-4}$ s based on the CFL number. The interference drag is evaluated for inter-cyclist spacing varying from d = 0.01 to d = 1 m. Although the RANS and LES approach provided similarly accurate results for pressure coefficients and aerodynamic drag of a single cyclist, the results of both approaches for the interference drag are quite different. Compared to a single cyclist, the drag reduction for the dropped position with d = 0.01 m and with RANS is 2% for the first cyclist and 26% for the second one, while with LES it is 3% and 34%, respectively. For the time-trial position with d = 0.01 m, the reductions with RANS are 3% for the first cyclist and 16% for the second one, while with LES these values are 2% and 36%, respectively. Additional wind tunnel experiments with two cyclists are scheduled for further validation studies. Additional analysis of the CFD results will be performed to analyze the reasons for the large differences between RANS and LES results.

1. INTRODUCTION

At racing speeds (± 50 km/h in time trails), the aerodynamic resistance experienced by a cyclist, also called drag, is about 90% of his/her total resistance (Grappe et al. 1997, Kyle and Burke 1984). The major part is caused by form drag, related to the position of the cyclist on the bicycle.

Many elite cyclists therefore try to optimise their position for drag by means of field tests or wind tunnel tests. More recently, also Computational Fluid Dynamics (CFD) has been applied in cycling (Hanna 2002, Lukes et al. 2004, Defraeye et al. 2010a, 2010b). Most studies were performed by solving the steady Reynolds-averaged Navier-Stokes (RANS) equations. Most studies have also employed wall-function modelling for the near-wall region. Recent studies however have explicitly resolved the boundary layer by low-Reynolds number modelling (LRNM) (Defraeye et al. 2010a, 2010b). These CFD simulations were validated with detailed wind tunnel measurements on a full-scale (real) cyclist (Defraeye et al. 2010a) and a ½ scale model (Defraeye et al. 2010b). The study by Defraeye et al. (2010a) compared CFD simulations with drag measurements on a full-scale cyclist and indicated that, for the dropped position, Large Eddy Simulation (LES) yields a deviation in the drag area of 3%, while steady RANS with the standard k-ε model yields a deviation of 7% compared to the measurements. However, for the reduced-scale (1:2) model (upright position), steady RANS with the standard k-ε model provided a deviation in the drag area of only 4% compared to 6% with LES (Defraeye et al. 2010b). These results indicate that the RANS and LES results for the aerodynamic drag are very close. Therefore, they might suggest that further studies in cyclist aerodynamics can be conducted with steady RANS and the standard k-ε model, and that more time-consuming and intrinsically more accurate simulations with LES would not be necessary. To analyze the validity of this hypothesis, this paper provides results of a numerical study with both RANS and LES of the interference drag of two cyclists, riding one behind the other, in still air (zero wind speed).

2. CFD SIMULATIONS: COMPUTATIONAL PARAMETERS AND SETTINGS

A digital model of the cyclist was obtained for the dropped position and the time-trial position using a high-resolution 3D laser scanning system (K-Scan, Nikon Metrology, Belgium), capturing the specific body characteristics of the cyclist. For meshing purposes, surface details were smoothed out to some extent and the bicycle was not included in the computational model. Two of these virtual cyclists were placed in a computational domain, one behind the other, with a spacing d varying from d = 0.01 m to 1m, including: 0.01 m, 0.25 m, 0.5 m and 1 m (Figs. 1 and 2).

The size of the computational domain, for the two cyclists with d = 0.01 m, is L x W x H = 21 m x 6 m x 7 m. For the other distances, the length of the domain is increased with the spacing d. The grid is a hybrid grid, consisting of very small prismatic cells in the boundary-layer region near the cyclist's surface, with the first computational cell at only 15 μm from the body surface. This high resolution is needed because low-Reynolds number modelling requires the y^* values of the wall-adjacent cells to be about 1 and certainly lower than 5 (Casey and Wintergerste 2000). Further away from the surface, tetrahedral cells have been used, with an average cell size in the wake region of about 0.03 m. The resulting grids for a single cyclist contain about 7.7×10^6 cells, while the grids for the two cyclists contain about 12.0×10^6 cells. The grids are based on grid-sensitivity analysis according to best practice guidelines in CFD (Casey and Wintergerste 2000, Franke et al. 2007, Tominaga et al. 2008). The grid discretisation error was estimated by means of Richardson extrapolation and was about 3% for the drag force of the single cyclist.

At the inlet, a uniform inlet velocity of 15 m/s is imposed, with zero turbulence intensity, which represents the relative air movement around the cyclists due to the cycling speed in still air

(zero wind speed). For the side and top boundaries, a slip-wall boundary (symmetry) was used. Slip walls assume that the normal velocity component and the normal gradients at the boundary are zero, resulting in flow parallel to the boundary. At the outlet of the computational domain, ambient static pressure was imposed. Two approaches are used: (1) 3D steady RANS with the standard k-ε turbulence model (Launder and Spalding 1972) and with low-Reynolds number modelling (LRNM), for which the one-equation Wolfshtein model (Wolfshtein 1969) is used in this study. Second-order discretisation schemes are used throughout. The SIMPLE algorithm is used for pressure-velocity coupling. Pressure interpolation is second order. (2) 3D LES simulations with the dynamic Smagorinsky subgrid-scale model (Kim 2004) with LRNM. Second-order discretisation schemes are used except for momentum, for which a central differencing scheme is used. Second-order implicit time stepping is used, and 20 iterations per time step were found to be sufficient to have convergence within a time step. The temporal discretisation is related to the spatial discretisation by the CFL (Courant-Friedrichs-Lewy) number: CFL = $u\Delta t/d$, where u is the characteristic velocity in the cell, Δt is the time step and d is the characteristic cell dimension. Time steps resulting in CFL numbers of 1 are suggested in the wake region (Spalart 2001). For the simulations, the choice of the time step and averaging period was also based on a sensitivity analysis. A time step of $3x10^{-4}$ s was chosen, resulting in CFL numbers below about 5 in the majority of the domain, with maximal values that do not exceed 10, and values of about 0.5 in the wake. A dimensionless simulation time of about 2 flow-through-times was found to be sufficient to obtain stationary, i.e. stable averaged, values for drag and surface pressures, where the flow-through-time is defined as: $t_{FT} = UT/L_D$, where U is the free-stream (approach flow) wind speed (15 m/s), T is the averaging period (2.8 s) and L_D is the length of the computational domain (21 m). The simulations were performed with the commercial CFD code Fluent 6.3, which uses the control volume method.

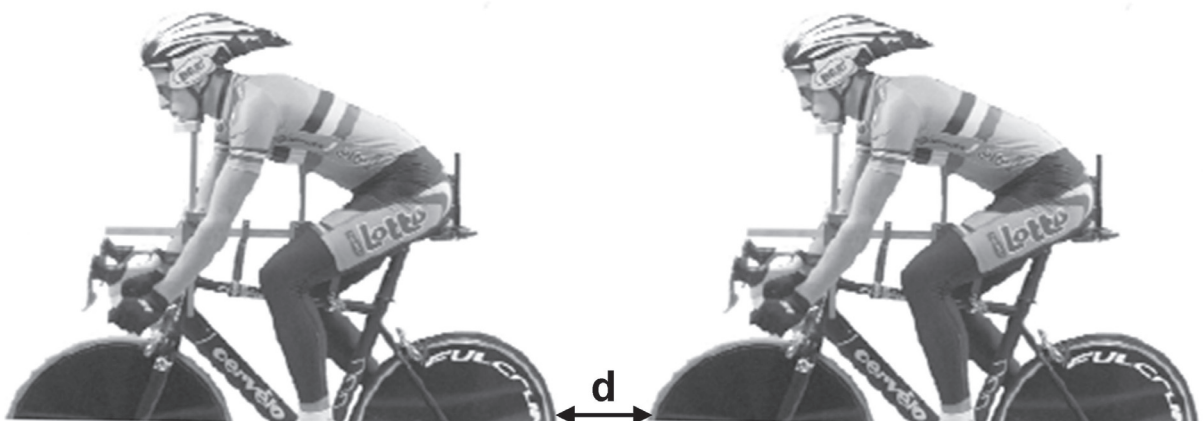

Figure 1. Two cyclists in dropped position at a variable spacing d.

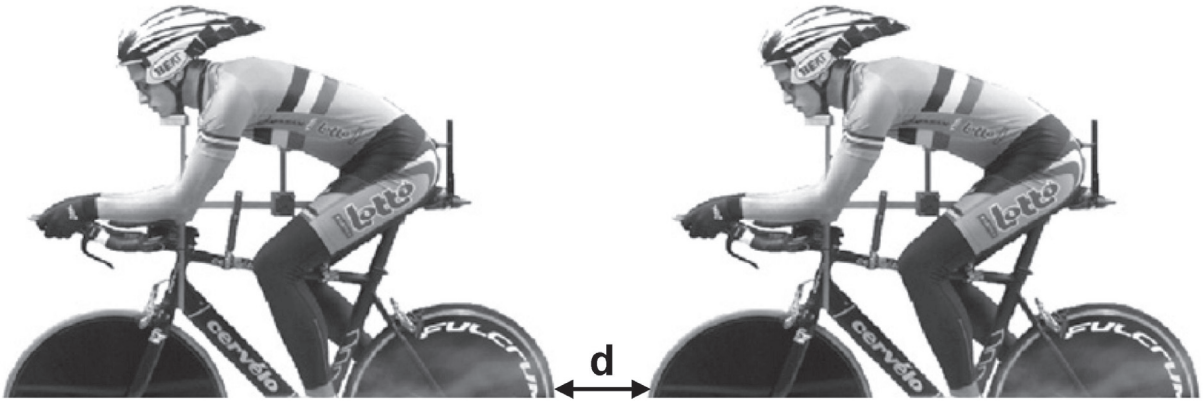

Figure 2. Two cyclists in time-trial position at a variable spacing d.

3. CFD SIMULATIONS: RESULTS

Figure 3 shows an instantaneous image of the velocity contours in a vertical centreplane for the two cyclists in dropped position and with spacing d = 0.01 m. The low-velocity stagnation regions directly upstream of every cyclist can be observed, as well as the turbulent low-velocity wake of the first cyclist that partly engulfs the second cyclist. In this vertical centreplane and in this dropped cyclist position, flow separation is observed at the top of the helmets. The figure also shows the very dense grid resolution on the cyclist bodies and helmets.

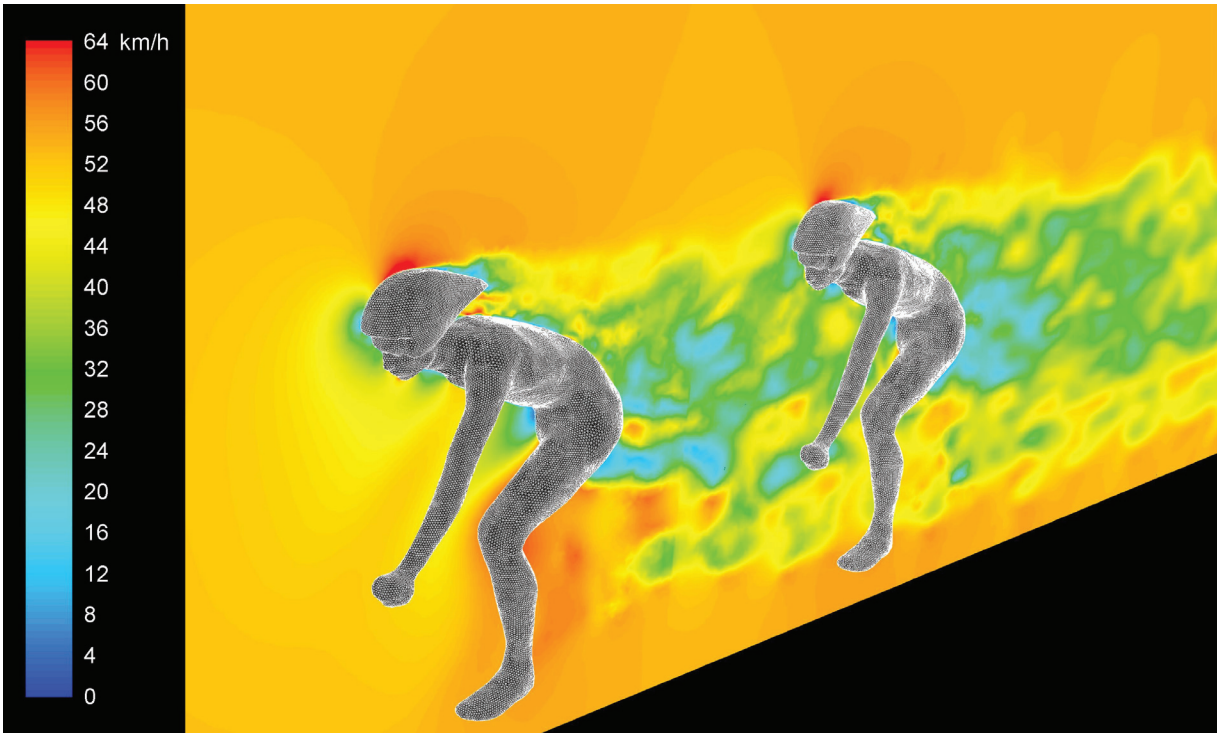

Figure 3. Instantaneous velocity contours in vertical centreplane for two cyclists in dropped position at distance d = 0.01 m.

The results of the simulations are reported in Figures 4 and 5, in terms of drag reduction (DR) for the two cyclists, with respect to a single cyclist, and as a function of the inter-cyclist spacing d. Figure 4 shows the drag reduction for the first and for the second cyclist in dropped position, as obtained with RANS and with LES. It is noteworthy that there is also a drag reduction for the first cyclist due to the proximity of the second cyclist behind him/her, although this drag reduction is limited and it rapidly disappears with increasing inter-cyclist spacing. The intrinsically more accurate LES simulations indicate a larger drag reduction for both cyclists compared to RANS. For d = 0.01 m, LES indicates a reduction of 3% for the first cyclist and 34% for the second cyclist, while RANS indicates 2% for the first cyclist and 26% for the second one. Both approaches indicate a near-linear decrease of the drag reduction with increasing inter-cyclist spacing, although this decrease is more pronounced according to the LES results. At a distance of 1 m, the drag reduction for the second cyclist is still 28% (LES), while that for the first cyclist has become negligible.

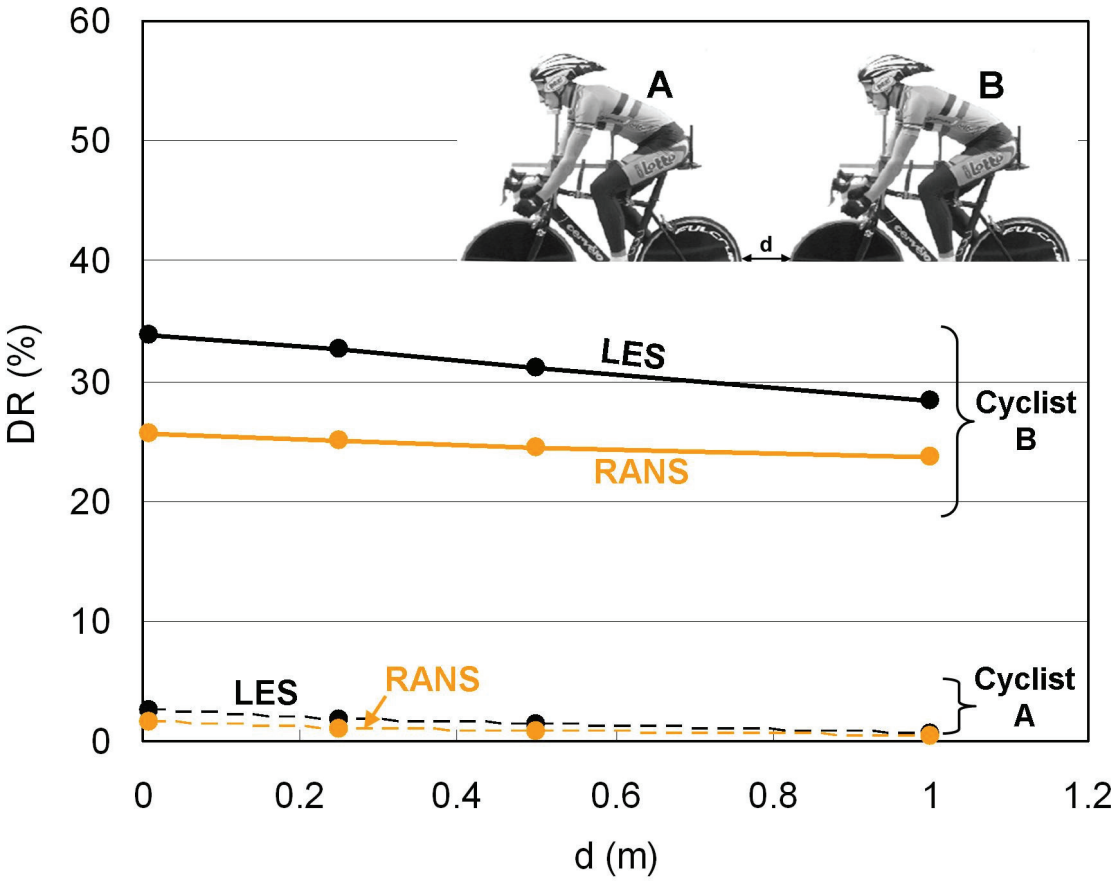

Figure 4. Drag reduction of two cyclists, with respect to a single cyclist, in dropped position at a variable spacing d, as obtained by RANS and LES simulations.

Figure 5 shows the drag reduction for the first and for the second cyclist in time-trial position, as obtained with RANS and with LES. Also here, the drag reduction for the first cyclist due to the proximity of the second cyclist is clearly present. As opposed to the results for the dropped position, the results for the time-trial position show a very large difference between RANS and LES results for the second cyclist, more than a factor 2, while the differences in results for the first cyclist are negligible. For d = 0.01 m, LES indicates a reduction of 2% for the first cyclist and 36% for the second cyclist, while RANS indicates 3% for the first cyclist and 16% for the second one. Both approaches indicate a near-linear decrease of the drag reduction with increasing inter-cyclist spacing, which is most pronounced for the second cyclist with LES. At a distance of 1 m, the drag reduction for the second cyclist is still 30% (LES), while that for the first cyclist has become negligible.

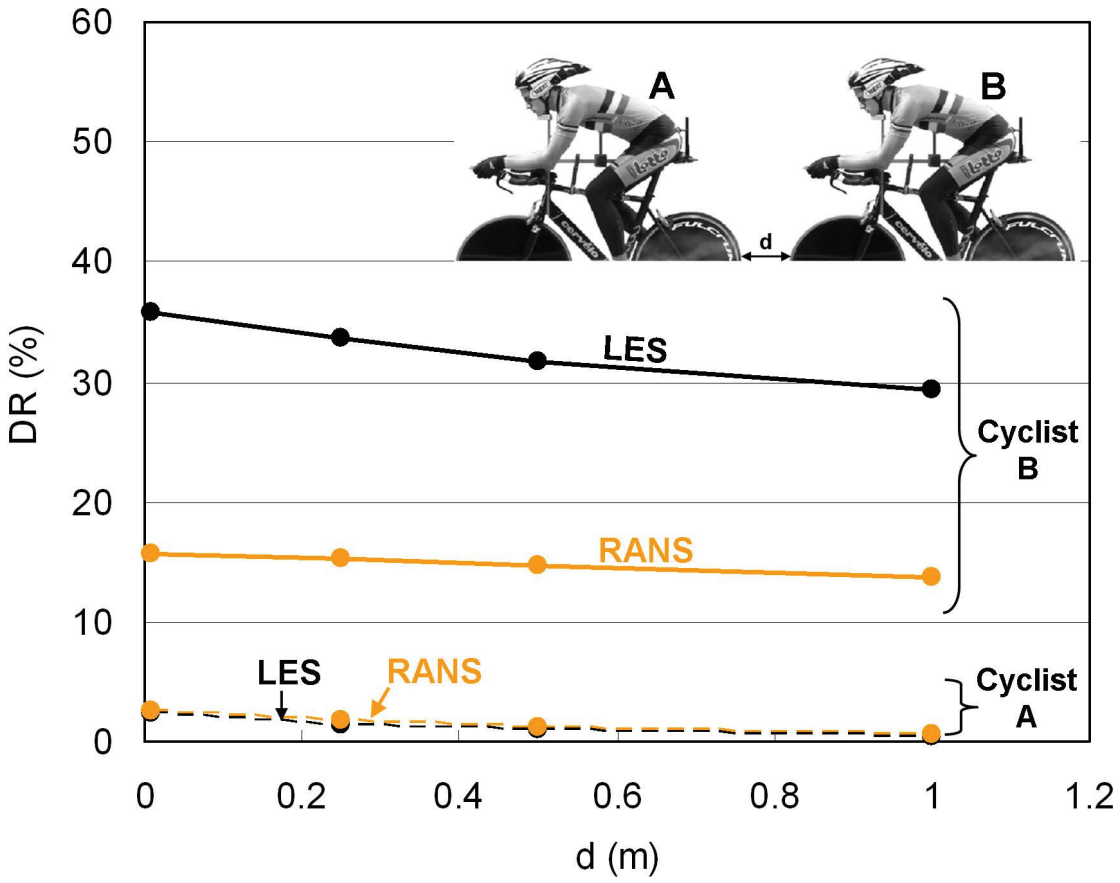

Figure 5. Drag reduction of two cyclists, with respect to a single cyclist, in time-trial position at a variable spacing d, as obtained by RANS and LES simulations.

4. DISCUSSION AND CONCLUSIONS

The interference drag (drag reduction) experienced by a second cyclist due to a cyclist in front of him/her is well-known. The fact that the first cyclist also experiences a drag reduction by the presence of the second one however, is less known, although there are some previous studies that suggest drag reduction of an upstream body by its downstream counterpart (e.g. Iniguez-de-la Torre and Iniguez 2009). The reason for the drag reduction of the first cyclist by the second one is the overpressure region in front of this second cyclist. This overpressure region merges with the underpressure region (wake) behind the first cyclist, thereby reducing the underpressure in this region and reducing the drag force. This effect is more pronounced as the cyclists ride closer behind each other.

Previous numerical studies on the aerodynamics of a single cyclist riding in still air (Defraeye et al. 2010a, 2010b) have shown that the RANS and LES approach provided similarly accurate results for pressure coefficients and aerodynamic drag. In particular, the study by Defraeye et al. (2010a) compared CFD simulations with drag measurements on a full-scale cyclist and indicated that, for the dropped position, Large Eddy Simulation (LES) yields a deviation in the drag area of 3%, while steady RANS with the standard k-ε model yields a deviation of 7%. However, for the reduced-scale (1:2) model (upright position), steady RANS with the standard k-ε model provided a deviation in the drag area of only 4% compared to 6% with LES (Defraeye et al. 2010b). These results might suggest that further studies can be conducted with steady RANS and the standard k-ε model, and that more time-consuming and intrinsically more accurate simulations with LES would not be necessary. However, the comparison of RANS and LES simulations of the interference drag of two cyclists show large to very large differences between both approaches. Compared to a single cyclist, the drag reduction for the dropped position with d = 0.01 m and with RANS is 2% for the first cyclist and 26% for the second one, while with LES it is 3% and 34%, respectively. For the time-trial position with d = 0.01 m, the reductions with RANS are 3% for the first cyclist and 16% for the second one, while with LES these values are 2% and 36%, respectively. Hereby not only the differences between RANS and LES is remarkable, but also the fact that this difference is much larger for the time-trial position than for the dropped position. Additional wind tunnel experiments with two cyclists are scheduled for further validation studies. Also, additional analysis of the CFD results will be performed to analyze the reasons for these large differences between RANS and LES results.

ABSTRACT: High-rise buildings can cause wind discomfort on the building balconies, necessitating remedial action. In this paper, a new facade concept is evaluated that is intended to significantly improve wind comfort on the balconies of a 78 m high-rise building. The concept consists of a staggered semi-open second-skin facade that partly shields the balconies from the wind. Evaluation of the concept is performed by steady Reynolds-Averaged Navier-Stokes (RANS) CFD simulations with the realizable k-ε turbulence model in combination with the Dutch wind nuisance standard. First, some results of a CFD validation study for buildings with balconies are briefly presented. Next, similar simulations are used to evaluate the new facade concept by comparing the wind comfort at the balconies with and without application of this concept. It is shown that the new facade concept is quite effective in improving wind comfort at the balconies.

KEYWORDS: Pedestrian wind environment, wind conditions, Computational Fluid Dynamics (CFD), building balconies

1. INTRODUCTION

High-rise buildings can cause high wind speed near ground level and on building balconies, necessitating remedial action. In order to reduce wind discomfort on balconies, different measures can be taken; such as closing the balcony, adding partition walls, etc. Recently a new facade concept was developed by ELD Partnership (ELD 2011). It consists of a staggered semi-open second-skin facade that partly shields the balconies from the wind. It is intended to significantly improve wind comfort on the building balconies. In this paper, the performance of this concept is evaluated by validated CFD simulations and by application of the Dutch wind nuisance standard for a case study with and without application of this new concept.

In the past, several CFD studies have been performed to investigate pedestrian-level wind conditions in complex urban environments (e.g. Stathopoulos and Baskaran 1996, Yoshie et al. 2007, Blocken et al. 2012). The use of CFD for complete wind comfort studies however is still relatively scarce, and this especially holds for studies of wind comfort at building balconies. Indeed, most of the previous CFD studies focused on wind comfort at pedestrian level around buildings. To the best of our knowledge, no CFD study has yet been published with focus on wind comfort on building balconies.

This paper presents the evaluation of the new second-skin facade concept by ELD Partnership to improve wind comfort at building balconies. First, some results of a CFD validation study for buildings with balconies are briefly presented. Next, the new concept is evaluated for the case of

a high-rise (78 m) building in the city of Antwerp. CFD simulations are performed for the building with and without second-skin facade concept implemented. The CFD simulations are performed with the 3D steady Reynolds-Averaged Navier-Stokes (RANS) approach and the realizable k-ε model (Shih et al. 1995). The obtained CFD results are combined with wind speed statistics and a comfort criterion to judge wind comfort on the balconies, according to the Dutch wind nuisance standard.

2. DESCRIPTION OF BUILDING AND URBAN AREA

The new high-rise building of the so-called EPA project is located in the northern part of the city of Antwerp, Belgium. It is north-south oriented and surrounded by other high-rise and low-rise buildings (Fig. 1a). It has dimensions L × B × H = 21.8 × 50.8 × 78.2 m³. The depth of the balconies on the north, east, south and west side of the tower is 1.32 m, 1.3 m, 1.59 m and 1.56 m, respectively. The facade concept is a second-skin concept, with a first and inner skin that acts as traditional facade and a second outer skin that acts as a wind shield for the balconies. The second skin consists of a staggered semi-open glass facade, as indicated in Figure 1b. It has a permanent solid glass balustrade of 1.2 m high, while above this 1.2 m, solid glass facade panels are applied in a staggered configuration. For the comparison study, a reference high-rise building with only the 1.2 m high balustrade will be considered.

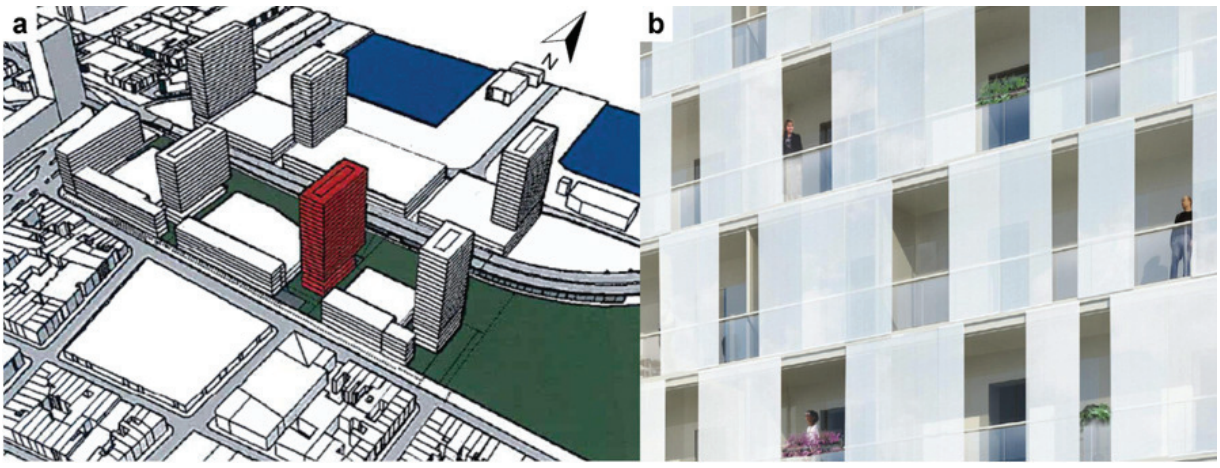

Figure 1. (a) High-rise building under study (red) and nearby urban surroundings. (b) Building facade with second-skin staggered facade concept.

3. CFD VALIDATION

CFD simulations based on the 3D RANS equations in combination with a turbulence model require validation. Validation can be performed by comparison of the CFD results with either full-scale measurements or wind tunnel data. Experimental data of wind conditions for buildings with balconies are very scarce. In this paper, a unique set of wind tunnel measurements of surface pressures on the facade of a building with balconies is used for validation purposes.

3.1. Wind tunnel measurements

Atmospheric boundary layer wind tunnel measurements of wind-induced surface pressure on the facade of a reduced-scale model (1:30) of a medium-rise building were conducted by Chand et al (1998). The incident vertical profile of mean wind speed (i.e. at the location of the test model) can be described by a logarithmic law with aerodynamic roughness length z_0 = 0.008 m and friction velocity u* = 0.72 m/s. Longitudinal turbulence intensity ranged from 13% near ground level to about 3% at gradient height. The building had dimensions $w_m \times d_m \times h_m = 0.25 \times 0.60 \times 0.50$ m^3 (reduced scale, see Fig. 2a) corresponding to full-scale dimensions $W_m \times D_m \times H_m = 7.5 \times 18 \times 15$ m^3. To evaluate the effect of building balconies on mean pressure, the measurements were carried out for an isolated building with and without balconies. Three balconies each with length 0.15 m, width 0.05 m and height 0.03 m were positioned at each floor (Fig. 2a). Surface pressures were measured along three vertical lines on the windward and leeward facade. Each line was in the middle of the balconies and 45 pressure taps were implemented along these lines. Pressure coefficients were related to the incident wind speed at building height (7.1 m/s).

3.2. Comparison of CFD results and wind tunnel measurements

The wind tunnel experiments are reproduced by solving the 3D steady RANS CFD simulations combined with the realizable k-ε model (Shih et al. 1995) and following the best practice guidelines by Franke et al. (2007) and Tominaga et al. (2008a). The computational grid was fully structured and was created using the surface grid extrusion technique presented by van Hooff and Blocken (2010). Figure 2b compares the numerically simulated and measured pressure coefficients at the windward facade of the building with balconies for wind direction 0°. It should be noted that in this validation study, only results for the windward facades are considered. It is important to note that steady RANS CFD is deficient in reproducing the wind flow pattern downstream of windward facades (Murakami 1993, Tominaga et al. 2008b). Nevertheless, this approach is used in this paper, because the accuracy of the wind-flow pattern at side and the leeward facades is less important in wind comfort studies. The reason is that wind comfort studies typically focus on high wind speed positions, i.e. where a certain threshold wind speed is exceeded. Other positions do not contribute to the exceedance probabilities. Figure 2b shows that for the windward facades, the trends are well predicted by the CFD simulations. For the building without balconies, the deviations between the experimental and CFD results are generally less than 10%, while for the building with balconies, they are generally less than 20%.

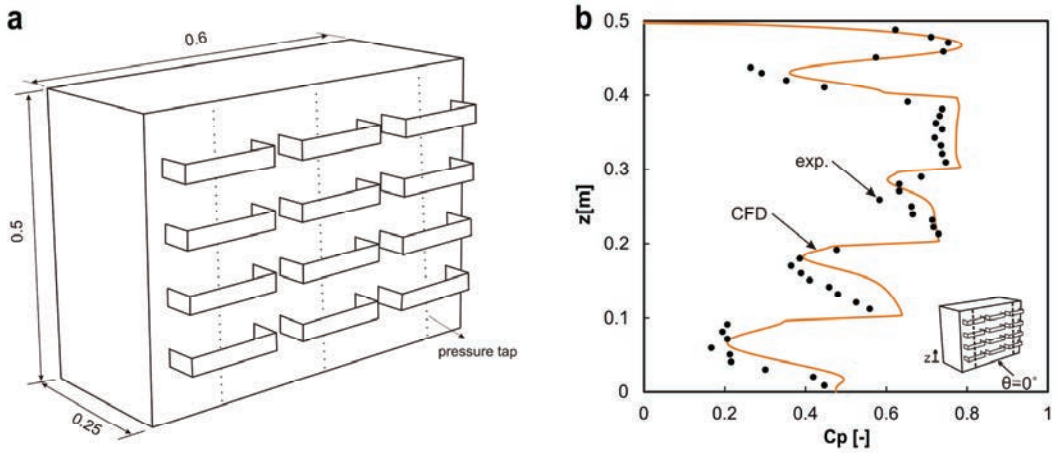

Figure 2. (a) Wind tunnel model of building with balconies and three vertical lines for pressure measurements (reduced-scale dimensions in m); (b) Comparison of wind tunnel and CFD results: pressure coefficient C_p along vertical line near building edge.

4. CASE STUDY: COMPUTATIONAL MODEL AND COMPUTATIONAL PARAMETERS

4.1. Computational geometry and grid

A computational model has been made of the tower and its urban surroundings, which are placed in a computational domain with dimensions of 2080 ×1770 ×400 m^3. The explicitly modeled buildings are the tower itself and the surrounding buildings in a radius of 350 m around the tower. Because of the existing densely built area to the east side of the tower, the buildings placed at that part within a distance of 670 m from the tower are also modeled. The tower is modeled in detail, including staggered facade elements, while the surrounding buildings are included only with their main shape. Special attention was given to the generation of a high-quality and high-resolution grid. The grid was constructed using the surface grid extrusion technique presented by van Hooff and Blocken (2010), which allows a large degree of control over the quality of the grid and its individual cells. It consists of only hexahedral and prismatic cells and does not contain any tetrahedral or pyramid cells. In addition, the grid was constructed following the best practice guidelines by Franke et al. (2007) and Tominaga et al. (2008a). The two grids for building with application of the second-skin facade and the reference building consist of 16,292,495 cells and 15,536,529 cells, respectively (Fig. 3).

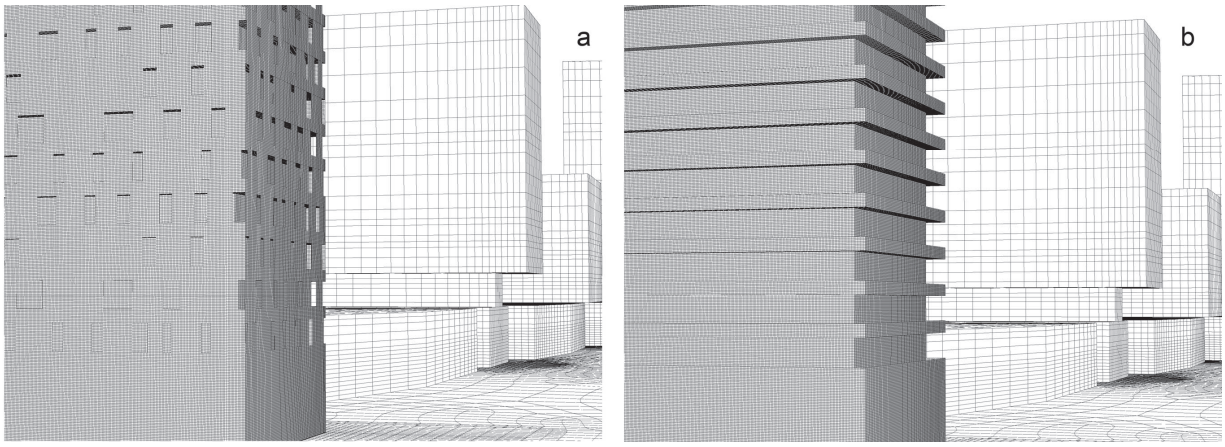

Figure 3. View from north-east at high-resolution computational grid on surfaces of high-rise building tower and surrounding buildings for (a) building with second-skin facade concept (16,292,495) and (b) reference building (15,536,529).

4.2. Boundary conditions

At the inlet of the domain, neutral atmospheric boundary layer inflow profiles of mean wind speed, turbulent kinetic energy and turbulence dissipation rate are imposed. These profiles are based on the aerodynamic roughness length z_0 of the upstream terrain that is not included in the computational domain. At the outlet, zero static pressure is specified. At the sides and the top of the domain, symmetry boundary conditions are imposed (i.e. zero normal velocity and gradients). At the ground surface, the standard wall functions by Launder and Spalding (1974) with the sand-grain roughness modification by Cebeci and Bradshaw (1977). The equivalent sand-grain roughness height k_S and roughness constant C_S are determined based on their relationship with z_0 according to Blocken et al. (2007). At the building surfaces, also standard wall functions are used, with the assumption of smooth walls (k_S = 0 m).

4.3. Solver settings

The CFD simulations are performed using the commercial CFD code Fluent 6.3.26. The 3D steady RANS equations are solved with the realizable k-ε turbulence model (Shih et al. 1995). The choice for this turbulence model is based on the recommendations by Franke et al. (2007) and on earlier successful validation studies for pedestrian-level wind conditions with this turbulence model (Blocken and Persoon 2009, Blocken et al. 2012). Pressure velocity-coupling is taken care of by the SIMPLE algorithm. Pressure interpolation is second order. Second-order discretisation schemes are used for both the convection terms and viscous terms of the governing equations. The simulations are performed for the 12 wind directions θ = 0-330° in 30° intervals.

5. CASE STUDY: CFD SIMULATION RESULTS

Figure 4 shows the local amplification factor U/U_{ref} in a horizontal plane at a height of 1.7 m at the 15th floor of the tower for the two situations and for southwest wind direction. The local amplification factor is defined as the ratio of the local mean wind speed U to the reference wind speed U_{ref} at the same height but in undisturbed (free-stream) conditions. It can be seen that the new concept provides a significantly reduced amplification factor on the balconies two at the windward facades. At the west facade, the amplification factor reduces from a value of about 1.0 to a value of about 0.6.

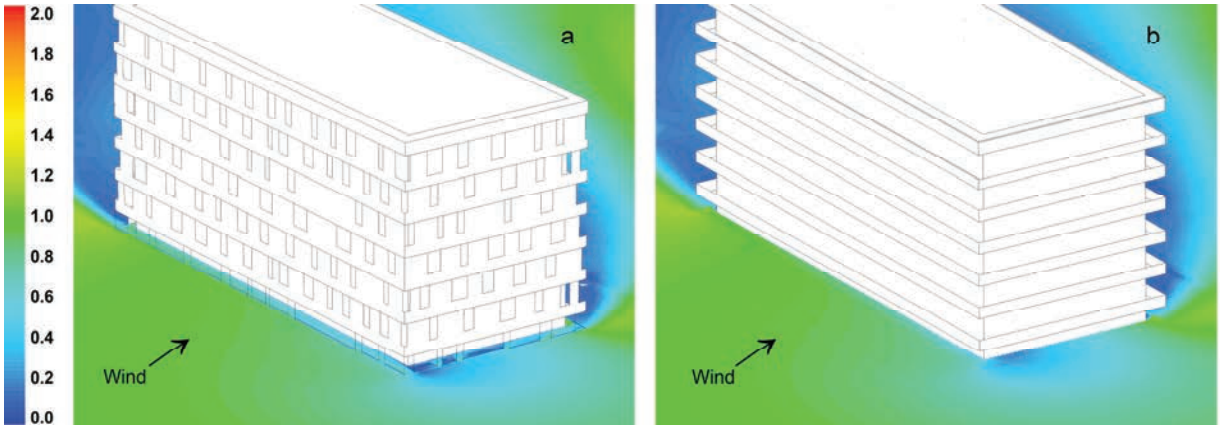

Figure 4. Contours of amplification factor for wind direction 210° in a horizontal plane at a height of 1.7 m above 15th floor for: (a) the building with application of the second-skin facade concept. (b) The reference building.

6. CASE STUDY: WIND COMFORT ASSESSMENT RESULTS

The wind speed amplification factors are used in combination with the Dutch wind nuisance standard for the assessment of wind comfort. For brevity, only some main items of this standard are given here, more details can be found in Willemsen and Wisse (2002, 2007), NEN (2006a, 2006b). The threshold wind speed in the standard is 5 m/s for all activities, while the maximum allowed exceedance probabilities of this threshold vary based on the activity, see Table 1.

Table 1: Criteria for wind nuisance according to NEN 8100 (2006a)

$P(U_{THR} > 5$ m/s (in % hours per year)	Grade	Activity		
		Traversing	Strolling	Sitting
< 2.5	A	Good	Good	Good
2.5 – 5.0	B	Good	Good	Moderate
5.0 – 10	C	Good	Moderate	Poor
10 – 20	D	Moderate	Poor	Poor
> 20	E	Poor	Poor	Poor

For the wind comfort analysis, the wind statistics of the nearby city of Eindhoven are used. Figure 5 illustrates the exceedance probability of the 5 m/s threshold on the 15th floor. Because southwest is the prevailing wind direction, the pattern of exceedance probabilities resembles that of the wind speed amplification factor for southwest wind direction (see Fig. 4). Figure 5 clearly shows that the second-skin facade concept improves wind comfort for a large part of the west facade and also for part of the south facade.

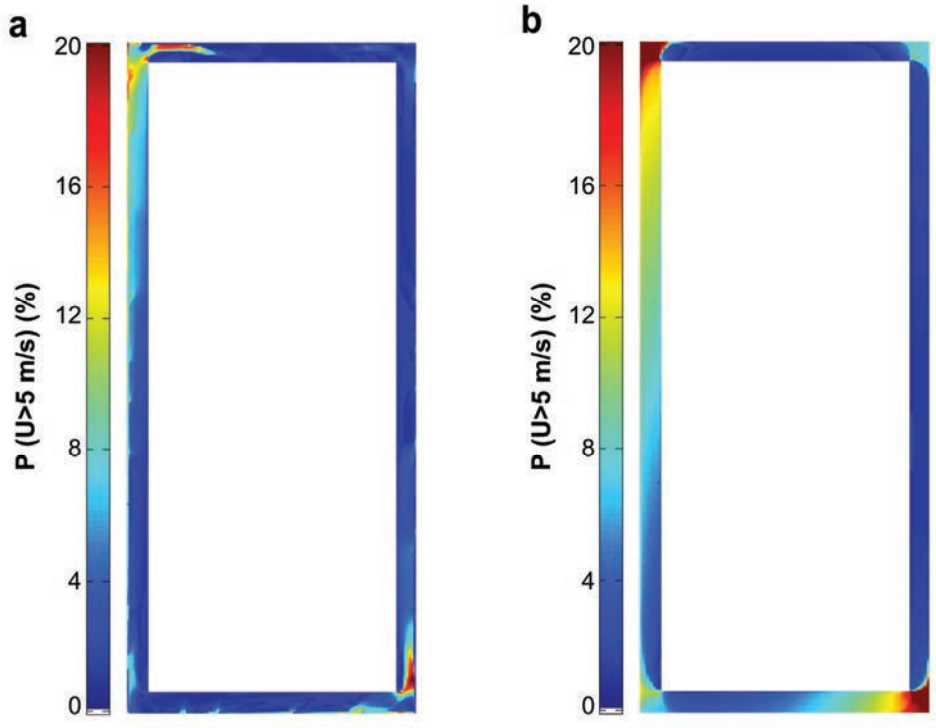

Figure 5. Contours of exceedance probability in a horizontal plane at a height of 1.7 m above 15th floor for: (a) the building with application of the second-skin facade concept. (b) The reference building.

7. DISCUSSION

Some important limitations of this study are mentioned.

- The 3D steady RANS equations have been solved with the realizable k-ε model. It is important to note that steady RANS CFD is generally deficient in reproducing the wind-flow pattern downstream of windward facades (Murakami 1993, Tominaga et al. 2008b).

Nevertheless, this approach is used in this paper, because the accuracy of the wind-flow pattern at side and the leeward facades is less important in wind comfort studies. The reason is that wind comfort studies typically focus on high wind speed positions, i.e. where a certain threshold wind speed is (5 m/s in the present study) is exceeded. Other positions do not contribute significantly or do not contribute at all to the exceedance probabilities.

- No grid-sensitivity analysis was performed. However, the computational grid has been made based on the best practice guidelines by Franke et al. (2007) and Tominaga et al. (2008a) and the grid resolution has been taken either similar or higher than in previous studies for which grid-sensitivity analyses were performed (van Hooff and Blocken 2010, Blocken et al. 2012)..

8. CONCLUSIONS

3D steady RANS CFD simulations have been used in combination with the new Dutch wind nuisance standard to evaluate the performance of a new facade concept. This concept consists of a staggered semi-open second-skin facade that partly shields the balconies from the wind. To achieve this particular purpose, the wind comfort at the balconies with and without application of this concept has been compared. It is shown that the new facade concept is very effective in shielding the balconies and improving the wind comfort.

ABSTRACT: Large-Eddy Simulation (LES) of wind flow around a high-rise building is performed with the Smagorinsky subgrid-scale model. Validation of the simulation is performed by comparing the numerical results to wind-tunnel measurements. Very good agreement is found for the mean streamwise velocity. Over-estimation of the turbulent kinetic energy by LES is observed in the wake of the building. Verification of the numerical solution is performed by evaluating the numerical and modeling error contributions with the Systematic Grid and Model Variation technique and by computing the amount of turbulent kinetic energy resolved by the numerical model. It is shown that the numerical and modeling errors are relatively high in magnitude but compensate each other, resulting in a low total error, and explaining the good accuracy of the model. With a computational grid using 20 cells per building side, 80% of the total kinetic energy is resolved on average in the region around the building.

1 INTRODUCTION

In most of the applications of Computational Wind Engineering (CWE) such as pollutant dispersion (e.g. Hanna et al., 2006; Gousseau et al., 2011a; Gousseau et al., 2011b) or pedestrian wind comfort (e.g. Yoshie et al., 2007; Blocken et al., 2012), the accurate simulation of the flow around buildings by the numerical model is needed. In this respect, the good performance of the Large-Eddy Simulation turbulence modeling approach has already been proven (e.g. Murakami, 1993; Shah and Ferziger, 1997; Tominaga et al., 2008a). However, despite the increasing attention given to the quantification of error and uncertainty in Computational Fluid Dynamics (CFD), the techniques that have been developed for general fluid engineering problems to assess the quality of CFD simulations are still marginally used in CWE (Franke, 2010). This is particularly true for LES.

The aim of the present study is to assess the quality of an LES computation of wind flow around an isolated building. The procedure is twofold: on the one hand the validation part and, on the other hand, the solution verification part (Oberkampf and Trucano, 2002).

Validation is defined as "the process of determining the degree to which a model is an accurate representation of the real world from the perspectives of the intended uses of the model" (AIAA, 1998). It will be performed here by comparing the numerical results with the measurements from a reference wind-tunnel experiment.

Verification is defined as "the process of determining that a model implementation accurately represents the developer's conceptual description of the model and the solution to the model"

(AIAA, 1998). The code verification will not be treated here; the solution verification will be performed by (1) evaluating the modeling and numerical error contributions in the LES solution with a multi-grid technique called Systematic Grid and Model Variation (SGMV) (Klein, 2005; Freitag and Klein, 2006; Klein et al., 2008; Celik et al., 2009) and (2) by evaluating the proportion of the total turbulent kinetic energy which is resolved by the LES model with the LES index of quality (*LES_IQ*) (Celik et al., 2005; Celik et al., 2006; Celik et al., 2009).

The reference experiment that will be reproduced with CFD is described in the next section, as well as the numerical model used in the present study. Next, the results are presented and analyzed.

2 NUMERICAL MODEL

2.1 Domain, grid and boundary conditions

The wind-tunnel experiment by Meng and Hibi (1998) has been reproduced with Ansys Fluent 12. It involves a building of dimensions $b \times b \times h$ ($b=h/2=0.08$m) in the streamwise (x), lateral (y) and vertical (z) direction, respectively, placed in the test section of a wind tunnel where an Atmospheric Boundary Layer (ABL) flow is simulated. The Reynolds number based on b and the mean velocity of the incident flow at building height (U_h) is equal to 2.4×10^4. The origin of the coordinate system is the center of the building's ground face.

The computational domain has been created and meshed with the surface-extrusion technique (van Hooff and Blocken, 2010). The domain dimensions are $2.64 \times 0.9 \times 0.9$ m^3 (Fig. 1a). A distance of $4h$ is allocated between the inflow boundary and the windward facade of the building and the outlet face of the domain is located $12.125h$ downstream of the building. In the vertical direction, the height of the wind-tunnel test section is used (0.9m=$5.625h$) and the top wall boundary is modeled. To avoid modeling the side-walls of the wind tunnel (which would require grid refinement and increase the total number of cells significantly), the width of the domain has been chosen slightly smaller than the test-section width (0.9m=$11.25b$ vs. 1.1m). Nevertheless, an empty distance of $5.125b$ is allocated on each side of the building, which ensures low influence of the side boundary conditions on the flow around the building. The resulting blockage ratio is equal to 1.6%, which is below the maximum values recommended by the COST action 732 and AIJ guidelines (Franke et al., 2007; Tominaga et al., 2008b).

The building has been discretized into 20 cells in the x- and y- directions and 40 in the z-direction. Away from the building, the cell dimension has been increased until a maximum of $b/2.2$ with a growth ratio kept around 1.08 to limit commutation error. In total, the grid contains 737,920 hexahedral cells. The grid on the building and ground surfaces can be seen in Figures 1b,c.

Symmetry boundary conditions are set at the sides of the domain (y=±0.45m), imposing zero normal velocity and zero gradients of all variables at these boundaries. At the outlet of the domain, zero static pressure is imposed.

The building and ground surfaces as well as the top boundary of the domain are defined as no-slip walls. The centroids of the wall-adjacent cells are assumed to fall either in the linear sublayer, in the buffer layer or in the logarithmic zone of the boundary layer, depending on the distance to the wall (Ansys Inc., 2009). Note that no special treatment has been applied to the ground surface to take into account its roughness but that the inflow boundary is located close enough to the building to limit the appearance of longitudinal gradients in the ABL profiles (Blocken et al., 2007a; Blocken et al., 2007b).

The time-dependent velocity profile at the inlet is generated by the Vortex Method (VM) (Sergent, 2002; Mathey et al., 2006). The VM consists in generating and transporting randomly in the inlet plane a given number (here: 200) of 2D-vortices whose intensity and size depend on the local value of the turbulent kinetic energy (k) and the turbulence dissipation rate, for which profiles are prescribed based on the experiment. These vortices allow computing the perturbations super-imposed on the mean velocity profile prescribed at the inlet, which corresponds to the one measured in the empty test section of the wind tunnel. Note that the VM showed good performance when applied to pollutant dispersion studies by the authors (Gousseau et al., 2011a; Gousseau et al., 2011b; Gousseau et al., 2012).

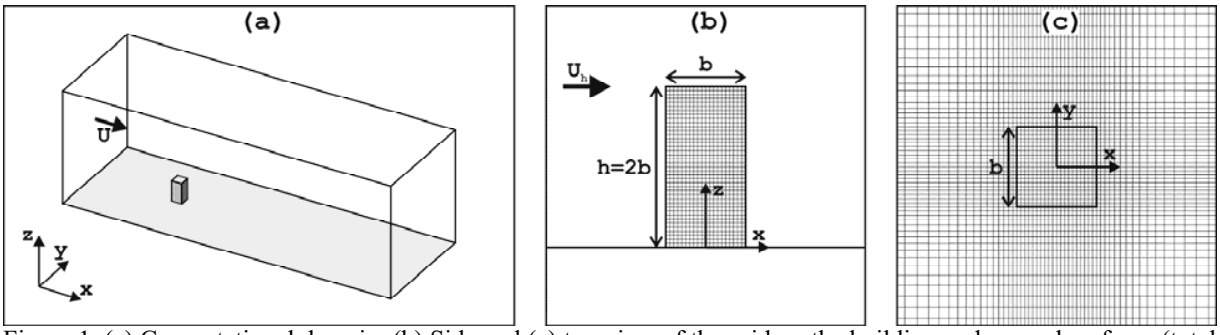

Figure 1. (a) Computational domain. (b) Side and (c) top view of the grid on the building and ground surfaces (total number of cells: 737,920).

2.2 LES modeling

Large-Eddy Simulation has been used with the standard Smagorinsky subgrid-scale (SGS) model. The filter width is directly related to the cell size (implicit filtering): it is equal to the cubic root of the cell volume. The Smagorinsky constant C_s, which allows computing the SGS turbulent viscosity, has been set to 0.1, which appears to be an appropriate value for flow around bluff bodies (Rodi et al., 1997; Thomas and Williams, 1997; Xie and Castro, 2009). Note that another simulation with a different C_s value (C_s=0.15) has also been run in order to estimate the modeling error (Section 4) but no plots of the results are shown here.

The bounded central-differencing scheme is used to discretize the convection term in the filtered momentum equation. From the pressure values at the cell centers, the face values are computed with a second-order scheme. Pressure-velocity coupling is performed with the fractional-step method (Kim and Moin, 1985; Bell et al., 1989).

Time discretization is second-order implicit. The non-iterative scheme is used for time advancement, which decreases the computational time significantly without affecting the overall accuracy of the simulation (Ansys Inc., 2009). The time-step value (Δt) has been set to 8×10^{-4}s, corresponding to 0.045 time units ($t_u=b/U_h$). Each simulation is initialized with the solution of a preceding RANS simulation on which random noise is super-imposed. After an initialization period T_{init}=3.2s corresponding to 5.4 flow-through times ($T_{ft}=L_x/U_h$, where L_x is the length of the computational domain), the statistics are sampled for T_{avg}=12.8s=21.8T_{ft}=718t_u. It has been verified that at the end of this averaging period the mean values of velocity are converged.

3 VALIDATION: COMPARISON BETWEEN EXPERIMENTAL AND NUMERICAL RESULTS

Figure 2 shows the experimental and numerical profiles of non-dimensional mean streamwise velocity (U/U_h) in the vertical mid-plane V0 (Fig. 2a) and in the horizontal plane H10 at 10 cm from the ground (Fig. 2b). The plotting lines are located at x/b=-0.75; -0.25; 0.5; 1.25; and 3.25. One can notice the very good agreement between the LES results and the measurements, along all lines, including in the wake recirculation zone of the building – a zone where the flow is known to be especially challenging to predict.

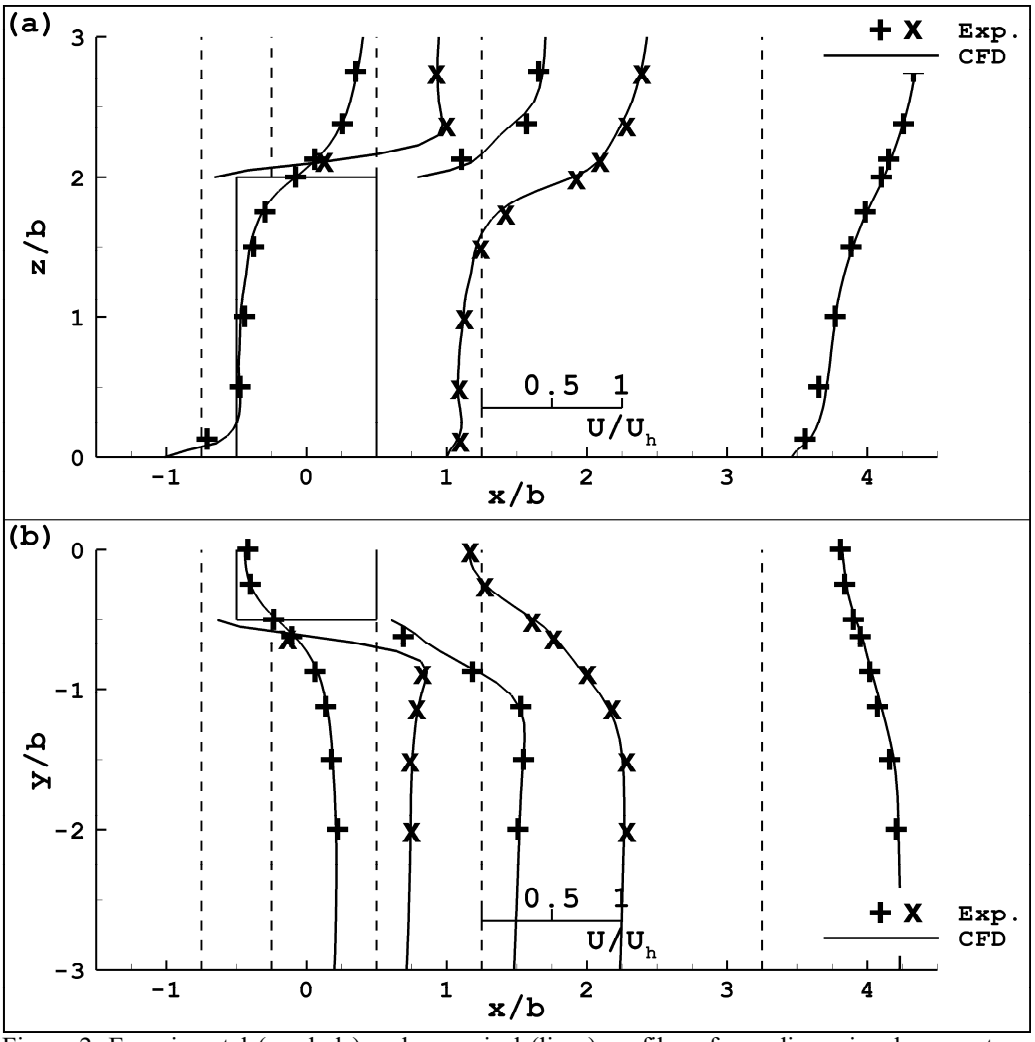

Figure 2. Experimental (symbols) and numerical (lines) profiles of non-dimensional mean streamwise velocity in the planes (a) V0 and (b) H10.

The profiles of non-dimensional turbulent kinetic energy (k/U_h^2) in the planes V0 and H10 are shown in Figure 3. Good agreement is found between experiments and LES, except in the wake of the building where the LES model over-estimates the measured turbulent kinetic energy values. Nevertheless, these results demonstrate the good performance of the vortex method to generate inflow turbulence in the case of ABL flow.

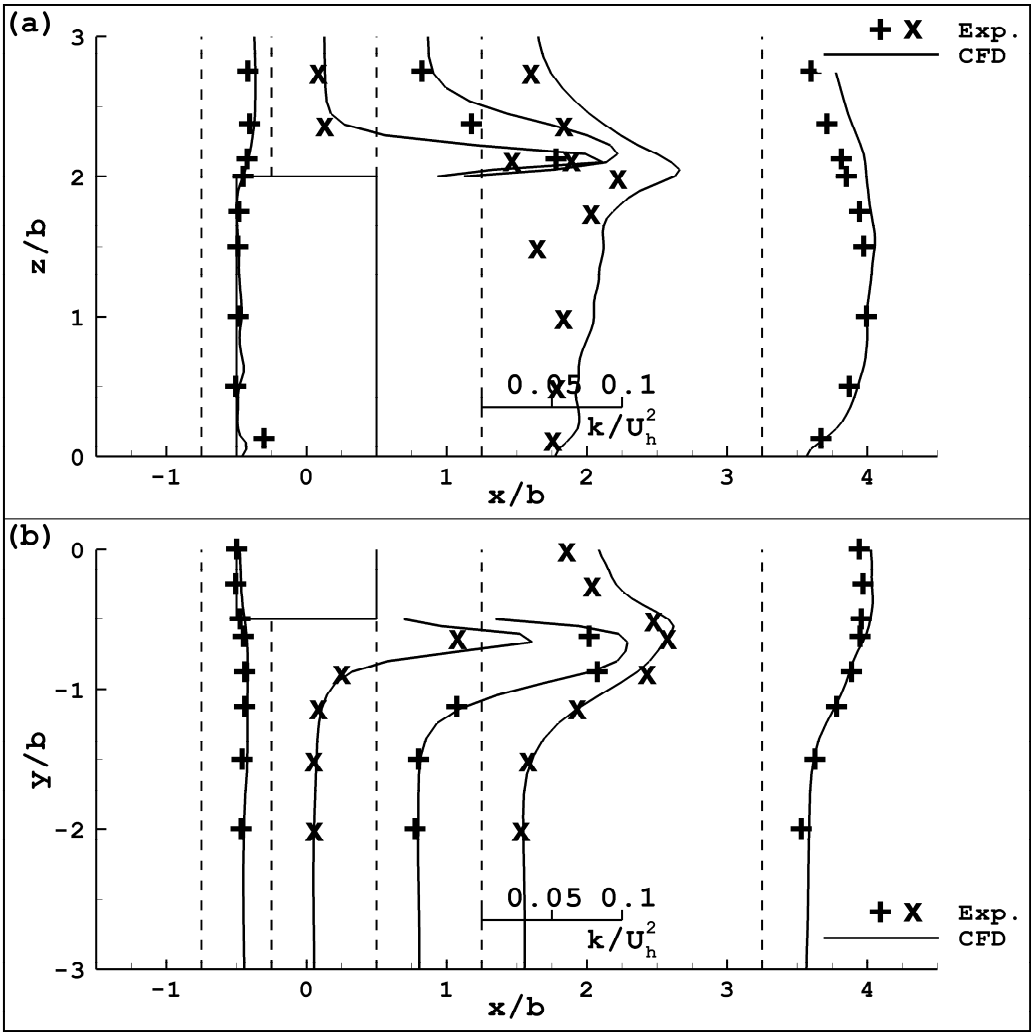

Figure 3. Experimental (symbols) and numerical (lines) profiles of non-dimensional turbulent kinetic energy in the planes (a) V0 and (b) H10.

4 ESTIMATION OF THE NUMERICAL AND MODELING ERROR

In the context of LES with implicit filtering, the modeling (ε_m) and numerical (ε_n) errors interact and cannot be evaluated separately. The Systematic Grid and Model Variation (Klein, 2005) is therefore used here to provide an estimation of these two types of error, based on Richardson extrapolation. The difference between the exact solution of the flow equations (u_e) and the numerical solution (u_1) is equal to the sum of these two error contributions which are assumed to scale with the filter width:

$$u_e - u_1 = \varepsilon_m + \varepsilon_n = c_m \Delta^m + c_n \Delta^n \tag{1}$$

where c_m and c_n are coefficients to be determined, Δ is the filter width, n=2 is the order of accuracy of the numerical scheme and m is taken equal to its theoretical value 2/3 as suggested in (Freitag and Klein, 2006). The LES simulation has been performed on the same grid with a modified model coefficient C_s=0.15 (solution u_2) and with C_s=0.1 on a finer grid with 30 cells per building side (solution u_3). Applying the same procedure to these two numerical solutions yields:

$$u_e - u_2 = \beta c_m \Delta^m + c_n \Delta^n \tag{2}$$

$$u_e - u_3 = c_m (\alpha\Delta)^m + c_n (\alpha\Delta)^n \tag{3}$$

where β=0.15²/0.1²=2.25 is the model variation factor equal to the ratio of the square of the C_s values and α=2/3 is the refinement factor equal to the ratio of the filter width/grid size on the fine grid to the one on the coarse grid. The combination of Equations 1, 2 and 3 allows determining the unknowns of the problem (u_e, c_m and c_n) and estimating ε_m and ε_n. The SGMV technique has been applied here for the mean velocity.

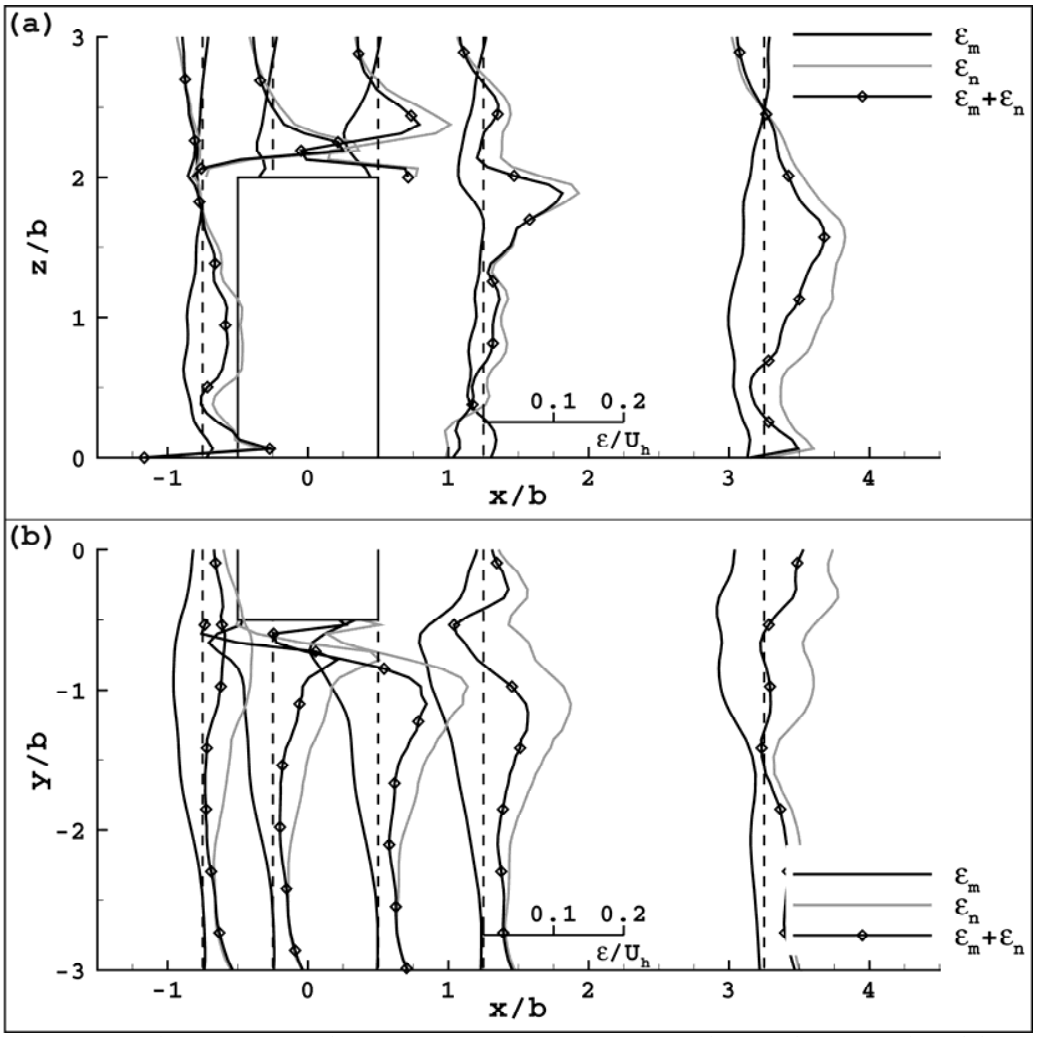

Figure 4. Results of SGMV technique for LES20-1: Estimation of the non-dimensional modeling, numerical and total error on mean streamwise velocity prediction in the planes (a) V0 and (b) H10.

Figure 4 shows the resulting estimation of ε_m and ε_n (normalized by U_h) for the "reference" simulation (i.e. the one presented in Section 3, on the coarse grid with C_s=0.1). The sum of these two error contributions is also shown. Note that it is advised to use the sum of the magnitudes $|\varepsilon_m|+|\varepsilon_n|$ to get an estimation of the uncertainty of the computation (Freitag and Klein, 2006). The numerical error is relatively high, especially above roof level and in the wake of the building (Fig. 4a) as well as in the side shear layer (Fig. 4b) where it can reach up to 15% of the reference

velocity. Noticeably, the SGS modeling error is generally of opposite sign than the one of ε_n, with similar order of magnitude, which significantly decreases the total error on mean velocity. This error compensation is an explanation for the good agreement between measurements and the LES results presented in Section 3. The uncertainty $|\varepsilon_m|+|\varepsilon_n|$, however, is rather high on this computational grid.

5 LES INDEX OF QUALITY

Since a grid-independent solution cannot be achieved with LES and implicit filtering, a way to determine whether a given grid is suitable is to evaluate the amount of turbulent kinetic energy that it allows resolving. This is the purpose of the LES index of quality (*LES_IQ*) (Celik et al., 2005): to evaluate the proportion of total kinetic energy (k_{tot}) resolved by LES on a particular grid. k_{tot} can be decomposed into the resolved part (k_{res} which was symbolized by k in the validation part), the contribution of the SGS model (k_{SGS}), and the contribution of the numerical dissipation (k_{num}):

$$LES\_IQ = \frac{k}{k_{tot}} = \frac{k}{k + k_{SGS} + k_{num}} = 1 - \frac{k_{tot} - k}{k_{tot}} \tag{4}$$

As suggested by Pope (Pope, 2000), an LES computation can be judged to be well-resolved when 80% of the turbulent kinetic energy is resolved. In some cases, k is found to be higher on a coarser grid than on a finer one (Celik et al., 2005). This was observed in the present computations (above roof level and in regions of very low k) so the generalized formula has been used to keep *LES_IQ* below the ideal value of 1:

$$LES\_IQ = 1 - \frac{|k_{tot} - k|}{k_{tot}} \tag{5}$$

Based on Richardson extrapolation, the combined contribution of SGS model and numerical diffusion is assumed to scale with the grid size/filter length (Celik et al., 2005):

$$k_{tot} - k = a_k \Delta^n \tag{6}$$

where n=2 is the order of accuracy of the numerical scheme and a_k is a coefficient that can be determined by running the simulation on two grids with different resolution. Here, the same fine grid as the one used in Section 4 (with 30 cells per building side) is used.

Figure 5 shows the profiles of *LES_IQ* along the same lines that were used in the validation part, as well as the averaged values of *LES_IQ* on each line for $z/b<3$ (plane V0) and $-3<y/b<0$ (plane H10). On the nine measurement lines in the plane V0 for $z/b<3$, on average 76% of k_{tot} is resolved by the LES computation with 20 cells per building side (Fig. 5a). The flow regions where the least energy is resolved are the upstream part of the roof ($-0.5<x/b<0$) and the far-wake ($x/b\approx3.25$). On the measurement lines in H1 and H10, for $-3<y/b<0$, on average 80% and 84% of the total turbulent kinetic energy are resolved. The profiles of *LES_IQ* for several lines in the plane H10 are shown in Figure 5b. On average over all the measurement lines, the LES modeling used here allows resolving 80% of k_{tot}. Thus, if the threshold of 80% is used to define a well-resolved LES (Pope, 2000), our simulation can be classified in this category.

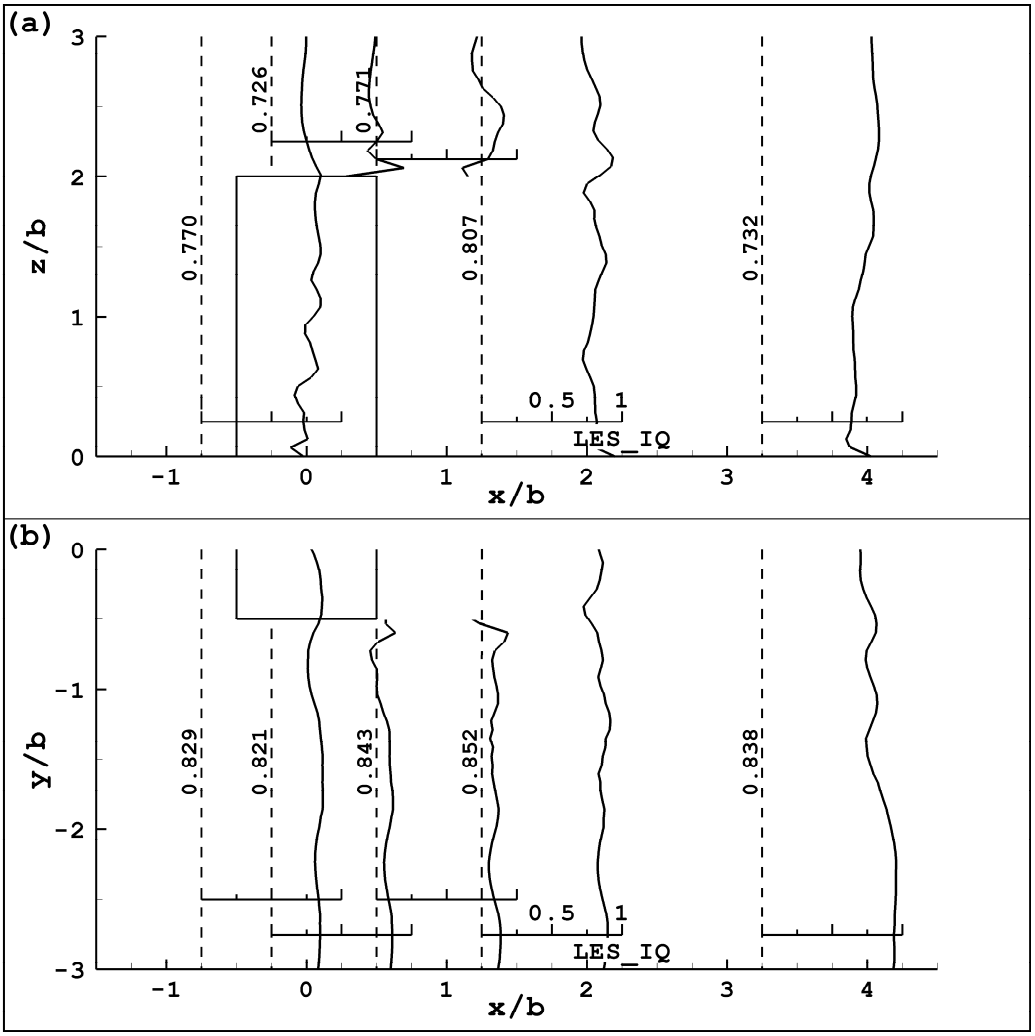

Figure 5. Profiles of *LES_IQ* in the planes (a) V0 and (b) H10. The values averaged on (a) $0<z/b<3$ and (b) $-3<y/b<0$ are indicated on each line.

6 DISCUSSION AND CONCLUSIONS

Large-Eddy Simulation of wind flow around a high-rise building with aspect ratio 1:1:2 has been performed. The standard Smagorinsky subgrid-scale model has been used, with C_s=0.1. A structured computational grid with 20 cells per cube side has been used.

Validation of the simulation has been performed in the first part of the study: the numerical results have been compared to the wind-tunnel measurements in terms of non-dimensional mean streamwise velocity and turbulent kinetic energy. Very good agreement between numerical and experimental values of U/U_h was found. Concerning k/U_h^2, a slight over-estimation of the experimental values by LES was observed in the wake of the building but the agreement remained fairly good in the other regions of the flowfield. These results demonstrate the good performance of the vortex method to generate inflow turbulence in the case of ABL flow.

The second part of the study presented some elements of solution verification. An estimation of the modeling and numerical error has been provided with the Systematic Grid and Model Variation technique. Both error contributions have been shown to be relatively high in magnitude

(which creates a high uncertainty on the results) but because they are of opposite sign, they compensate each other. Consequently, the resulting total error is low, which explains the good accuracy of the present LES modeling in mean velocity prediction.

The LES index of quality (*LES_IQ*) has been used to evaluate the proportion of total turbulent kinetic energy which is resolved by the present LES modeling. On average, in the zone around the building, 80% of the total turbulent kinetic energy is resolved which qualifies the present numerical modeling as "well-resolved LES". The regions of the flow field where the least energy is resolved are the far-wake and roof detachment region.

The procedure applied here to the case of an isolated building will be repeated on other configurations representative of urban geometry in future research.

Study on characteristics of ore storage-pile fugitive-dust based on wind tunnel experiments

Yonghua Xue [a]

[a]*Tianjin Research Institute for Water Transport Engineering of Ministry of Transport, 2618#, Xingang Road No.2, Tanggu, Binhai New Area, Tianjin, China*

ABSTRACT: Dust is the main pollution issue of the bulk port. This paper investigated characteristics of ore storage-pile fugitive-dust by means of wind tunnel experiments. Three typical ore, including Australia, Indian and Brazil ore, were selected, since these ore are common in ports. The proportion of model and corresponding boundary conditions was determined under wind tunnel parameters. Relationship between amount of dust and ore particle size distribution, startup wind velocity and mean wind velocity were investigated by regression analysis. Furthermore, difference on amount of dust between single-pile and multi-piles was also examined. The paper presents a mathematical model of ore dust and a new practical method for calculation of ore fugitive dust.

KEYWORDS: Ore dust, Wind tunnel, Windblown particles, Regression analysis

1 INTRODUCTION

Wind erosion is a major cause of particulate pollution in the yard of ports [1]. Recently, atmospheric dispersion of wind-blown dust particles from coal piles in the open storage yards has brought about severe air pollution and environmental problems due to fugitive dust emission. Therefore, it is of great importance to analyze the motion of wind-blown particles in order to develop effective means for controlling the particulate pollution.

Studies have been carried out to investigate the mechanisms of wind-blown particles. Bagnold (1941) investigated the wind-induced sand movement in a Libyan desert [2]. Finney (1934) used wind tunnel simulations to investigate snowdrift phenomena [3]. Zingg (1952) investigated the movement of sedimentary materials and particle saltation by means of a wind tunnel test [4].

Coal pile has been the research focus of windblown particles regularity, while few model established for ore pile. There is considerable throughout of ore in most ports, which continued to grow rapidly. Since coal and ore are very different in particle size distribution, density and moisture content, the research on ore windblown particle regularity and the associated coefficient is very urgent.

Wind-induced movement of small particles has been classified into three transport processes: saltation, suspension and surface creep [1]. Saltation is the primary wind erosion mechanism, referring to a bouncing motion of particles. In general, particles with diameters ranging from about 100 to 1000 μm are involved in the saltation process. These particles lift off the surface and travel in curved trajectories under the influence of wind and gravity. The particles engaged in saltation are sufficiently massive that air turbulence has little influence on their motion. The ballistice trajectory of particles undergoing this kind of motion is 5-10 times longer than the maximum height. Most mass transportation occurring near the ground surface is due to saltation [5].

The study carried out s series of wind tunnel experiments and the data collected were analyzed by mathematical methods. Particle size distribution, startup wind velocity, mean velocity and stacked pattern were discussed separately.

2 EXPERIMENTAL APPARATUS AND METHODS

Experiments were performed in a opened blow-out boundary wind tunnel with a test section size of 4.4m (W) × 2.5m (H) × 15.0m (L). Wind tunnel fan speed is controlled in direct mode and the maximum wind speed is 30 m/s. Wind tunnel turbulence intensity is less than 1% and axial static pressure gradient (d*p*/d*x*) is less than 0.01m. Spires and roughness elements were installed along the span wise direction to creat a neutrally buoyant atmospheric boundary layer.

2.1 *Similarity criteria*

Geometry similarity

Geometry similarity is the basic condition of flow similarity. For the wind tunnel test, model scale is the ratio of corresponding length of several similar objects. According to the yard of the actual situation and the wind tunnel size, the model scale of experiment is 1:100.

A schematic diagram of the wind tunnel test section is shown in figure 1(a) and size description of standard ore pile tested in experiments is shown in figure 1(b).

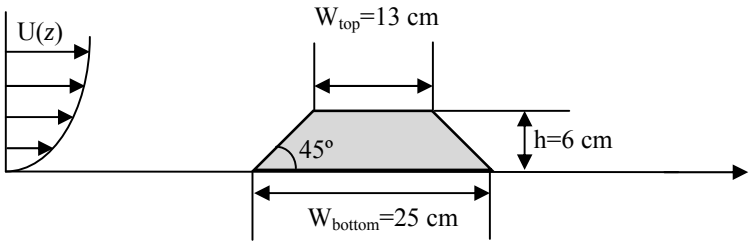

Figure 1(a). Schematic diagram of ore pile settings in the test section of wind tunnel

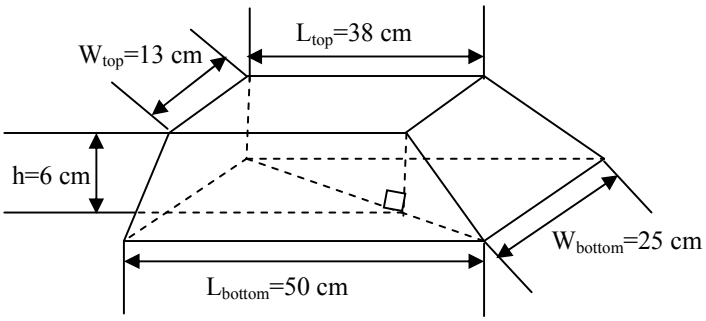

Figure 1(b). Schematic diagram of standard single ore pile size.

Long side of ore pile was set facing the wind stream in the wind tunnel test section in the single pile experiment. On the other hand, settings of ore piles in multi-pile experiments were similar to single pile, but in the 2×2 pattern.

One or four Ore-pile were placed in the middle of test section of the wind tunnel.

Atmospheric boundary layer similarity

Artificial boundary layer was simulated by spires and roughness elements. Expression of the power functions of wind velocity profile deduced by near the ground and neutral stratification and underlying surface conditions as follows:

$u/u_1=(z/z_1)^m$

where u is the mean wind velocity (m/s), u_1 is the wind velocity (m/s) of height z_1 and m is a function of surface roughness and temperature stratification, which values depending on different regions and atmosphere stability.

Renault similarity

In addition to similarity of geometry and atmospheric boundary layer, Renault similarity is also an important prerequisite for the wind tunnel experiments. This study experimental wind velocity range of 4.5~12 m/s meets the Renault similarity requirements.

2.2 *Experimental apparatus*

Ore size distributions were measured by sonic vibration of semi-automatic screening particle size analyzer. ESJ200-4A and YP 200K-1 electronic balance were employed to weight measurement.

2.3 *Materials*

Three typical ore, including Australia ore, Indian ore and Brazil ore, were collected in port of Xiamen. All of ore samples were flattened and natural dried for 20 days in laboratory. Australia ore nature moisture content was 3.8%, while Brazil and Indian ores were 3.5% and 2.9%. Data of size distribution were acquired by particle size analyzer referred above. The size distribution of three ore type is illustrated in Figure 2.

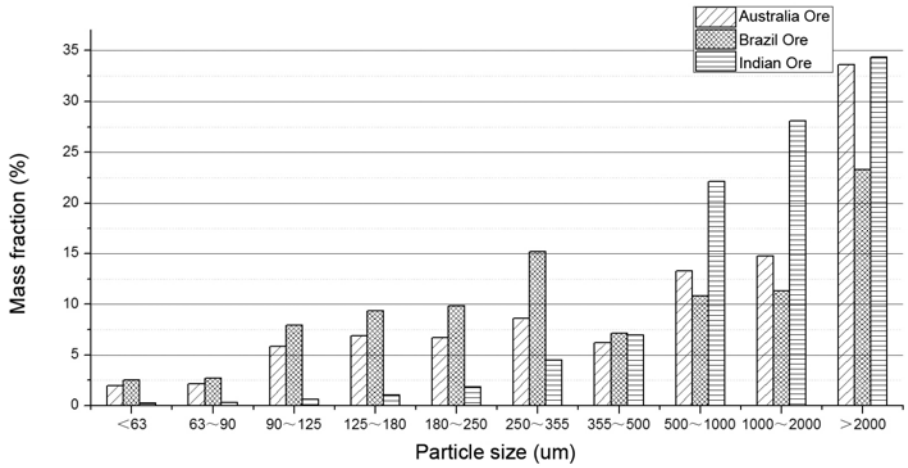

Figure 2. Size distributions of three typical ore

Smaller size was observed in Australia and Brazil ore, while Indian ore dust particle size is larger. This may lead to different dust characteristic, including startup wind velocity and amount of windblown dust. Furthermore, finer particles were observed in Brazil ore samples than Australia ore.

2.4 *Particle startup wind velocity experiments*

Method for the determination of the startup wind velocity as follows:
Ore powder with natural moisture was spread evenly on a sheet as much as possible to avoid surface wrinkles. Digital camera was mounted above the tested ore pile to monitor particle status. Start the wind tunnel, gradually increasing wind velocity and observe the movement of particles at the same time.

The wind velocity was recorded when obvious particles movement was observed. Repeat this test process 5 times to acquire the mean startup velocity for each type of ore. The results of startup velocity are list in table 1.

Table 1. Startup wind velocity for tested ore.

Ore type	Startup wind velocity (m/s)
Australia	4.0
Brazil	4.6
Indian	4.9

2.5 *Windblown experiments*

Each of ore pile put in the wind tunnel for experiment was placed on a thin enough sheet, which weighted together with the ore pile both before and after test. Each test lasted 15 minutes. The test wind velocity (U) includes 4.5, 6, 8, 10 and 12 m/s. weight of ore blown off could be calculated by weight difference.

3 RESULTS AND DISCUSSION

Figure2 shows the relationship between quantity of windblown dust and mean wind velocity, which obtained by regression analysis. With wind velocity increases, the quantity of windblown dust increases rapidly and then slowly.

According to data collected in the wind tunnel experiments of three ores, quantity of windblown dust was deduced as follows:

$Q=A\times(U-U_0)^3$

Where Q is the quantity of windblown dust, A is species coefficient, U is mean wind velocity during an experiment and U_0 is the startup wind velocity of corresponding species. The detailed values are shown in table 2 and the regression curves are illustrated in the figure 3.

Table 2. Coefficient of quantity of windblown dust on mean velocity

Coefficient	Australia Ore	Brazil Ore	Indian Ore
A	0.0206	0.0263	0.0284
U_0	4.0	4.6	4.9

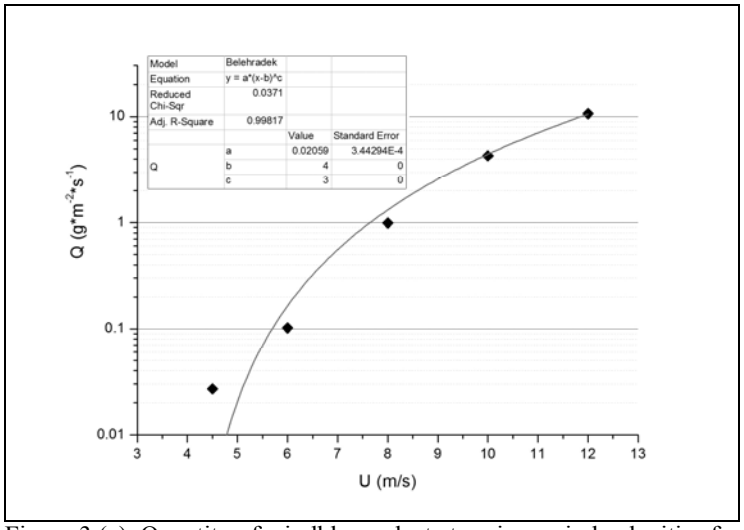

Figure 3 (a). Quantity of windblown dust at various wind velocities for Australia ore.

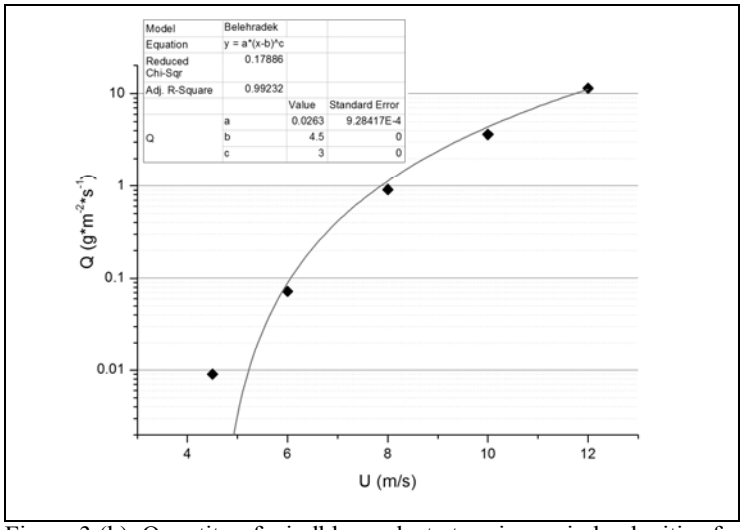

Figure 3 (b). Quantity of windblown dust at various wind velocities for Brazil ore.

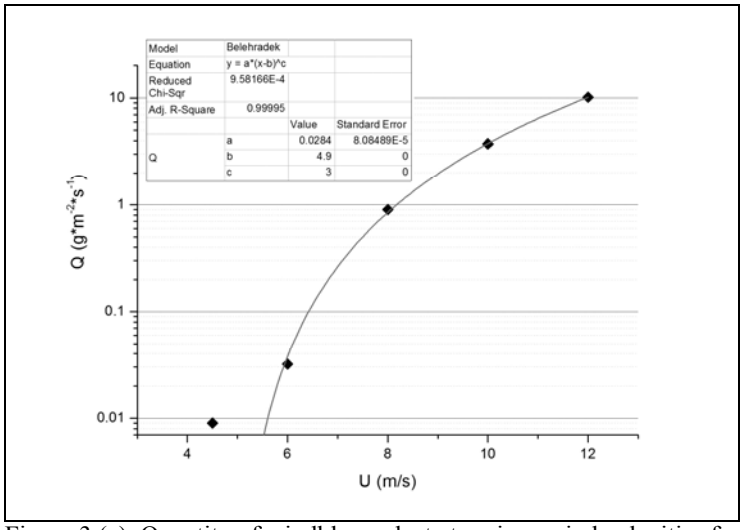

Figure 3 (c). Quantity of windblown dust at various wind velocities for Indian ore.

In the case of ore natural moisture content, similar regularity of windblown dust was observed between Australia and Brazil ore. However, less dust blown off was observed in Indian ore experiment at lower velocity (< 8 m/s). This phenomenon may relate to greater particles than the other two ores.

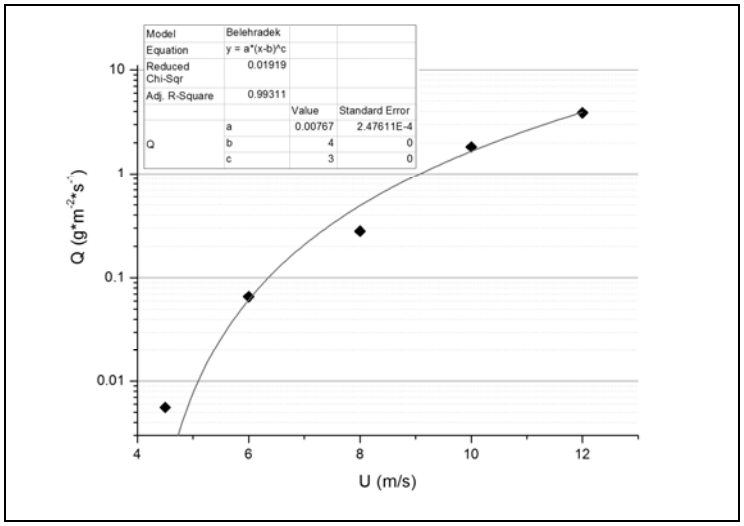

Figure 4. Quantity of windblown dust at various wind velocities for Australia ore.

Figure 4 shows the curve regressed of multi-pile experiment. In this case, the coefficient A value is 0.00767. Contrast to single pile result, only 30% dust was blown off under the same conditions. The result indicated that less dust be blown off in the multi-pile pattern, which may be due to mutual shelter effect of the piles and then reduced wind velocity.

4 CONCLUSION

In this paper, a preliminary study on windblown dust law of different ore was carried out by wind tunnel simulation. Quantity of windblown ore increases with increasing wind velocity, especially when the wind speed is greater than 8 m/s. Expressions were regressed by mathematical

method, which could be used to estimate windblown dust. Because of shelter effect of piles between each other, the quantity of windblown dust of multi-pile is far less than single pile.

ABSTRACT: A method for dynamic coupling simulation of flow and vehicle motion was developed based on large eddy simulation technique with moving boundary methods. The method was applied to investigate the aerodynamic stability of vehicle under a transient driving situation. A coefficient to quantify the aerodynamic damping was defined. For the sedan-type, simple body models investigated, the underbody provides the highest proportion of aerodynamic damping. However, it is the trunk deck contribution that causes the different damping magnitudes in the models with distinct A- and C-pillar geometrical configurations.

KEYWORDS: Aerodynamics, transient, LES, vehicle, stability, damping, pitching.

1 INTRODUCTION

In principle, automotive aerodynamics comprises the drag, lift, and side force coefficients, in conjunction with the rolling, yawing, and pitching moment coefficients. In real-world situation, the aerodynamic forces and moments which act on a vehicle are of transient nature. However, development of vehicle aerodynamics to date has mainly been focused on the steady-state components, particularly the drag coefficient, C_d. This coefficient can only be used to evaluate performances related to fuel efficiency and top speed, and provides no indication in regard to the vehicle's performance in terms of stability.

To consider the stability factors under the effect of transient aerodynamics, several assessment methods have been proposed in the literature. These methods rely on either drive test (e.g. Howell and Le Good, 1999; Okada et al, 2009) or wind tunnel measurement (e.g. Aschwanden et al, 2006). The former can only be performed after a development mule is produced, while the latter requires a complex test rig to manipulate the vehicle motion for a dynamic assessment. In addition, due to limited numbers of probe that can be attached to the test vehicle without altering the surrounding flow, drive test and wind tunnel measurement provide very limited flow information about the test. The lack of flow information could impede detailed flow analysis which is needed for identifying the underlying mechanism.

To overcome these limitations, thus the main objective of the present study is to develop a numerical method for the assessment of vehicle aerodynamic stability performance under a transient driving situation. The method allows manipulation of vehicle body motion during flow simulation, and quantification of vehicle stability performance on the basis of the aerodynamic damping generated by the vehicle, which is depending on the vehicle's body shape configuration.

2 SIMPLE BODY MODELS

Okada et al (2009) reports that the main differences between the upper body geometry of vehicles with different pitching stability characteristics lie in the A- and C-pillar shapes; the lower stability vehicle has a more angular A-pillar and rounder C-pillar configurations. Hence, to emphasis these differences, the present study creates two simple body models with opposite A- and

C-pillar geometrical configurations. In particular, the model that represents the lower-stability sedan adopts an angular A-pillar and rounded C-pillar configurations. Whilst, the model represents the higher-stability sedan adopts the opposite configurations. For convenience of discussion, the model represents the sedan of lower stability is designated "model A", and the one represents the higher stability sedan is "model B", respectively, hereafter (see Figure 1(a)).
In general, both models are the 1:20-scale, simple bluff-bodies with same height h, width w, and length l measurements of 65, 80, and 210 mm, respectively. The models have A- and C-pillars with the same slant angles of 30° and 25°, respectively, which are based on the configurations of real vehicle.

3 NUMERICAL METHODS

3.1 *Governing equations*

The LES solves the following spatially filtered continuity and Navier-Stokes equations:

$$\frac{\partial \bar{u}_i}{\partial x_i} = 0 \tag{1}$$

$$\frac{\partial \bar{u}_i}{\partial t} + \frac{\partial}{\partial x_j}\bar{u}_i\bar{u}_j = -\frac{\partial \bar{P}}{\partial x_i} + 2\frac{\partial}{\partial x_j}\left(\nu + \nu_{\mathrm{SGS}}\right)\bar{S}_{ij} \tag{2}$$

$$\bar{P} = p/\rho + \left(\overline{u_i u_j} - \bar{u}_i\bar{u}_j\right)/3 \tag{3}$$

where u_i, p, ρ, ν and S_{ij} are the i-th velocity component, pressure, density, kinematic viscosity and strain rate tensor. The over-bar denotes a spatially filtered quantity. Meanwhile, the standard Smagorinsky model is adopted to model the subgrid-scale (SGS) eddy viscosity ν_{SGS} of Eq. (2).
The simulation software is an in-house CFD code, namely, the "FrontFlow/red-Aero". Originally, the researchers develop the code for the "Frontier Simulation Software for Industrial Science" project. Then, Tsubokura et al. (2009a) optimizes it for vehicle-aerodynamics simulation. Tsubokura et al. (2009b) has validated the code on the basis that the results obtained with the code compared favorably with the wind-tunnel measurements on the pressure distribution along

the centerline of ASMO model and the flow field around a full-scale production car (including a complicated engine room and under-body geometry).

3.2 *Discretization*

The governing equations were discretized by using the vertex-centered unstructured finite-volume method. We adopted the second-order central differencing scheme for spatial derivatives, and exploited the blending of 5% first-order upwind scheme for the convection term for numerical stability reason. Meanwhile, pressure-velocity coupling was preserved by the SMAC (simplified marker and cell) algorithm.
For time advancement, the LES adopts the Euler implicit method. This is because an implicit scheme can accommodate larger time difference than an explicit one without causing numerical instability, especially in the case of a vehicle simulation in which the velocity and mesh size vary strongly. With larger permissible time difference (Δt = 1×10-5 s), the scheme needs lesser time steps (hence, shorter simulation time) to obtain a reliable time- and phase-averaging statistic. Such feature is important in dynamic LES cases, because they normally need over hundred thousand of time steps to obtain an adequate phase-averaging statistic. In the present study, the computations took about 50,000 simulation steps (over five pitching cycle) to reach a stable periodic condition and the subsequent 150,000 steps to covers 15 cycles of pitching oscillation for obtaining an adequate phase-averaging statistic.

3.3 *Computational domain and boundary conditions*

The computational domain resembles a rectangular wind-tunnel test section. Its cross section covers 1.52*l* on both sides of the model and height of 2.23*l*. This set-up produces a small blockage ratio of 1.53%, which is well within the typically accepted range of 5% in automotive aerodynamic testing (Hucho and Sovran, 1993). The model was situated near the domain floor at a ground clearance of 0.071*l*. The inlet boundary was located 3.14*l* upstream, while the outlet boundary was 6.86l downstream.
At the inlet boundary, the air flow approaches at a constant velocity of 16.9 m/s, corresponding to Re of 2.3×10^5 (based on vehicle length *l*). Meanwhile, a zero-gradient condition is imposed at the outlet boundary. The ceiling and side boundaries of the domain were treated with free-slip wall-boundary condition. The ground surface is divided into two zones. The upstream zone (which covers 3*l* from the inlet boundary) is defined as a free-slip wall condition to avoid boundary-layer formation. This setting simulates the wind-tunnel experimental condition, thus ensure the consistency of flow condition between the LES and wind tunnel test so that direct comparison between their results is allowed during validation. The remaining ground and vehicle surface are treated with the logarithmic-law ($y^+ > 11.63$) or linear law functions ($y^+ < 11.63$) depending on the obtained y^+ values. We have found that the very fine spatial resolution adopted produces the $y^+ < 4$ around the vehicle surface, thus the estimation is by the linear law function, which corresponds to the no-slip wall condition.

错误！未找到引用源。FORMULATION OF AERODYNAMIC DAMPING COEFFICIENT

4.1 *Periodic-pitching-oscillation condition*

By employing the ALE technique, we imposed a periodic pitching oscillation on the models during flow simulation to probe their dynamic response. The axis of rotation is located at the lower part of the front section of model at 0.821*l* from the rear end, corresponding to the front-wheel axle of a real vehicle. This setting is in accordance with the road-test results of Okada et al.

(2009), in which the notchbacks experienced more significant ride-height fluctuation at the back than the front. Hence, the models were rotated in a manner that simulates the rear-ride height fluctuation of the real vehicles. The pitch angle θ of the models is defined as:

$$\theta = \theta_0 + \theta_1 \sin\varphi(t) \quad , \quad \varphi(t) = 2\pi f_p t \tag{4}$$

By setting θ_0 and θ_1 equal to 2°, the vehicle models were forced to oscillate at amplitude of 2°. Although this value is larger than the range a vehicle would encounter under normal driving conditions, it has the advantage of producing more distinct aerodynamic damping effect in vehicles of different stability characteristics. Thus make it easier to interpret the underlying physical mechanism. Frequency f_p was 10 Hz, which corresponds to a Strouhal number (St) of 0.13, normalized by l and U_{inlet}. This value was chosen in consideration of the St of 0.15 obtained by road test by Okada et al. (2009). Figure 2 shows the sign convention for aerodynamic pitching moment M and angle θ.

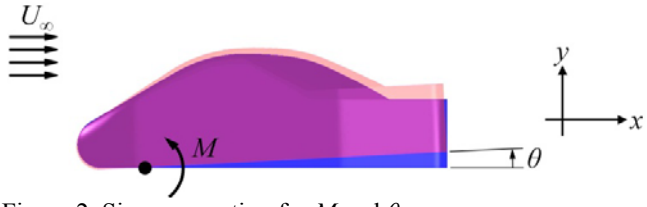

Figure 2. Sign convention for M and θ.

4.2 *Periodic-pitching-oscillation condition*

The estimated phase-averaged pitching moment $<M>_p$ can be decomposed into steady and unsteady components. The equation for phase-averaged pitching moment $<M>_p$ in terms of pitch angle θ is given as the following expansion:

$$< M >_p = C_0 + C_1\theta + C_2\dot{\theta} + C_3\ddot{\theta} \tag{5}$$

where, respectively, the single dot and double dots in the third and fourth terms indicate the first and second derivatives with respect to time t. Both C_0 and C_1 are static components; the former denotes the pitching moment M at zero pitch, while the latter describes the quasi-static behavior by taking into account the pitch-angle variation in a static manner. C_2 is associated with aerodynamic damping, and C_3 is an added moment of inertia that is proportional to angular acceleration.

Substituting Eq. (4) into (5) and rearranging gives:

$$< M >_p = \left(C_0 + C_1\theta_0\right) + \left[C_1 - \left(2\pi f_p\right)^2 C_3\right]\theta_1 \sin\varphi(t) + 2\pi f_p \theta_1 C_2 \cos\varphi(t) \tag{6}$$

The above equation can then be rewritten by using new parameters, namely, M_{stat}, M_{dis} and M_{ang} as

$$< M > p = M_{\text{stat}} + M_{\sin}\sin\phi(t) + M_{\cos}\cos\phi(t) \tag{7}$$

where, M_{stat} is a constant, which set the baseline for the $<M>_p$. M_{dis} is the amplitude of the term which in-phase with the imposed pitching displacement, and M_{ang} is the amplitude of the term in-phase with the angular velocity.

4.3 *Definition of aerodynamic damping coefficient*

During one pitching cycle, time t varies from 0 to $2\pi/\omega$. Hence, the work done by the aerodynamic pitching moment M on the vehicle model during one pitching cycle is:

$$W = \frac{1}{\omega}\int_0^{2\pi} M \ \frac{\mathrm{d}\theta}{\mathrm{d}t}\mathrm{d}(\omega t) \tag{8}$$

Substituting Eq. (7) and (10) into eq. (11), the work done during one pitching cycle becomes

$$\begin{aligned} W = {} & M_{\mathrm{stat}}\theta_1 \int_0^{2\pi} \cos\omega t \ \mathrm{d}(\omega t) \\ & + M_{\mathrm{dis}}\theta_1 \int_0^{2\pi} \sin\omega t \cos\omega t \ \mathrm{d}(\omega t) \\ & + M_{\mathrm{ang}}\theta_1 \int_0^{2\pi} \cos\omega t \cos\omega t \ \mathrm{d}(\omega t) \end{aligned} \tag{9}$$

The first and second integrals yield the value zero, and that the third one is π. Hence, the net work per pitching cycle is:

$$W = M_{ang}\theta_1\pi \tag{10}$$

The result of the integration reveals that the net work done on the vehicle by aerodynamic pitching moment M over a pitching cycle is depends on the component in-phase with the angular velocity M_{ang}. In Eq. (10), θ_1 and π are given. Hence, the parameter M_{ang} reflects the dynamic response of the vehicle. This parameter can be presented in a non-dimensional form. If normalized in a similar manner to the pitching-moment coefficient, it becomes:

$$C_{\mathrm{AD}} = \frac{M_{\mathrm{ang}}}{\frac{1}{2}\rho U_\infty^2 A l_w} \tag{11}$$

where ρ, U □ , A, and l_w are fluid density, mainstream velocity, vehicle frontal area, and wheelbase. It depends on the sign of C_{AD}, a negative value implies a tendency for aerodynamics to damp the pitching oscillation, whereas a positive value enhances the vehicle motion (i.e. negative damping). The coefficient thus enables quantitative evaluation of vehicle stability; therefore, it is termed "aerodynamic-damping coefficient."

5 RESULTS AND DISCUSSIONS

5.1 *Aerodynamic damping coefficient of simple body models*

Figure 3 shows the $<M>_p$ as a function of phase angle φ for models A and B. The coefficients in Eq. (7) are obtained by fitting the equation to the $<M>_p$ data set by nonlinear least squares regression. Solid lines in Figure 3 are the fitted functions for the two models. Table 1 summarizes the corresponding C_{AD} for comparison. As shown in the table, the aerodynamic damping coefficient C_{AD} for the two models are negative, implying a tendency to resist the pitching motion. Between them, however, model B has a higher aerodynamic-damping coefficient C_{AD}, by about 37%. This finding is consistent with the fact that model B was created on the basis of the pillar-shape configurations of real vehicle with higher stability.

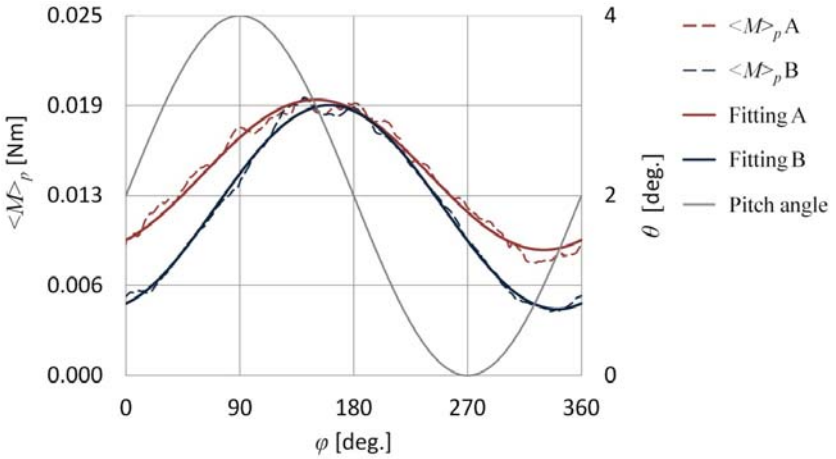

Figure 3. Phase-averaged M and fitted functions.

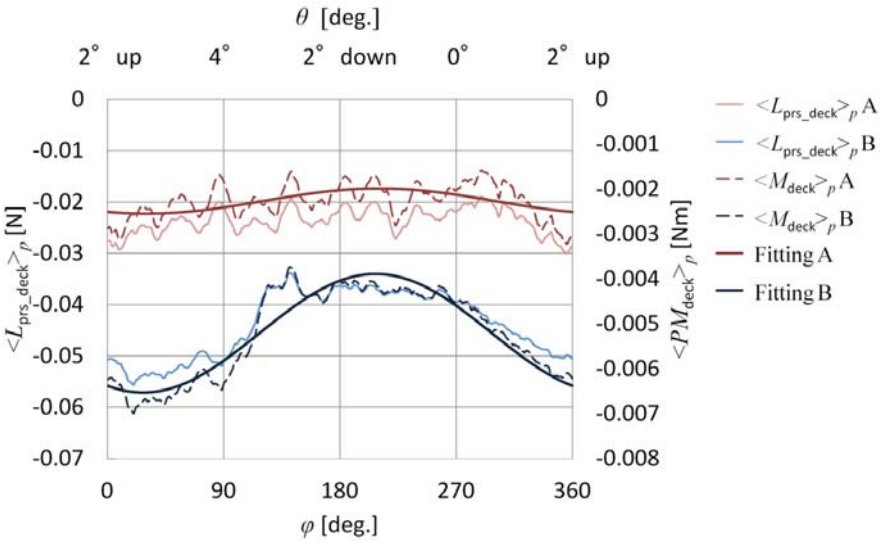

Figure 4. Phase-averaged M and fitted functions.

In general, as shown in Table 1, the main contribution in model A, which was created based on the characteristic aerodynamic features of lower stability sedan, is from the underbody and roof. Whilst, the main contribution in model B is from the underbody, upper rear section (i.e. trunk deck and rear shield) and roof. The reason for the models to have a different damping magnitude is because of the relatively high damping contribution from the upper rear section of model B,

particularly the trunk deck. Figure 4 shows that the curves of trunk deck fitted function of the two models have very similar phase shift. However, the relatively low trunk deck contribution in model A is caused by the smaller fluctuation amplitude.

5.2 *Aerodynamic damping mechanism*

5.2.1 *Main aerodynamic damping contribution*

The underbody has the highest damping contribution due to two reasons: First, the dynamic effect, i.e. vehicle motion, has caused the phase of phase-averaged underbody pitching moment $<M_{underbody}>_p$ curve to shift (by about 128° and 134° in model A and model B, respectively) at the pitching oscillation frequency (see Figure 5), thus produces a negative M_{ang}; Second, its relatively large surface area and moment arm produce a significantly larger M_{ang} magnitude then other body parts.

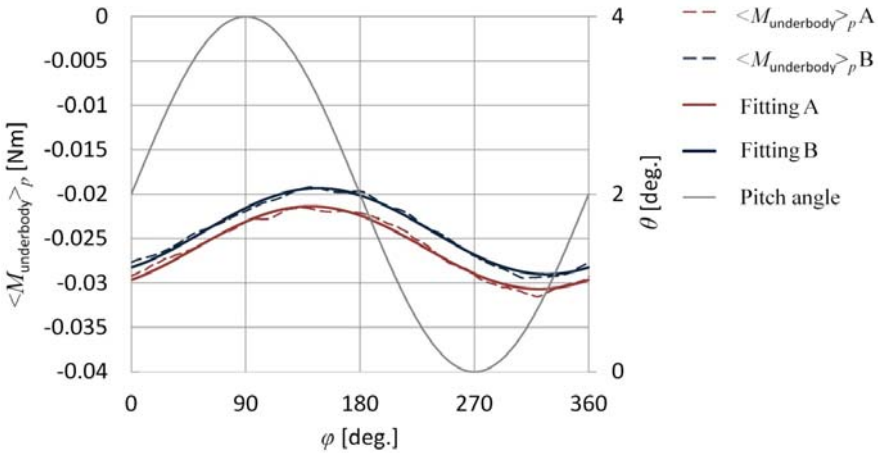

Figure 5. $<M_{underbody}>_p$ and fitted functions of underbody: (a) Model A; (b) Model B.

The behavior of $<M_{underbody}>_p$ curve can be explained by first considering the quasi-steady flow conditions with the model fixed at a range of pitch angle θ. As the underfloor clearance downstream of the pitch axis increases with θ, the flow decelerates and causes the static pressure to rise. The increase of static pressure with increasing θ causes a corresponding increase in underbody pitching moment. Hence, in the quasi-steady conditions, the maximum and minimum peaks would lie at 4° and 0° pitch, respectively. However, due to the pitching motion of models, there is an additional dynamic effect which causes the curve to overshoot. Figure 6 shows the properties of airflow in the underfloor clearance of model B at four pitching stages (similar trend is obtained in model A, thus only the results of model B is used for the discussion). As the underbody moves downwards from 4° pitch, the decreasing underfloor clearance is accompanies by flow acceleration, which may be evident by the relatively high streamwise velocity component during the 2° tail-down pitching cycle. However, the static pressure of underbody increases despite the acceleration of streamwise velocity component. In addition, for the same underfloor clearance at 2° tail-up and tail-down pitching cycles, the former exhibits a relatively strong cross flow velocity. Hence, it may be deduced that the increment of static pressure during a tail-down pitching cycle is caused by the conversion of cross flow kinetic energy into the dynamic pressure at the underbody. Meanwhile, the further decrement in static pressure during the tail-up pitching cycle is associated with "suction" effect (i.e. surrounding fluid is being "pull" away) the leeward side of a bluff body immersed in a flowing fluid would normally experienced, as the underbody surface is now at the leeward side.

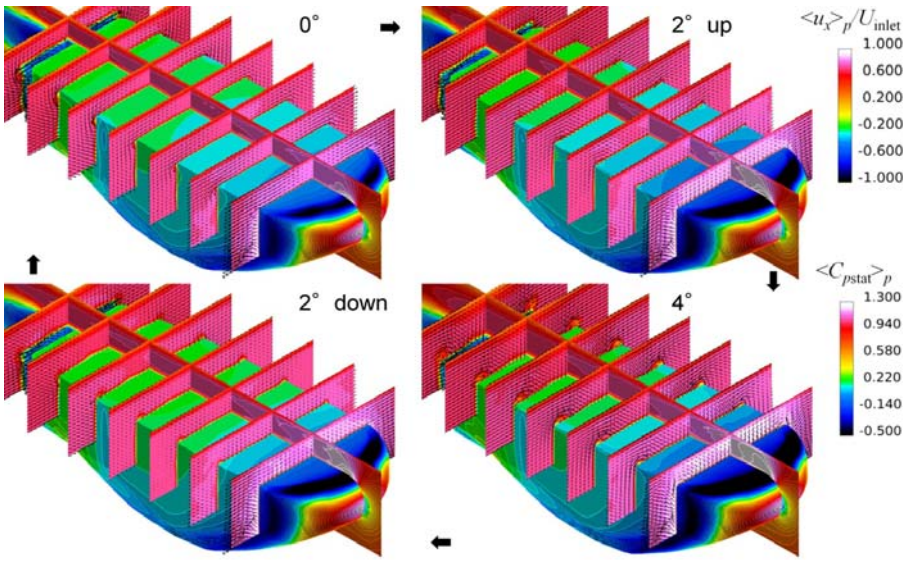

Figure 6. Phase-averaged velocity distribution at underfloor clearance and static pressure of underbody; model B.

5.2.2 *Comparison between two aerodynamic configurations*

Figure 4 shows that the phase-averaged trunk deck pressure lift $\langle L_{prs\_deck} \rangle_p$ and phase-averaged trunk deck pitching moement $\langle M_{deck} \rangle_p$ curves of the two models are matching well, implies that the $\langle M_{deck} \rangle_p$ is mainly caused by the trunk deck surface static pressure. Ideally, the pressure force should be in-phased with the angular velocity of pitching to produce a maximum damping. That is, the $\langle L_{prs\_deck} \rangle_p$ peaks at φ = 180°, and reaches the minimum at φ = 0 or 360°. The $\langle L_{prs\_deck} \rangle_p$ curves for the two models nearly meet this criterion, with only a slight phase shift. Hence, the C_{AD} obtained from the two models are having the same sign. However, the relatively large fluctuation range in model B has resulted in a higher damping magnitude.

Next, we discuss the reasons that cause the trends observed in Figure 4. As shown, model B has a relatively low attainable $\langle L_{prs\_deck} \rangle_p$, which is caused by its concentrated C-pillar vortices (marked "B" in Figure 7). The concentrated vortices induced a narrow, low-static-pressure region at the sides of its trunk deck (marked "A" in Figure 7). In contrast, the C-pillar vortices in model A were weaker and less concentrated (marked "D" in Figure 7). As a result, the vortices induced a wider low static pressure region (marked "C" in Figure 7), which results in the higher attainable $\langle L_{prs\_deck} \rangle_p$ in model A.

At φ = 0 or 360°, $\langle L_{prs\_deck} \rangle_p$ in the two models were at the lower range, which was due to the increase of static pressure at the sides of trunk deck (i.e. the low pressure region narrows down). This tendency is caused by the decrease in the slant angle of C-pillar during tail-up pitching cycle. Hence, the models generate the weaker C-pillar vortices which diminish the drop in static pressure.

At φ = 90°, the C-pillar vortices in model A were elevated by the trunk deck surface, thus its distance from A-pillar vortices (marked "E" in Figure 7) decreases (see Figure 7). These two pillar vortices, which rotate in directions opposite one another, interact with each other and generate a strong cross flow which passing through them and rolled upwards at the centerline, forming an upwash inducing, circulatory structure (marked "F" in Figure 7). Due to the strong cross flow and the upwash inducing circulatory structure, the static pressure in the central region drops and causes the $\langle L_{prs\_deck} \rangle_p$ in model A to rise.

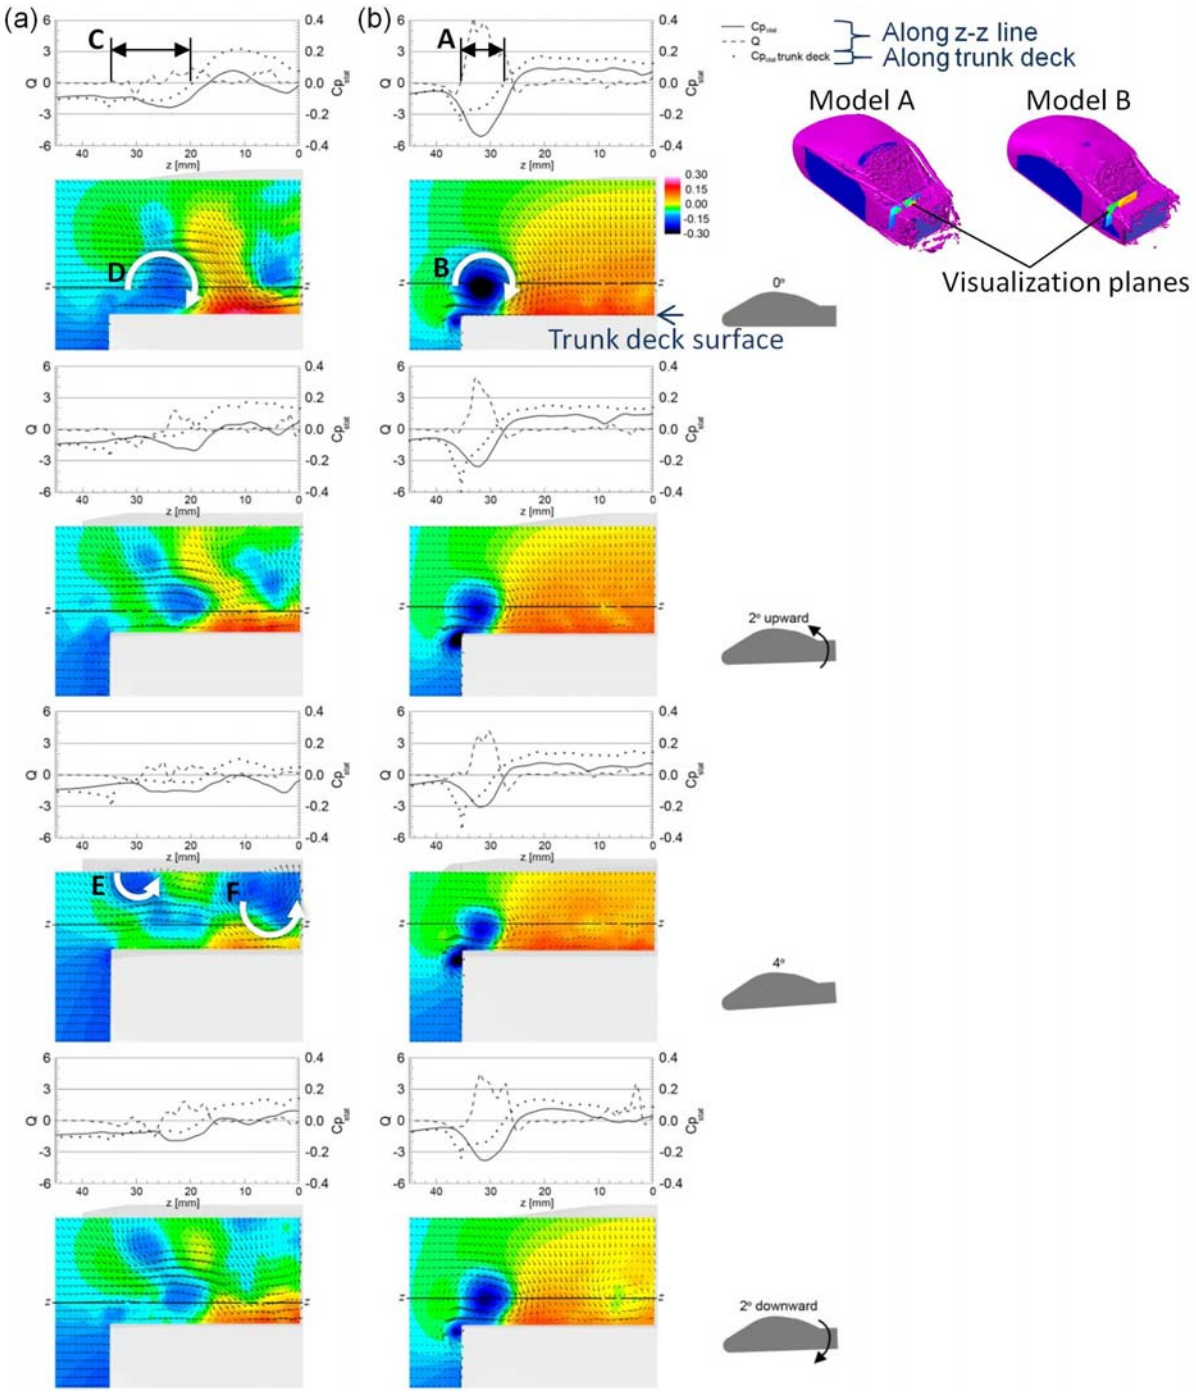

Figure 7. Distribution of cross flow velocity and static pressure above trunk deck at four different pitching stages: (a) Model A; Model B.

At φ = 180 and 270°, $<L_{prs\_deck}>_p$ in the two models are at the higher range. The higher $<L_{prs\_deck}>_p$ in these instances was mainly caused by the decrease of static pressure at the sides of trunk deck. The slant angle of C-pillar increases with decreasing pitch angle. Hence, during the tail-down pitching cycle, the models generate the stronger C-pillar vortices which result in larger pressure drop on the trunk deck surface.

Although the models share the same tendency in how the C-pillar vortices affect the surface pressure at the side of trunk deck, but the distinct flow topology in the central region has caused the $<L_{prs\_deck}>_p$ curves to behave differently at $\varphi = 180°$. In model A, despite the larger pressure drop at the side, the $<L_{prs\_deck}>_p$ failed to reach a much higher value because of the increased of static pressure in the central region. This increment is caused by the attenuation of cross flow velocity and circulatory structure with decreasing pitch angle. As has been discussed earlier, with decreasing pitch angle, the gap between the A- and C-pillar vortices becomes larger, and thus their interaction which promotes the cross flow, becomes weaker. In model B, however, the drop in static pressure in the central region is due to the formation of the circulatory structure, and the dynamic effect (i.e. low static pressure at the leeward side) has caused the $<L_{prs\_deck}>_p$ to further increase. This produces the relatively large M_{ang}, and hence, a higher damping coefficient.

6 CONCLUSIONS

The present study has shown the potential use of LES as a tool to assess the aerodynamic stability of vehicle which takes into account the effect of transient aerodynamics. The proposed aerodynamic damping coefficient enables direct comparison of aerodynamic stability performance between two vehicle. For the simple body models investigated, the underbody provides the highest proportion of aerodynamic damping. However, it is the trunk deck contribution that causes the different damping magnitudes in the models with distinct A- and C-pillar geometrical configurations.

Large Eddy Simulation of the flow around a train passing a stationary freight wagon

Yebo Liu [a], Hassan Hemida [b], Zhiming Liu [a]

[b] *School of Civil Engineering, University of Birmingham, Birmingham , UK*

ABSTRACT: The aerodynamic performance of a stationary double-stacked freight wagon passed by a high speed passenger train was investigated using Large-Eddy Simulation (LES). The passenger train was a 1/20 scaled model of the ICE2-like shape high speed train, consisted of nose, two coaches, inter-carriage gap and tail. The simulation was performed at Reynolds number of 2×10^5 based on the speed and height of the passenger train. To isolate the effect of the mesh resolution on the LES results, three different LES computations were performed using three different meshes: course, medium and fine, consisted of 3.2 million, 6.9 million, and 9.0 million nodes, respectively. The aerodynamic loads on the freight containers and passenger train were obtained during the passing process. High side force coefficient was observed on the containers when the passenger train approaches the freight wagon followed with a sudden reduction. The near wake flow of the passenger train generated suction side forces, which is followed by a significant increase in side force in the far wake flow. Similar behavior was noticed in the lift and drag coefficients. The effect of track spacing was investigated by performing simulations at two different track spacings: 3.5m and 4m. The results showed that reduction in track spacing generally increased the aerodynamic forces on both the freight wagon and passenger train.

KEYWORDS: LES, Train aerodynamics, Sliding mesh, Aerodynamic coefficients, Train pressure pulses, Train passing

1 INTRODUCTION

Freight trains with double-stacked containers are used worldwide (such as North America, China and Australia) for their high loading capacity compared to single-stacked freight trains. However, high loading capacity also means a relatively large volume and a correspondingly large exposed surface area and hence side forces when exposed to cross winds [1]. Apart from larger drag force than that of passenger trains, the increase side force in the cross wind induces more critical aerodynamic problems, such as overturning or derailment, especially when the containers are empty. A recent example is the derailment of freight train 3DA2K near Tarcoola, SA, in 2006 [2]. Although the train was travelling at a relatively low speed of 67km/h, two double stacked wagons derailed, primarily because of a strong wind gust. As a consequence, 15 of the 31 wagons subsequently detached. Another example of these accidents was in 2008, when two empty single-stacked containers were blown off the freight train 4E90 by aerodynamic force [3].

To assess the aerodynamic performance of freight trains, various researches have been carried out. Li and Tian [4] and Watkins et al [5] have found out that there is a significant effect of the inter-car gaps in the aerodynamic performance of freight trains. Smaller inter-car gaps or reducing the inter-car gaps by placing smaller containers in between can reduce the drag force effectively. Xiong and Liang [6] have conducted an experiment on a full scale double-stacked con-

tainer trains passing through the tunnel and found that the drag force of the freight train significantly increases at the entrance of the tunnel and continuously drops thereafter. They have also concluded that the drag force is proportional to the square of the train speed. Another issue is the aerodynamic response of the freight train when subjected to crosswinds. Hemida and Baker [7] investigated the flow around a freight wagon subjected to a side wind of 90° yaw angle using Large Eddy Simulation (LES) and they showed that the flow topology in the wake of the wagon is much more complex than that around passenger trains. Alam and Watkins [8] came to the conclusion that crosswinds have significant effect on the lateral stability of double-stacked wagons. Baker et al [9] have integrated the aerodynamic forces into train modeling to study the critical wind speed for both passenger and freight trains in regard to derailment. However, strong winds are not the only cause of side wind problems, as the passing of high speed trains produces strong winds and pressure pulses generated in the slipstream. These winds and pressure can add additional challenge to the stability of double stacked containers.

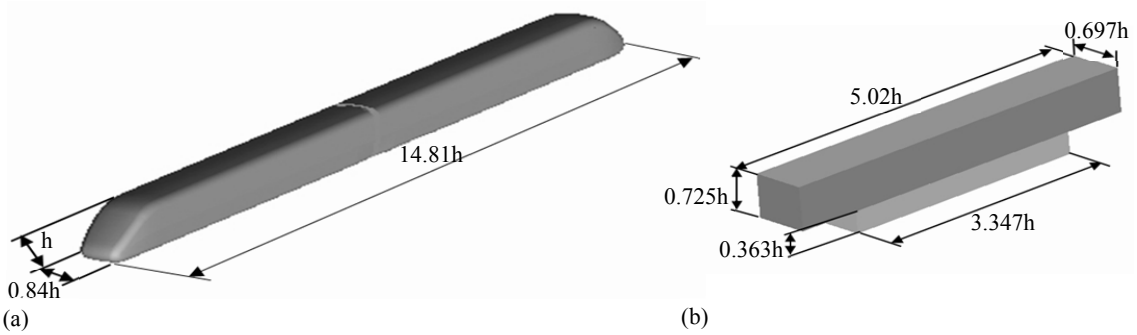
Mancini and Malfatti [12] conducted a full scale study of a high-speed ETR 500 train, passing another ETR 500 train and a freight train in open air. The results showed that the magnitude of pressure pulses are dramatically reduced on the roof and the side not facing the passing train compared to the active side. Johnson and Dalley [13] conducted a physical experiment using a 1/25 scale model on a moving model rig. Their results were consistent with the ones gained from the full scale experiments of Mancini and Malfatti [12]. By performing over 60 firings, it was confirmed that the pressures varied linearly with the square of the train speed and that, increasing track spacing led to a decrease in pressures regardless of the nose shape. Li and Liu [14] gained the formulae for calculating the amplitude of the air pressure pulse according to the track spacing and train velocity, by simulating about 100 operating cases for CRH3 high speed train, including 6 track spacings (from 4.26 m to 5.26 m) and 38 speeds of train passage (from zero to 500 km/h). Other formulae are in the literature [15-16]. These formulae differed from one author to another, but they all came to the same conclusion, that a higher speed and a closer track spacing cause higher pressures. The risk of derailment of double-stacked container trains passed by high speed trains has been assessed by combining CFD simulation with a vehicle dynamic model by Holmes and Schroeder [17] but they haven't considered track spacing effect. Full scale measurements of a high speed train passing a stationary double-stacked container wagon were also carried out by MacNeill et al [18], in which pressures at different positions of the wagon were measured at different speeds. They have showed that the surface pressure increases with increasing the train speed. There is however limited information on the effect of track spacing on the aerodynamics of freight trains passed by high speed passenger trains and thus these is a necessity for research into this area to improve operational safety of the rail network as a whole.

The work detailed in this paper, thus, studies the aerodynamic performance of a stationary double-stacked freight wagon passed by a high speed passenger train using LES. Two track spacings of 3.5m and 4m were considered. The accuracy of LES was investigated through performing three different computations using three different meshes and by comparing the results with available experimental work. The computational package CFX5 is utilized to simulate the passing train using the sliding mesh technique.

2 TRAIN MODELS

The models used in this work are a 1/20 scale of a high speed ICE2-shape passenger train and a double-stacked freight wagon. The high speed passenger train is shown in Figure 2(a). The model is simplified by omitting the bogies and protruding equipment (such as the pantograph), while the inter-carriage gap, nose and tail are kept. The ICE2-like shape train consists of a lead-

ing car and an end car with height of h = 0.179m, width of 0.84h and total combined length of 14.81h. The leading car is separated geometrically as two parts, the head and car 1. Accordingly, the end car is also separated as two parts, the tail and car 2. The clearance between the train and the floor is 0.24h. The double-stacked wagon, shown in Figure 2(b), has top and bottom containers, both with the same width of 0.70h. The length and height of the top container are 5.0h and 0.73h, respectively, while the corresponding dimensions for the bottom container are 3.35h and 0.36h, respectively. The clearance between the wagon and the floor is 0.16h.



(a) (b)

Figure 2. (a) ICE2-like shape train model. (b)Double stacked wagon mode

3 COMPUTATIONAL DOMAIN AND BOUNDARY CONDITIONS

The computational configuration consists of two domains: stationary and rotating. The coordinate system is shown in Figure 3, where X points to stream-wise direction, Y points to span-wise direction and Z points to the upward direction. The length and width of the domain is 83.678h and 6.35h respectively, with the rotating domain having a downstream length of 22h from the tail of the high speed train. The distance between the freight wagon and the passenger train in the stream-wise direction is 23.44h while two different track spacings are modeled (3.5m and 4m) in the span-wise direction. There is an extension of approximately 3h for the stationary domain in the span-wise direction while it is 5.26h for the rotating domain (see Figure 3(b)). To simulate a train passing event, the rotating domain follows the path of a curve with radius of 5587howards the stationary domain (see Figure 4). A radius of 5587h is chosen here so that the passing event approximates a straight line. The angular velocity is defined equivalently to the moving train speed of 20m/s, which corresponds to a Re of $2x10^5$ based on the height and speed of the moving train.

No-slip boundary conditions are applied on the surfaces of both the train and the wagon, as well as on the floor of the stationary domain. Symmetrical boundary conditions are employed on the roof and sides (normal to the span-wise direction) of the computational domain while translational periodicity is used at inlets and outlets. A counter rotating wall boundary condition is applied on the floor of the rotating domain to suppress the early build-up of the upstream boundary layer. The transient general grid interface (GGI) is employed between the two domains for exchanging information at each time step. Both stationary and moving domains are initialized by zero velocity at the start of the simulation. Considering the length of the computational domain and the train speed, a time step of 0.0001s is applied, which allows the model to capture more details of the air flow for the simulation time of 0.5s. This covers the complete procedure of high speed train approaching, passing and leaving the freight wagon. The viscous diffusion and subgrid fluxes are approximated by a second order accurate central difference scheme for better accuracy in boundary layers.

4 RESULTS

This section reports the LES results for the aerodynamic performance of the freight wagon passed by the ICE2-like shaped train. The passing speed is 20m/s, which corresponds to a Re of 2×10^5 based on the height and speed of the train. The flow can therefore be considered turbulent with the aerodynamic coefficients being independent of Reynolds number. Aerodynamic coefficients are analyzed for three scenarios with two different track spaceings: 3.5m and 4m, for both the wagon and the passenger train.

5.1 *Assessment of the numerical accuracy*

To simulate the train passing event, GGI frame change connections are used in the simulation. There are three types of GGI frame change connection models available in CFX: Frozen Rotor, Stage and Transient Rotor-Stator. Since the transient interaction effects at the sliding interface are of interest to this research, the Transient Rotor-Stator model is applied, which predicts the true transient interaction of the flow between the stationary and rotating domains. This is also the reason for choosing the curved sliding interface (See Figure 4).

To assess numerical accuracy, three computations were carried out for the track spacing of 3.5m based on different meshes: coarse, medium and fine, which contain 3.2 million, 6.9 million, and 9.0 million nodes, respectively. The ICEM-CFD package is employed to generate the hexahedral type meshes. The two domains (rotational and stationary) are meshed separately since a

sliding mesh technique is adapted to simulate the passing event. An O-type grid is deployed around the ICE2-shape train to generate a smooth mesh in all directions, as shown in Figure 5 (a), whilst the H-type grid is adapted everywhere else in the model. To reduce computational cost the hyperbolic stretching meshing law was applied in the upward direction to make the mesh coarser in the regions further away from the model area of interest (see Fig. 5 (b)). The same logic is applied in the span-wise direction. The stretching ratio in both directions is kept within 2.0. A uniform meshing law is applied in the stream-wise direction. To ensure both sides of the interface have similar mesh revolutions, the maximum ratio between the largest and the smallest cell in this direction was about 1.6 in both domains. This increases the accuracy of information transferred through the interface. A constant time step of 1×10^{-4} s is used throughout the entire simulation.

The aerodynamic coefficients: drag coefficient (C_D), side force coefficient (C_S) and lift coefficient (C_L), are defined as:

$C_D = \frac{\int p_s dA_x}{0.5\,\rho\,A\,V^2}$, $C_S = \frac{\int p_s dA_y}{0.5\,\rho\,A\,V^2}$ and $C_L = \frac{\int p_s dA_z}{0.5\,\rho\,A\,V^2}$, respectively, where p_s is the surface pressure, A_x, A_y and A_z are projected surface areas in the X, Y and Z directions, respectively. A is the reference area, chosen as 10 m^2 for the full scale dimensions. ρ is the air density.

Figure 6 shows C_S values of the top container using three different meshes against the distance between the freight wagon and the passenger train. The distance of 0 m corresponds to arrival of the passenger train at the wagon whilst the distance of around 3.56 m refers to when the high speed train just leaves the wagon. With the approach of the high speed train to the freight wagon, the Cs of the top container increases, with the first positive peak occurring just after the high speed train arrives. Following this, the gradient falls sharply to a trough which is of similar magnitude to the first peak, but of negative value. This all occurs within the relatively short time of 0.05s. The next positive peak displayed in Figure 6, follows on the heel of another negative through when the tail of the train leaves the wagon. Both the latter peaks are of smaller magnitude than the former two, indicating that the influence of the head of the train on C_S is stronger than the tail of the train. These results are consistent with both experiments and numerical simulations [12-14]. Figure 6 also shows that the Cs values gained from the fine mesh are in good agreement with the ones gained from the medium mesh, meaning that no mesh refinement is needed. To reduce the computational cost, a medium mesh is used to perform the LES for the track spacing of 4m.

5.2 *Passing phenomena and the effect of track spacing on the wagon*

To assess the influence of different track spacings on the wagon, the aerodynamic coefficients, C_S, C_D and C_L, were obtained for track spacings of 3.5m and 4m.

Figure 7 (a) and (b) show the side force coefficient on the top and bottom containers, respectively, for different track spacings (TS) against the distance between the passenger train and the freight wagon. For the top container, both track spacings show a similar trend in Cs, with the first pulse caused by the approaching of the head of the train while the leaving of the tail of train causes the second pulse, but of smaller amplitude than the preceding one. The positive peak presents a lateral push force to the container whereas the negative one means a lateral pull force. These push-pull forces reduce the lateral stability of the wagon and could potentially lead to derailment. Generally, larger track spacing induces smaller C_S values, and this effect is highlighted in the peaks and troughs of the data, with a 20% decrease in amplitude evident at these points, while the differences are negligible between the two pulses. Similar information is displayed in Figure 7 (b) for the bottom container. However, the peak values of Cs are considerably smaller than the corresponding ones for the top container. In according with Equation (8), this variation is due to the difference in the pressure distribution p_s, and the fact that, the top container has larger area (A_y) than the bottom container. Figure 8 shows the pressure distribution on the side surfaces of the containers when the train arrives. The dark color represents areas of high pressure, most of which is located at the front part of the top container and is the reason for the high side force coefficients in Figure 7 (a).

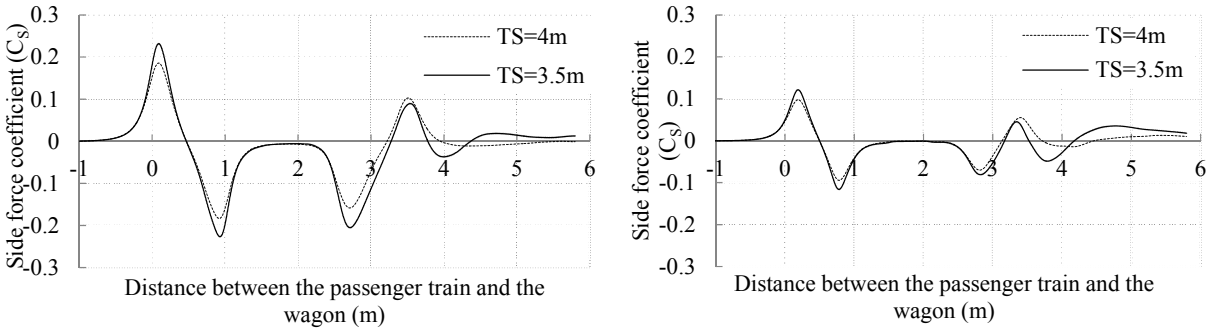

Figure 7. Side force coefficients of the containers (a) C_S of the top container (b) C_S of the bottom container

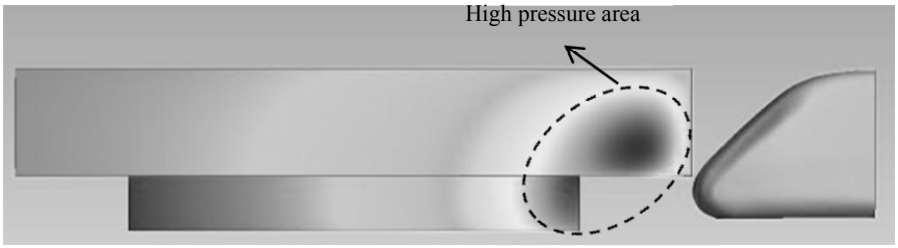

Figure 8. Pressure distribution on the side surfaces of the containers

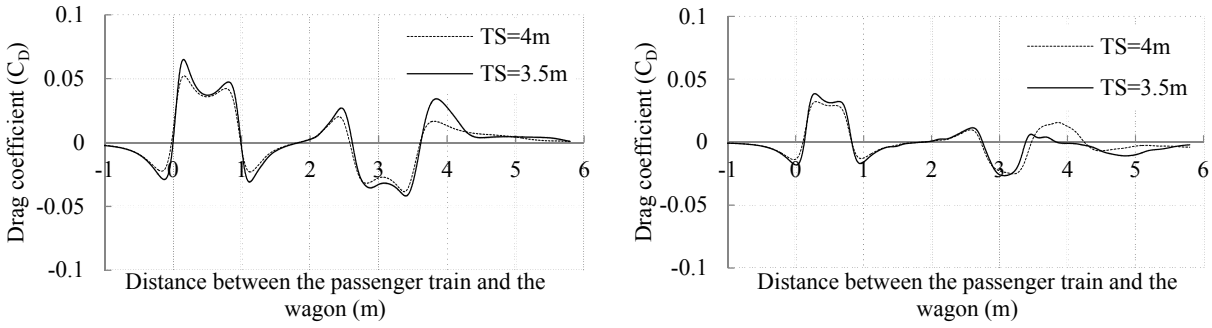

Figure 9. Drag coefficients of the containers (a) C_D of the top container (b) C_D of the bottom container

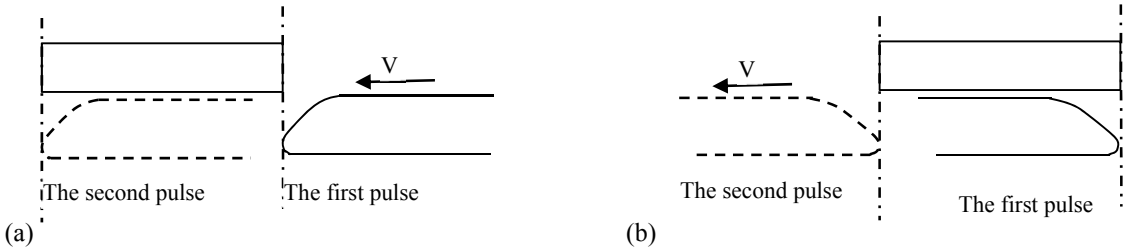

Figure 10. (a) Positions of the head of the train for the pulses (b) Positions of the tail of the train for the pulses

Figure 9 (a) shows C_D variation with the two different track spacings for the top container. With the head of the train approaching, the drag coefficient begins to fall the first negative peak and then increases sharply to the first positive peak. The C_D then drops a little but begins to increase after the head of the train reaches the middle of the wagon, to produce a second positive peak. There is then a subsequent sharp decline to the second negative trough when the head of the train leaves the tail of the wagon. It's noticed that the second pulse at the end of the train passing has smaller amplitude than the first one occurring when the passenger train approaches the freight wagon. Two pulses are also observed when the tail of the train arrives at the front of the wagon and when it leaves the tail of the wagon. Similar to the side force coefficient, the pulses in C_D caused by the tail of the train are weaker than the ones caused by the head of the train. Figure 10 (a) portrays the positions where the peaks occur. C_D values from the track spacing of 3.5 m are generally slightly larger than the one from the track spacing of 4m. During the head and the tail of the train passing, this difference is distinct with approximate 19% decrease when

considering the track spacing of 4m. A similar phenomenon occurs to the bottom container with smaller peak values of C_D than for the top container, as shown in Figure 9 (b).

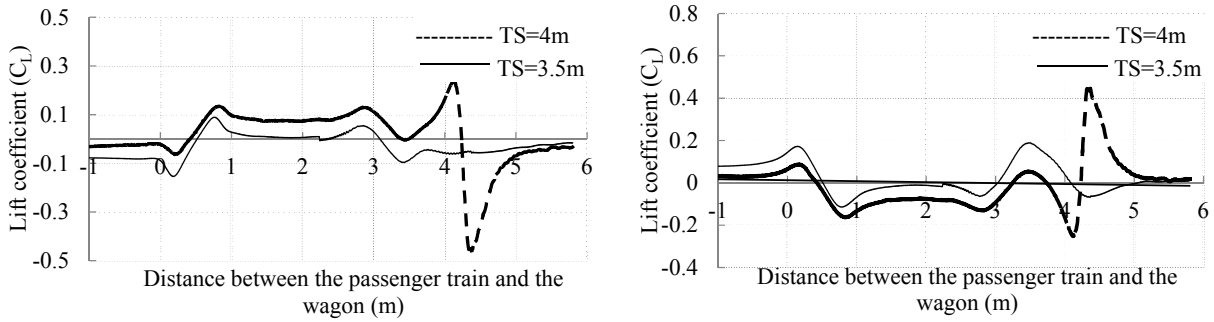

Figure 11. Lift coefficient of the containers (a) C_L of the top container (b) C_L of the bottom container

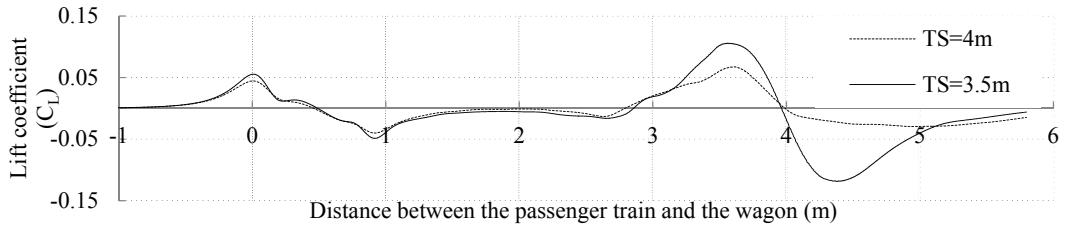

Figure 12. Combined lift coefficient from both containers

A comparison of the lift coefficients is shown in Figure 11. It can be seen from Figure 11 (a) that, when the train approaches the freight wagon, the top container is first exposed to a negative lift force, which means a force is acting vertically downwards on the container. After the head of the train arrives at the middle of the wagon, this force changes to being positive and a peak is observed in C_L just before the head of the train leaves the tail of the wagon. Then during the train passing, the force keeps almost steady until the tail of the train arrives at the front of the wagon, causing another peak and then another drop when leaving the wagon. It's remarkable that larger track spacing causes higher lift force on the top container. Figure 11 (b) shows the lift coefficient observed on the bottom container, of larger amplitude than on the top container. Different from the top container, increasing track spacing causes significant decrease in C_L on the bottom container. For the majority of the passing event, the top and bottom containers have alternative results of lift coefficient--one has positive value at the same time as the other has negative, and vice versa. Figure 12 shows the combined lift coefficient from the top and bottom containers to allow for analysis of the wagon as a whole. It is clearly showed that the maximum value occurs when the tail of the train passes the wagon. This means that the tail of the train passing has a stronger influence on the lift coefficient than the head of the train. Last, larger track spacing finally decreases the C_L for the whole wagon although increases C_L of the top container.

Table 1. The peak values decrease of aerodynamic coefficients of the wagon from track spacing 3.5m to 4m

Track spacing (m)	Side force coefficient (CS)	Drag coefficient (C_D)	Lift coefficient (C_L)
3.5m	-0.276	0.036	0.0992
4m	-0.220	0.026	0.0576
Percentage drop (%)	20	27	42

From the analysis above, it's known that increasing the track spacing generally decreases the peak value of the coefficients for the whole wagon. The maximum percentage decrease of the peak values from TS=3.5m to TS=4m are listed in Table 1.

5.3 *Passing phenomena and the effect of track spacing on the passenger train.*

In this section only the side force and lift coefficients of the head of the passenger train are investigated, limited to the space of the paper. As shown in Figure 13 (a), when approaching the wagon, the side force coefficient of the head of the passenger train drops to the first trough which means the maximum push force occurs here. Right after this, the side force coefficient increases to the first positive peak, of much smaller amplitude, when the head of the train leaves the wagon. This means when passing the wagon, the head of the train is exposed to a first push force and then a pull force, which potentially worsens the lateral stability. Figure 13 (b) shows the lift coefficient of the head of the train. When the head of the train approaches and leaves the wagon, a pulse occurs in the lift coefficient. It is noticeable that C_L stays negative, which means that the head of the train is loaded under a downward lift force throughout the passing event. Typically, the coefficients are smaller in the results from the track spacing of 4m than for the track spacing of 3.5m. However, this difference is most prominent for the lift coefficient results (as shown in Figure 13 (b)), where a track spacing increase from 3.5m to 4m results in roughly a 10% decrease in C_L for the majority of the passing procedure.

CONCLUSIONS

This work has investigated the aerodynamic performance of a double-decker stationary freight wagon being passed by a high speed train using LES. The influence of two different track spacings, 3.5m and 4m were assessed in terms of three aerodynamic coefficients: side force coefficient, drag coefficient and lift coefficient. Principal conclusions from the simulations are:

1. Increasing the track spacing from 3.5 m to 4m results in a larger decrease in the lift coefficients in comparison to the side and drag coefficients for both the freight wagon and passenger train. The peak C_L of the wagon decreases up to 40% in value when the track spacing increases from 3.5m to 4m, which occurs when the tail of the train leaves the wagon. The passing event has almost negligible effect on the lift coefficient of the passenger train, which reduces by a small amount during the passing procedure.
2. When the track spacing increases the lift coefficient of the top container increases, whilst the values of the bottom container decrease. It is noticeable that while the top container is

exposed to a positive lift force, the bottom container is simultaneously exposed to a negative lift force, and vice versa. However, the combined coefficient of the two containers still shows the tendency of increasing coefficients with decreasing track spacing.

3. The reduction in the track spacing also generally increases the side and the drag coefficients for both the wagon and the passenger train, especially at the moment when the passenger train approaches or leaves the wagon. The top container is on the whole subjected to larger side forces than the bottom one.

ABSTRACT: The running safety analysis of a vehicle subjected to crosswinds is one of the issues concerned in wind engineering. Particularly as a vehicle moves passing by a bridge tower, the shielding effect of the tower on wind forces of the vehicle occurs, which leads to a sharp change of aerodynamic forces on the vehicle in danger. To explore the aerodynamic forces acting on the vehicle passing by the bridge tower, the flows around the vehicle immerged in different positions to the bridge tower are simulated using the computational fluid dynamics (CFD) technique in this study. The aerodynamic forces measured in the wind tunnel are used to confirm the simulation results. Meanwhile, the aerodynamic characteristics of the vehicle immerged in the wake of the bridge tower and the flow field features are explored in detail.

KEYWORDS: vehicle, bridge tower, crosswinds, aerodynamics, computational fluid dynamics

1 INTRODUCTION

Vehicle behavior under crosswinds is one of the issues concerned in wind engineering. The running safety analysis of a vehicle subjected to crosswinds probably started from the Baker's work in 1986 (Baker[1]). Since then, several studies on the safety of a vehicle subjected to crosswinds have been carried out. Particularly as a vehicle moves passing by a bridge tower, the shielding effect of the tower on wind forces of the vehicle occurs, which leads to a sharp change of aerodynamic forces on the vehicle in danger. The safety of a vehicle running through a tower region is therefore concerned. The aerodynamic forces of a vehicle in the wake of a bridge tower should be studied to make sure the running safety of the vehicle. Wind tunnel tests are a common method to obtain the aerodynamic forces on a vehicle. Charuvisit et al.[2] tested the transient aerodynamic side force and yawing moment on a vehicle when it passed by a bridge tower subjected to crosswinds. Argentini et al.[3] carried out wind tunnel tests to measure the aerodynamic forces and the surface pressure distributions of the stationary vehicle model. With the rapid development of computer hardware, computational fluid dynamics (CFD) can be employed as an alternative tool, practically in the flow visualization which cannot be achieved easily by wind tunnel tests. In this study, the flows around a bridge tower and a vehicle in different positions behind the bridge tower are simulated using the CFD technique. The aerodynamic forces measured in a wind tunnel are used to confirm the simulation results. Then, the aerodynamic characteristics of the vehicle immerged in the wake of the bridge tower and the flow field features are explored in detail.

2 MODELS

A typical high-sided articulated lorry, which was investigated extensively by Baker and his colleagues in wind tunnels and later used in the dynamic analysis of wind-vehicle-bridge systems (Xu & Guo[4], Cai & Chen[5], Chen & Wu[6]), is selected as the reference vehicle. The geometric scales of the vehicle are shown in Fig.1. A long span highway bridge is also selected. It is a cable-stayed bridge of double towers with a main span of 688m (see Fig.3). The tower composes of a pair of side by side legs and a transverse beam to support and restrain the deck (see Fig.2). The tower legs are inclined from the height of deck to both the ends with a chamfered rectangle section. The transverse beam connected the two legs with a rectangle cross section. A flat box girder with side fairing is selected as the bridge deck, as seen in Fig.4. The cross section of the deck was 34.0m wide and 3.5m high carrying a dual two-lane highway on the upper surface. Two lines of handrail, four lines of protection rail and two lines of I-shape maintenance trace are mounted on the bridge deck. Both the vehicle and bridge models are scaled with a length ratio of 1:25. Under the crosswinds, the vehicle running on the upwind first lane is impacted by the bridge tower more seriously than the one running on the other lanes. Therefore the vehicle is arranged on the upwind first lane in this study. Because of the complex flow field around the tower, the vehicle in different locations with reference to the tower may suffer distinct wind flow. To reflect the influence of distance from the tower, three different positions of the vehicle in the wake of bridge tower are considered. They are (1) the vehicle immerged behind the tower entirely (position Xd1 in Fig.5), (2) half-length of the vehicle immerged behind the tower (position Xd3 in Fig.5), and (3) the vehicle just getting rid of the tower (position Xd5 in Fig.5). Aerodynamic forces of the same vehicle model were tested in the TJ-3 wind tunnel of the State Key Laboratory for Disaster Reduction in Civil Engineering at Tongji University in Mainland China. The models mounted in the wind tunnel are shown in Fig.6.

3 NUMERICAL METHOD

3.1 Governing equations

In order to explore the flow characteristics around and the aerodynamic forces on the vehicle-bridge system, the large eddy simulation (LES) method is adopted for this study. In LES, turbulent flows are decomposed into large and small scales of turbulence by means of a high-pass filter in space. The large-scale turbulence flows can then be computed accurately by using the LES governing equations while the effect of the small-scale turbulence can be estimated through the subgrid-scale (SGS) model with the understanding that the small scales of turbulence tend to more homogeneous and universal, and less affected by the boundary conditions than the

large-scale ones. A box filter expressed by Eq. (1) is used for performing the spatial scale separation and a filtered variable is expressed by Eq.(2).

$$G(x,x') = \begin{cases} 1/V, x' \in v \\ 0, x' \notin v \end{cases} \tag{1}$$

$$\overline{\varphi}(x) = \int_v G(x,x')\varphi(x')dx' \tag{2}$$

where G is the filter function; φ is the variable before filtering; $\overline{\varphi}$ is the variable after filtering; v denotes the computational cell; and V is the computational volume. By applying the filtering operation to the momentum and continuity equations, the LES governing equations can be derived as

$$\rho\frac{\partial \overline{u_i}}{\partial t} + \rho\frac{\partial}{\partial x_j}\left(\overline{u_i}\,\overline{u_j}\right) = -\frac{\partial \overline{p}}{\partial x_i} + \mu\frac{\partial^2 \overline{u_i}}{\partial x_j \partial x_j} - \frac{\partial \tau_{ij}}{\partial x_j} \tag{3}$$

$$\frac{\partial \overline{u_i}}{\partial x_i} = 0 \tag{4}$$

where μ_i (i=1, 2, 3) is the filtered velocity component in the Cartesian coordinates; p is the filtered pressure; ρ is the fluid density; μ is the dynamic viscosity coefficient; and τ_{ij} is the subgrid-scale stress expressed by

$$\tau_{ij} = \rho\overline{u_i u_j} - \rho\overline{u_i}\,\overline{u_j} \tag{5}$$

The subgrid-scale stress must be modeled, and the subgrid-scale turbulent model employed in this study is based on the Boussinesq hypothesis.

$$\tau_{ij} = -2\mu_t\overline{S_{ij}} + \frac{1}{3}\tau_{kk}\delta_{ij} \tag{6}$$

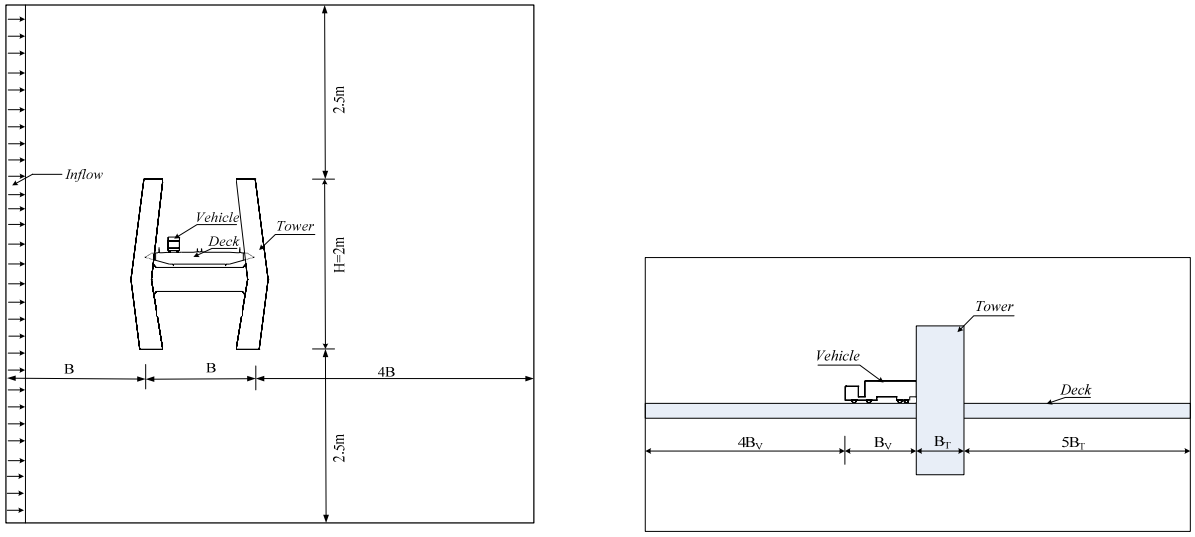
$$\overline{S_{ij}} = \frac{1}{2}\left(\frac{\partial \overline{u_i}}{\partial x_j} + \frac{\partial \overline{u_j}}{\partial x_i}\right) \tag{7}$$

where μ_t is the subgrid-scale turbulence viscosity; τ_{kk} is the isotropic part of the subgrid-scale stress. The subgrid-scale turbulence viscosity can be determined by using the Smagorinsky-Lilly model. The Smagorinsky constant equal to 0.1.

3.2 Numerical models

In the simulation, only one wind direction (wind perpendicular to the bridge deck) is considered. Fig.7 shows the computational flow domain when the vehicle is located at Xd3. The entire computational domain is a box shape enclosed by six boundary faces. B, BV and BT represent the width of the deck, the length of the vehicle and the width of tower, respectively. The height of the computational domain is 7m which leads a blockage ratio at the level of the wind tunnel

tests. All those sizes determining the computational flow domain are optimized through parameter studies.



(a) (b)

Figure 7. Computational domain sketch: vehicle-bridge system

3.3 Boundary conditions

The input boundary face is set as flow inlet with a uniform velocity of 10m/s, which leads to a Reynolds number of 1.13×10^5 in terms of the height of the vehicle. The output boundary face is specified as flow outlet with zero pressure. The other boundaries are all defined in such a way that the gradients of flow variables (including velocity and pressure) normal to those boundary faces are zero. The surfaces of the vehicle and the bridge are all modeled as nonslip wall boundaries.

3.4 Meshing

The characteristic sizes of components of the vehicle-deck-tower system vary from the size of rails to the size of tower greatly. The complex geometric shape and the large variation of characteristic size lead to a complicated flow field around the system in space. In order to obtain a relative adequate spatial discretization grid system corresponding to the ability of the current using PC, the grid optimization is achieved. Since the simulation with the LES method is time-consuming for the flow around three-dimensional complex geometric body, steady RANS equations enclosed with SST two-equation turbulence model are solved during the process of grid optimization.

3.5 Computational scheme

The LES governing equations are discretized using a three-dimensional finite volume method. The convective and diffusive terms are approximated by the bounded central differences of second-order accuracy and central difference respectively. The time integration is performed using the second-order implicit method. Pressure and velocity are solved with the SIMPLEC algorithm.

4 SIMULATION RESULTS

4.1 Aerodynamic forces and coefficients

The numerical simulation provides the pressure distribution over the surfaces of the vehicle. The aerodynamic forces acting on the vehicle can then be acquired by integrating the pressures over the surface. The aerodynamic forces and coefficients discussed below refer to the mean values. There are six aerodynamic force components on the vehicle in the Cartesian coordinate system: lift force FL, drag force FD, side force FS, pitching moment MP, yawing moment MY and rolling moment MR, as shown in Fig.8. The non-dimensional aerodynamic coefficients are defined by

$$C_L = \frac{F_L}{qA}; \; C_D = \frac{F_D}{qA}; \; C_S = \frac{F_S}{qA} \tag{8}$$

$$C_P = \frac{M_P}{qAL}; C_Y = \frac{M_Y}{qAL}; C_R = \frac{M_R}{qAL} \tag{9}$$

$$q = 0.5\rho U^2 \tag{10}$$

where ρ is the air density; U represents the mean wind speed at the inlet boundary of the computational domain; A is the frontal project area of the vehicle without wheels and it refers to the project area in the X-Y plane in this study as shown in Fig.8; and L represents the maximum length of the vehicle in the Z-Y plane as shown in Fig.8. The aerodynamic force coefficients of the vehicle at different positions are listed in Table 1 for wind perpendicular to the length of the vehicle. From the comparative results of aerodynamic forces between the simulation and the wind tunnel texts, it can be seen that the simulated aerodynamic coefficients agree well with the experiment in general. The simulated coefficients demonstrate the same trend with the change of the vehicle location as the wind tunnel tests. The lift force coefficients are sensitive to the experimental conditions (Coleman & Baker[7]) and the calculated lift force coefficients are a slightly larger than the test values for all three locations. Compared with the test results, the calculated side force coefficients are a slightly larger while the calculated pitching moment coefficients are lower than the test results. When the vehicle moves out of the shielding area of the tower (from Xd1, Xd3 to Xd5), its side force, drag force, pitching and rolling moment all increase while its lift force decreases. The yawing moment decreases first and increases late.

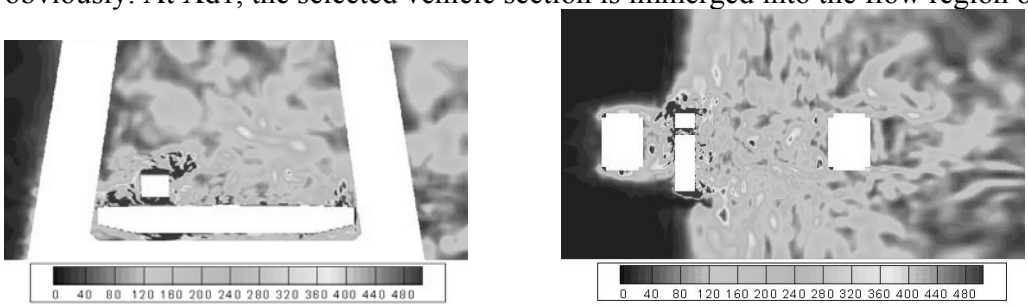
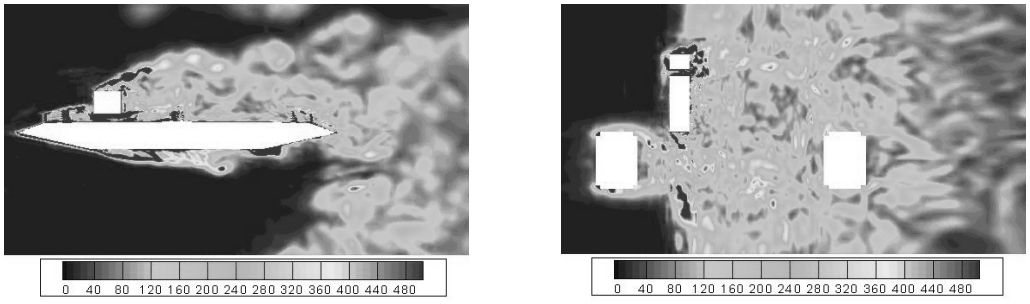
4.2 Flow fields

The visualization ability of CFD simulation is used here to analyze the flow fields around the vehicle. The instantaneous flow structures in terms of vorticity magnitude and the averaging flow structures in terms of projected streamlines and velocity contours are included. Sections shown as 1-1 and 2-2 in Fig.1 are selected to present the characteristic flow structures around the vehicle. The instantaneous contours of vorticity magnitude around the vehicle at different locations from the tower in the selected sections are shown in Fig.9, Fig.10 and Fig.11. Influenced by the tower, the flow environment becomes more and more complex from Xd5 to Xd1. At Xd5, the vortex street in the wake of vehicle-deck is disturbed slightly by the tower. At Xd3, the vortex street in the wake of vehicle-deck is interfered by the flow around the tower obviously. At Xd1, the selected vehicle section is immerged into the flow region of tower totally.



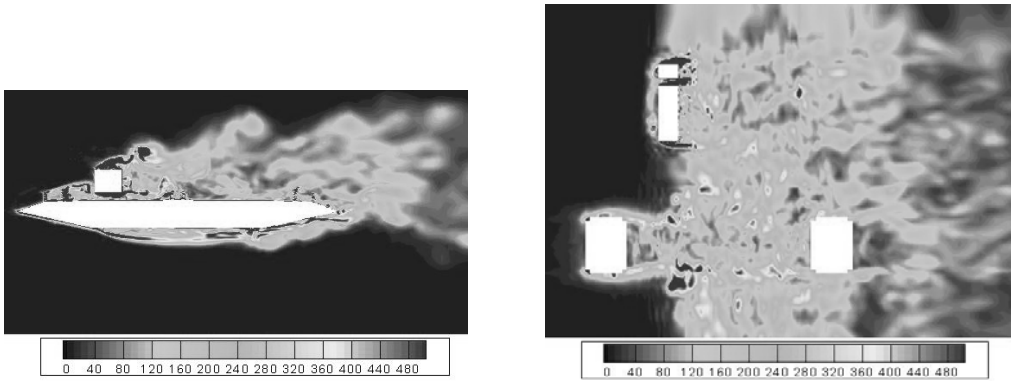
(a) section 1-1 (b) section 2-2

Figure 9. Contours of instantaneous vorticity magnitude for vehicle at Xd1 (unit: s-1)



(a) section 1-1 (b) section 2-2

Figure 10. Contours of instantaneous vorticity magnitude for vehicle at Xd3 (unit: s-1)



(a) section 1-1 (b) section 2-2

Figure 11. Contours of instantaneous vorticity magnitude for vehicle at Xd5 (unit: s-1)

The averaging projected streamlines and velocity contours of the vehicle at different locations are displayed in Fig.13, Fig.14 and Fig.15. Different flow structures are formed. Flow separates at the upwind tower leg. At Xd1, the vehicle is almost totally immerged in the separating wake of the upwind tower leg while the separated flow from the tower pushes on the tail part of the vehicle. The symmetric flow feature around the tower is disturbed slightly by the vehicle. At Xd3, the accelerated flow around the upwind tower leg pushes to the vehicle. The separated flow around the vehicle in Section 1-1 reattaches to the bridge deck again. At Xd5, the vehicle nearly gets rid of the impact of the wake of the tower. The separated flow around the vehicle in Section 1-1 does not reattach to the bridge deck.

4.3 Surface pressure distributions on vehicle

The mean pressure distributions over the surfaces of the vehicle under the three conditions are computed and displayed in Fig.16 for the case of wind perpendicular to the vehicle. The flow acts on the upwind side surface of the vehicle directly and some stagnation areas are formed. All the surfaces except the upwind one are in the flow separate region of the vehicle with negative pressure due to the flow separations around these surfaces. Compared with Xd5, the stagnation area for Xd3 moves to the head part while the area for Xd1 focuses on the tail part of the vehicle.

5 CONCLUSIONS

By using large eddy simulation method, the aerodynamic characteristics of a vehicle across a bridge tower have been investigated. The simulated aerodynamic coefficients agreewith the experimental results in general. The simulated coefficients demonstrate the same trend with the change of the vehicle location as the wind tunnel tests. When the vehicle moves out of the shielding area of the tower, its side force, drag force, pitching and rolling moment increase while its lift force decreases. The yawing moment decreases first and increases later. The instantaneous contours of vorticity magnitude show a complex flow environment around the vehicle due to the tower. The averaging projected streamlines and velocity contours show different flow separation phenomena around the vehicle at different locations. The flow acts on the upwind side surface of the vehicle directly and some stagnation areas are formed. All the surfaces except the upwind one are in the flow separate region of the vehicle with negative pressures.

ABSTRACT: This paper analyses the flow field and the power wasted by a heavy-duty truck of modified GTS standard shape (equivalent to GCM class 8). Computational fluid dynamics has been used to analyze truck models at cruise conditions. The selected test matrix includes the study of an isolated truck and of a train of two and three trucks to evidence interaction effects. For each case three different velocities have been considered. The numerical campaign is able to quantify the drag coefficient distribution, the losses generated on the roof by viscous phenomena and the changes in velocity distributions. An in-situ experimental campaign is also settled in the truck lane of Venice highway using ultrasonic anemometers and video cameras set on the same measurement frame. Non-dimensional velocity distributions along the vehicle confirm that the height of the separation bubble is dependent on the number of trucks.

2 INTRODUCTION

The effects induced by the transit of heavy-duty trucks have been widely addressed in the open literature. Experimental results mainly derive from works on road sign resistance, some insights being captured with accuracy and wealth of details. From a numerical point of view, much information are provided on the turbulence modeling effects, ranging from simple Reynolds Averaged Navier-Stokes (RANS) calculations to Large Eddy Simulation (LES), and on the unsteady flow field occurring in the rear part of the vehicles. Research on the premature failure of the USA type cantilevered traffic signal structures and deficiencies in the UK design standards on road signs gave the opportunity to obtain details about what happens in the proximity of a passing truck. A review of the work done in the field of induced gust loads on cantilevered structures can be found in the work of Albert [1]. The works by Cali and Covert [2] and Quinn et al. [3] are of interest for the reliability and size of their experimental databases. Cali and Covert [2] performed experimental measurements of the loads on a 1:30 scale model of an overhead highway sign with varying sign height and truck length, speed and shape. They described in detail the interaction between a road sign and a passing truck through the force coefficient evaluated on the sign itself. Vehicle passing was divided into four phases that always occur, the last one depending on the dimension of the truck only. Quinn et al. [3] studied the phenomena responsible for the vehicle-

induced loads. Their experimental apparatus was used to evaluate longitudinal loads on real signs of different size and shape placed at the side of the carriageways of two different roads. They demonstrated that the load induced by the truck passing is due to the pressure field related to the potential flow region of the vehicle slipstream, rather than a significant vehicle induced gust effect. Considering the evaluation of the drag coefficient of moving trucks, the works of Ougburn et al. [4], Storms et al. [5], Wood and Bauer [6] and Diebler and Smith [7] provide detailed information on the power wasted for aerodynamic effects. From a numerical point of view, Salari et al. [8], Roy et al. [9] and Veluri et al. [10] demonstrated that the RANS approach is able to predict pressure fields on trucks surfaces except for the base region. It is also concluded that although in the latter zone pressure field and flow structure predictions do not match with experimental data, an accurate prediction of the vehicle drag depends on the turbulence model only. Veluri et al. [10] quantified that error in around 5% when using k-ε or k-ω models, while higher discrepancies have been individuated when using Spalart-Allmaras or SST. The latter results have also been confirmed by the RANS simulations performed by Pointer [11], with an improved performance of SST model. Hyams et al. [12] presented a detailed study using RANS and Unsteady RANS (URANS) approaches. There are no relevant differences between the steady and the time-averaged data, neither in terms of pressure distributions along surfaces nor in terms of drag coefficient evaluation. There is also a good agreement with experimental data, except for the base region where an improved approach seems to be necessary. The work of Maddox et al. [13] deals with the comparison between purely RANS prediction and Detached Eddy Simulation (DES), both working with the Spalart-Allmaras turbulence model. They demonstrated that the a RANS approach is equivalent to DES except for the evaluation of the base region, where the recirculation flow is well captured by the resolution of large eddies. A detailed description of the flow field occurring in the base region has been proposed by Krajnović and Davidson [14] using LES on a simplified geometry. A more realistic vehicle is investigated with LES by Östh [15]. Although the accuracy of LES is very high, the computational load is unacceptable while the discrepancy between the experimental and the numerical drag coefficients is of the same order of magnitude found for a simple RANS calculation with a k-ε closure. Although there is a wide literature on the selected topic, information on the energy transfer due to the skin-friction on the roof of trucks as well as a detailed description of the flow field generated by the truck movement is missing. The present paper studies this topic both from an experimental and a numerical point of view. Results are discussed also considering the literature data and an insight on the separated boundary layer occurring on the trailer roof is presented.

3 DESCRIPTION OF THE PROPOSED APPROACH

The power wasting related to the skin-friction effect occurring on the roof of a truck has been estimated by means of a mono-dimensional approach based on the data available in the open literature for a scaled GTS. Once that activity has been concluded, the analysis of the induced pressure and velocity fields generated by trucks has been performed considering both an experimental and a numerical approach. The latter has been used to study a controlled environment where the truck passing effect could be isolated and the truck-truck interaction studied for typical cruise conditions. Furthermore, the numerical results have been used to quantify the amount of power that is transferred to the turbulent boundary layer, thus validating the simplified approach. The experimental approach demonstrated the accuracy of the numerical analysis and provided further information on the realistic situation, including the individuation of velocity peaks as well as the presence of long lines of trucks over the investigated area.

3.1 *The numerical approach*

Computational Fluid Dynamics (CFD) allows for detailed analysis of complex geometries. Incompressible, steady simulations have been performed on a specific vehicle model, which is defined to represent the typical European truck. The inherent complexity of the research demands for simplified approaches, and then a 2D numerical campaign has been completed using the commercial code ANSYS Fluent®. Calculations have been performed in the relative frame of reference and are second order accurate in space. Turbulence is modeled using the two equations k-ε model with standard wall functions. Simulations have been performed considering up to three trucks to study the aerodynamic effects. A total amount of 18 simulations have been performed, as reported in Table 1.

Table 1. Test matrix

Section	Vehicles	Distance (m)	Domain H x L (m2)	Number of elements	Speed (km/h)
W,NW	1 truck	0	100 x 120	~250,000	90 ,100 ,110
	2 truck	10	100 x 148	~300,000	90 ,100 ,110
	3 truck	10, 10	100 x 176	~360,000	90 ,100 ,110

A vehicle with a shape like that of the GTS has been considered, including the tractor-trailer gap. The computational domains represent both a section at the centerline of the truck (called No-Wheels, NW) and a section that includes the wheels (identified by W, Wheels). Minor details are neglected since the main contribution to the wasted power and air displacement comes from the bulk of the vehicle. Computational domains are discretized with an unstructured mesh where both triangular and quadrilateral elements are used (Figure 1a). Special attention has been paid to the discretization of the gap between the trucks and the lower region of the domain, where the re-circulating phenomena should occur (Figure 1b). The top of the domain has been modeled using a far-field condition where the total pressure is uniform and the flow is undisturbed. Those dimensions provide a vertical blockage of approximately 5% that will introduce an overshoot of velocity in the near-truck region. That effect will be considered while discussing the obtained results. For each investigated case, the last truck has been maintained at a constant distance from the outlet section to keep unchanged the reference pressure value for the pressure coefficient calculation.

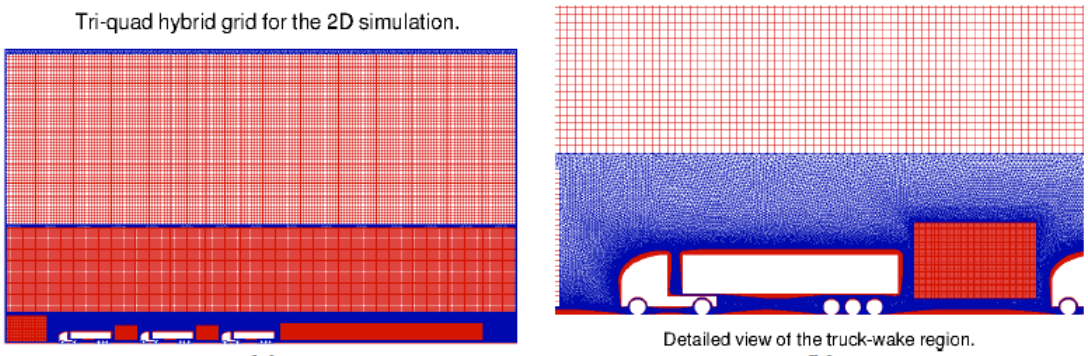

Figure 1. Computational grid of the three-trucks case: full domain (a) and wake region (b)

3.2 *The experimental apparatus*

The aim of the experimental campaign is to reconstruct the wind velocity profile on the top of truck in the lane axis, with an approach taking into account three-dimensional components attributed both to viscous fluid transportation properties and to interaction between pressure wave, rear wake, and vehicles gap in high traffic density. To this aim, the Venice link highway offers steel bridge frames of 200mm squared hollow sections bearing the traffic messages led panels and pictograms. To prevent interferences in wind measurements, at the chosen frame the 2.5m high panel in the instruments approaching direction has been removed, and substituted by a low solidity 50x50mm net handrail only 2mm thick. Each lane is instrumented with 3 ultrasonic tri-axial anemometers (USA) 40 Hz hi-freq. sampling, cantilevered > 2m from frame and placed at 5.50 m minimum headroom from road, at 6.50 m and at 7.50 m. The vertical alignment is avoided for two adjacent instruments in order to maximize mutual distance, and achieve not-interfering condition according to the ILAC MRA certified instrument. Another tri-axial USA is placed at 12 m height, sampled 8 Hz and interpolated to 40 Hz in order to get an ambient wind survey to calibrate traffic wind from aerodynamic losses. To correctly estimate interactions in high traffic density, an image tracking system is integrated with synchronous wind speed sampling. A couple of video cameras are set on the top of the measurement frame bridging the roadways. While the USA network is acquiring the environmental wind speed and the vehicle induced wind gusts, the cameras extract the size and speed of those vehicles, which generated the perturbations exciting the measurement system. Once truck geometry, speed and trajectory are estimated with a stereo tracking algorithm, a statistics is made on the collected data and estimates. A typical anemometry set for a single lane 3.5m wide is illustrated in Figure 2.

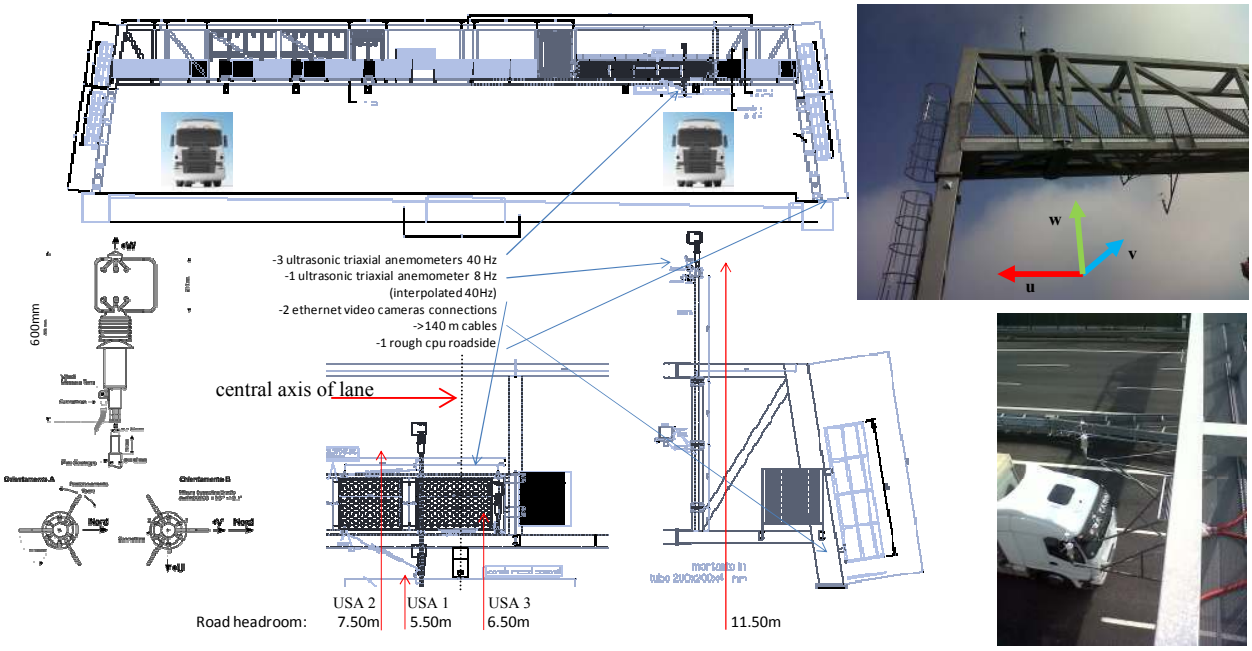

Figure 2. Experimental apparatus on the highway for a typical single-lane one directional set-up: the wind speed co-ordinates system and the USA numbering conventions are indicated. Note that USAs are placed symmetrically respect to central axis of the lane (1,2 one side, 3 other side)

4 NUMERICAL ANALYSIS OF LOSSES AND OF THE PRESSURE/VELOCITY PROFILES

The aim of the numerical activity is to investigate the pressure and velocity profiles generated by a moving truck and to quantify the amount of power lost by skin-friction on the roof of the truck itself. For the latter analysis the data available in the open literature for a Class-8 tractor-trailer are used. According to Ougburn et al. [4], the engine of a truck moving at 100km/h provides an amount of power of approximately 132kW. The 48% of that amount, around 63kW, is wasted for aerodynamic effects that are accounted for when the drag coefficient (Cd) is evaluated. The use of CFD will provide detailed information on the Cd distribution and then on the distribution of losses.

4.1 *Evaluation of the power losses related to the trailer roof skin-friction*

A preliminary analysis based on the assumption that the trailer roof can be treated as a flat plate will provide an estimation of the energetic content of the developing turbulent boundary layer. The skin-friction values for the full-scale GTS case can be estimated considering the drag coefficient values proposed by Storms et al. [5] for a 1/8-scaled model. Dynamic similarity is considered to scale the truck velocity and maintain the same Reynolds numbers. Being the flow incompressible and maintaining the flow viscosity unaltered, the ratio between the model and the full-scale truck velocities is 8. As a consequence, for a truck moving at 100km/h a Re of 4.8E+06 must be considered. According to Storms et al. [5] the total drag coefficient is almost constant for Re number higher than 1E+06, and then a constant value can be assumed. A C_d value of 0.249 is calculated integrating on the trailer the experimental skin friction distribution for the GTS model as found in Storms et al. [5] and depicted in Figure 3 with red squares (the leading edge starting at x/w = 2), together with its interpolation curve (in blue) and the theoretical turbulent flat plate prediction for a Reynolds number of 2.E+06 (dashed black).

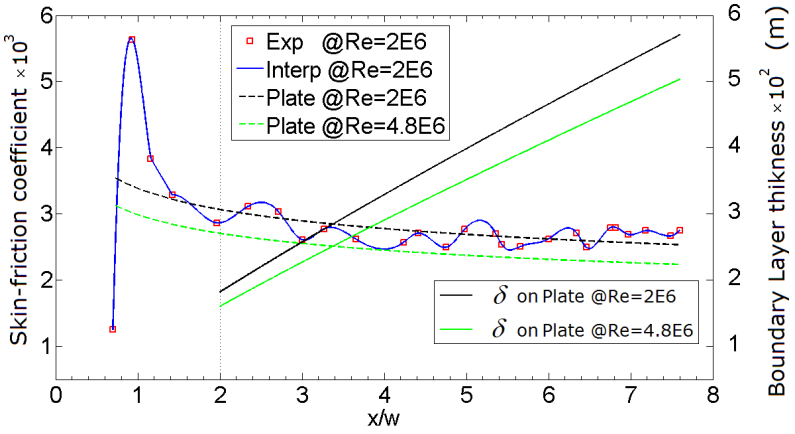

Figure 3. Skin friction and boundary layer thickness distribution for the GTS model at 2.E+06 and 4.8E+06 Reynolds numbers

The evaluation of the skin-friction drag can be performed considering a flat plate subject to the selected conditions. The skin-friction distribution at the needed Reynolds number of 4.8E+06 can be evaluated using Equation 1 (dashed-green curve in Figure 5).

$$c_f = \frac{0.034}{\mathrm{Re}_x^{1/7}} \tag{1}$$

The experimental results obtained on the 1/8-scaled model are compared with the data obtained for a full-scale flat plate at 100km/h in Table 1. Subscript $_c$ stands for "corrected", the latter being used to indicate the GTS total drag coefficient accounting also for the wheels (+0.1, Wood and Bauer [6]), the tractor-trailer gap (+0.1, Wood and Bauer [6]) and the under-body (+0.07, deduced from Diebler and Smith [7]) contributions. It can be evidenced that the $C_{df,roof}$ value obtained for a full-scale truck leads to an underestimated value of total drag contribution (around -13.8%) with respect to the experimental data.

Table 2. Comparison between GTS drag values for different Re numbers

Case	Re	C_d	$C_{d,c}$	$C_{df,roof}$	$C_{df,roof}/C_{d,c}$ (%)
Experimental	2.E+06	0.249	0.519	0.0101	1.95
Flat-plate (full scale)	4.8E+06	0.249	0.519	0.0087	1.68

As suggested by White [16], it is possible to calculate the boundary layer thickness on the roof of the GTS at full-scale. Assuming for simplicity that the boundary layer can be modeled using a power law as suggested by Prandtl, its growth is reported in Figure 5 for Re = 2.E+06 (black curve) and for Re = 4.8E+06 (green curve). Similar evaluations could be performed starting from the data obtained by Storms et al. [5] and varying the Reynolds number to mimic different truck velocities. Values of the boundary layer thickness with varying speed at the leading edge (LE), at the middle point (MP) and at the trailing edge (TE) of the trailer for the full scale GTS are shown in Table 3.

Table 3. Boundary layer thickness at the trailer's roof and skin-friction power losses computed using an approximate approach based on the full-scale flat-plate assumption for a GTS model

Speed	δ (cm)			$P_{f,roof}$
(km/h)	LE	MP	TE	(kW)
90	13.0	27.6	40.9	0.91
100	12.8	27.2	40.3	1.23
110	12.7	26.8	39.7	1.61

Once the value of the skin-friction drag is available it is also possible to evaluate the power transferred to the boundary layers using Equation 2:

$$P_{f,roof} = \frac{1}{2}\rho_r U_r^3 A_r C_{df,roof} \tag{2}$$

In that equation U_r is the vehicle's speed, ρ_r is the air density at ambient conditions and A_r is the projected area of the truck as seen from the main-flow. Although skin-friction coefficients are made non-dimensional basing on the wetted area, the truck frontal area is now used for homogeneity with the drag coefficient definition. The truck power transferred to the roof boundary layer is reported in Table 2. As can be seen, at 100 km/h the power losses generated by the skin-friction on the roof of the trailer amounts to 1.23kW, which is around 1% of the total power produced by the engine and around 2% of the aerodynamic losses. The obtained results demonstrate that the skin-friction on the trailer roof provides a negligible contribution to the net aerodynamic

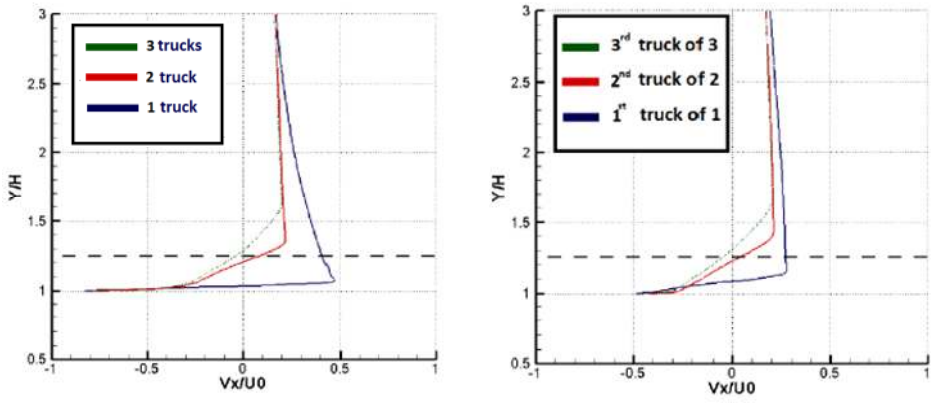
losses. It is worth noting that these flat-plate predictions assume implicitly that the boundary layer transition locates at the same point of the experimental case, while increasing the Reynolds number implies that transition occurs somewhere before and that boundary layer becomes thinner. Therefore, numerical simulations are necessary to focus into the flow field around the truck, where the prevailing losses are spent to displace the fluid from the vehicle way.

4.2 *CFD of the selected cases*

As already pointed out, the RANS approach is used to study a truck moving in a leveled and windless highway. Several simulations have been performed to gain general rules for the phenomena involved, also considering the effects of trailing trucks.

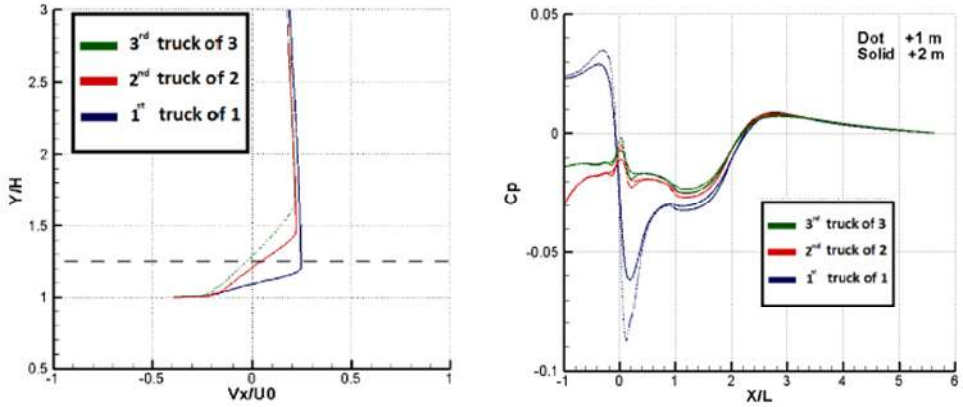
4.2.1 *2D results*

Since one of the objectives of the activity is to evaluate the height of the recirculating boundary layer over the trucks, comparisons are always performed considering the last truck of the row. Only the results obtained for 100km/h will be shown, being negligible the differences between the non-dimensional profiles obtained for the other cases. Furthermore, there are no relevant differences between the case with wheels and the case that mimic the central section of a real truck, and then only the case with wheels will be shown. The data obtained for the no-wheels case will be used in the evaluation of the total drag coefficient. The non-dimensional absolute axial velocity profiles are shown in Figure 4 and Figure 5-a for the case with wheels. Velocity profiles are depicted for three axial positions: the leading edge (LE) and trailing edge (TE) of the trailer and its mid-point (MP). The absolute axial component of the velocity is divided by the truck velocity U_0; the distance from the road is divided by the height of the truck. Dashed lines indicate the minimum height where obstacles position is allowed in European countries. For each profile, the Y/H position that corresponds to the $V_x/U_0 = 0$ value can be considered as the height where the separation bubble ends. As can be observed, the highest value of the separation bubble height, reached near the TE, is almost negligible when considering a single truck moving along the lane, being Y/H around 1.1 at the TE for $V_x = 0$. A different behavior can be observed looking at the last truck of a row of two or three, being the Y/H value correspondent to the bubble closure always equal to or higher than 1.2. In fact, at the LE the Y/H value reaches values of 1.3 for a row of three (Figure 4-a) and maintained over 1.25 also at MP (Figure 4-b) and TE (Figure 5-a). The latter result indicates that the separation bubble never reattach on the third truck when considering a row of three, which is a conditions that often occurs.



(a) 100km/h @LE, W (b) 100km/h @MP, W

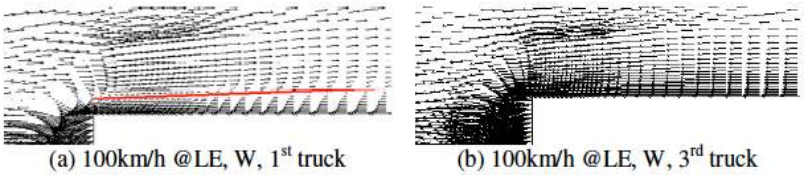
Figure 4. Leading edge and mid-point profiles for wheel (W) case at 100km/h



(a) 100km/h @TE, W (b) 100km/h, W

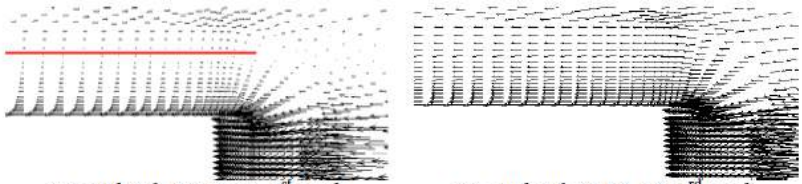
Figure 5. Trailing edge profiles for wheel (W) case and pressure coefficient distribution at 100km/h

That differences between the flow fields are also evidenced by the absolute velocity field near LE and TE for the cited cases, as shown using the same velocity scales in Figure 6 and Figure 7. The flow separation is depicted with a red line (that indicates $V_x = 0$) in Figure 6-a near the LE and in Figure 7-a near the TE of the first truck. As can be seen, the effect induced by the skin-friction on the shear layer is limited and the flow velocity turns to 0 not far from the trailer roof. Looking at the velocity field generated by the third truck (Figure 6-b and Figure 7-b), it is clearly visible that the flow is almost constant and moves in the direction of the truck, which means that the flow is completely separated. It can be supposed that the longest the truck row will be, the higher will be the separated region. It is worth mentioning that the Y/H value where an undisturbed flow can be individuated is at least 1.15 for the first truck at MP (Figure 5-a). Considering a value of 4m for H, which is the value chosen in this study as representative of European trucks, the height of the boundary layer is at least 60cm instead of the 40cm predicted for 100km/h by the flat plate approach (Table 3). The latter neglect the presence of flow separation, which is the driving phenomenon when studying trucks aerodynamics. It must be observed that in a 2D simulation, the blockage effect of the truck height is a crucial parameter and that the velocity modules are slightly overestimated. Nevertheless, the observed trends will not change in a realistic environment, as demonstrated by the experimental campaign described below.



(a) 100km/h @LE, W, 1st truck (b) 100km/h @LE, W, 3rd truck

Figure 6 Leading edge profiles for wheel case at 100km/h



(a) 100km/h @TE, W, 1st truck (a) 100km/h @TE, W, 3rd truck

Figure 7 Trailing edge profiles for wheel case at 100km/h

A final comment can be done on the pressure fields associated to the already discussed velocity profiles. In Figure 5-b the pressure coefficient C_p is reported for two different heights above the truck roof. As expected, the pressure fluctuation associated with the first truck is quite high (from +0.35 to -0.9) and the overall C_p trend is coherent with the description provided by Cali and Covert [2]. The subsequent trucks are subject to a smaller pressure drop that results in a smaller drag coefficient associated to the truck progress.

4.3 *C_d distribution*

The drag coefficients calculated using the data obtained from the numerical simulation of a single truck are shown in Table 4 for three different velocities. The C_d value is evaluated considering both the pressure (C_{dp}) and the skin-friction (C_{df}) effects. The relative contribution of the roof skin-friction to the total C_d can be compared with the data found in the open literature and from the flat plate approach (Table 2). It can be observed that the $C_{df,roof}/C_d$ value obtained for 100km/h is very similar to the experimental one (1.95%). That means that a 2D analysis is able to predict with reasonable accuracy the viscous drag effects also with a steady assumption, and that such kind of approach could be considered as a preliminary step in the truck shape optimization, prior to the use of accurate but demanding approaches as URANS or LES.

Table 4. Drag values calculated using both NW and W data

Speed (km/h)	C_{dp}	C_{df}	C_d	C_{df}/C_d (%)	$C_{df,roof}/C_d$ (%)
90	0.466	0.0172	0.483	3.50	1.79
100	0.464	0.0173	0.481	3.16	1.81
110	0.463	0.0168	0.432	3.47	1.80

5 EXPERIMENTAL TESTS ON A HIGHWAY

Vehicle-induced turbulence, hence the mark of the wind flow generated by road traffic, is highlighted via TKE turbulent kinetic energy:

$$e_i = \frac{1}{2}\left(\overline{u'^2_i} + \overline{v'^2_i} + \overline{w'^2_i}\right) \tag{3}$$

In particular, according to Kalthoff et al. [17], TKE difference between anemometer position lee and windward, normalized to wind speed u directed across highway, shows a strong correlation (R=0.77) with hourly traffic density of heavy duty vehicles circulating at a mean speed V=120 km/h. This is globally a sign of non-negligible energy along a non-ambient wind direction, due to highway traffic. Stemming from these global findings, the experimental campaign illustrated in Figure 2 goes further into the reconstruction of the wind profile due to heavy-duty traffic. A first signal processing gives the time domain results as presented in Figure 8. Mean ambient wind speed is evaluated each 10' and subtracted to obtain turbulent components (blue to green lines in Figure 8). The issue of filtering possible turbulent ambient wind speeds is addressed considering that atmospheric wind spectrum is generally characterized by a macro meteorological peak, followed by a spectral gap (10' to 60') and a micro meteorological peak (45"-50"). While single vehicle passages occur at sub 1" periods (gray bands in Figure 8), columns of trucks are also encountered collectively giving non negligible TKE during up to 50" periods: applying a multi-band filter to exclude both macro and micro atmospheric peaks is therefore not advisable, preferring a base band (random noise) Parks-McClellan FIR linear phase filter at 0.05 Hz cut-off (red line in Figure 8). It is worth noting from wind speed sign in Figure 8 that the flow moves in the direc-

tion of the truck and not opposite, as previously discussed and obtained via CFD. Finally, the peak detector fed with such a filtered signal, could detect the correct local maxima by looking for downward zero-crossings in the smoothed first derivative that exceeded a certain pre-determined minimum "slope threshold" at those points where signal exceeded a certain minimum "amplitude threshold", determining the coordinates (time instant and height), and approximate width of each peak by least-squares curve-fitting the top part of the peak (Oppenheim et al. [18]).

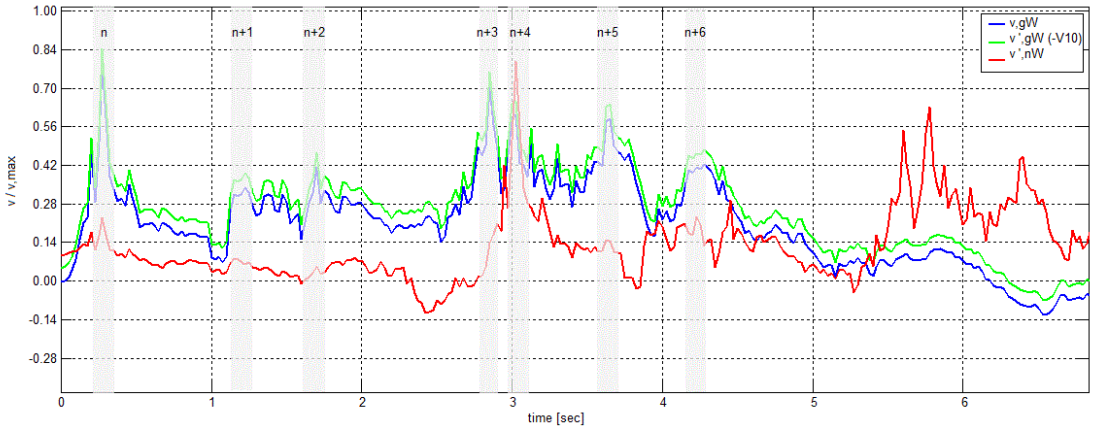


Figure 8 Sub-process n°6/12: 12h00 to 14h00: Time series of the normalized wind speed component directed along highway at 5.50m high USA: gross wind (blue), turbulent wind (green), turbulent filtered wind (red). Leading edge passages are also highlighted in gray bands.

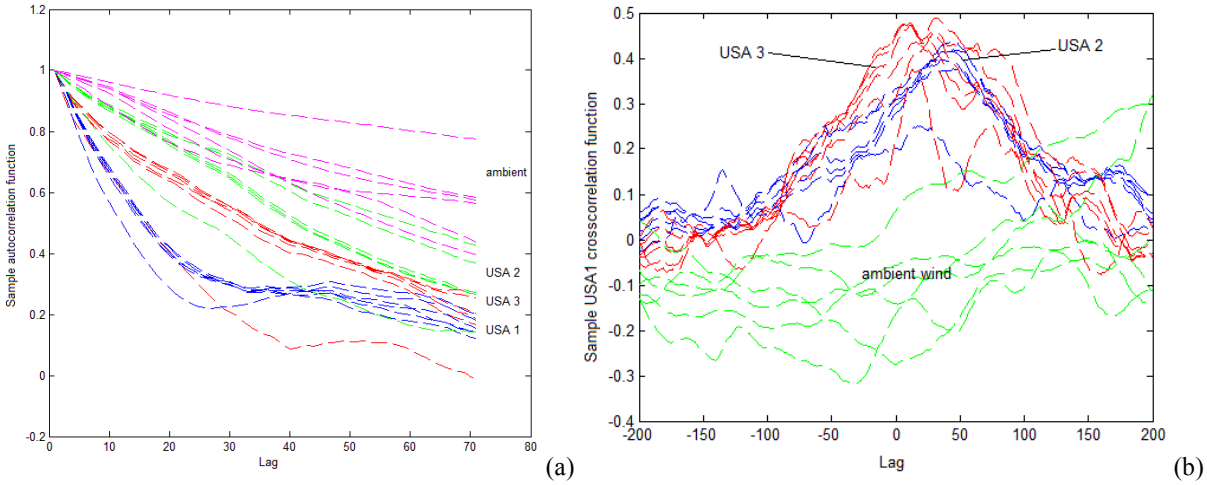

(a) (b)

Figure 9. Sub-process n°6/12: 12h00 to 14h00: (a) Sample autocorrelation functions of the single lane USA for multiple days realizations: USA 1 blue, USA 2 green, USA 3 red, ambient wind magenta; (b) Sample cross-correlation functions of USA 1 with USA 2 (blue), USA 3 (red) and ambient wind (green) for multiple days realizations. Refer to Figure 3 for USA numbering convention and geometry.

Frequency domain signal analysis is aimed at extracting the PSD of the daily traffic process, which is conveniently divided into 12 homogeneous sub-processes of 2 hours slice. Such hypothesis of circadian rhythm can be verified by a look at Figure 9-a, where multiple samples of different days (Monday to Friday population) show autocorrelation functions of the single lane USAs (see Figure 2 for numbering) that are generally less scattered than ambient wind USA. Furthermore USA 1, closest to top of truck, shows the narrowest band autocorrelation. Figure 9-b shows sample cross-correlation functions of the closest USA 1 to top of truck with other instruments of

the single-lane set: low coherence of the traffic induced turbulence with ambient wind results self-evident, while peaks and phase shifts in vertical upper USA 2 and lateral intermediate USA 3 positions (please refer to Figure 2 for USA numbering convention) tell us something about the three-dimensional structure of the separated wave induced by traffic. In fact, a high correlation and a minor shift with lateral intermediate position indicates possibly a proof for the experimental set-up assumption of the flow acting similarly in the 3.5m lane width as a whole; note also that symmetrical truck side edges vorticities can be considered in USA 1-USA 3 cross-correlation measurements, as the anemometers are placed symmetrically respect to central axis of truck (assumed to coincide with central axis of the lane, see Figure 2). Similarly, coherence of the three-dimensional structure of the wave can be assessed from the fact that in Figure 9-b cross-correlation peak with upper USA 2 is delayed from the peak of lower USA 3, closer to the wave source.

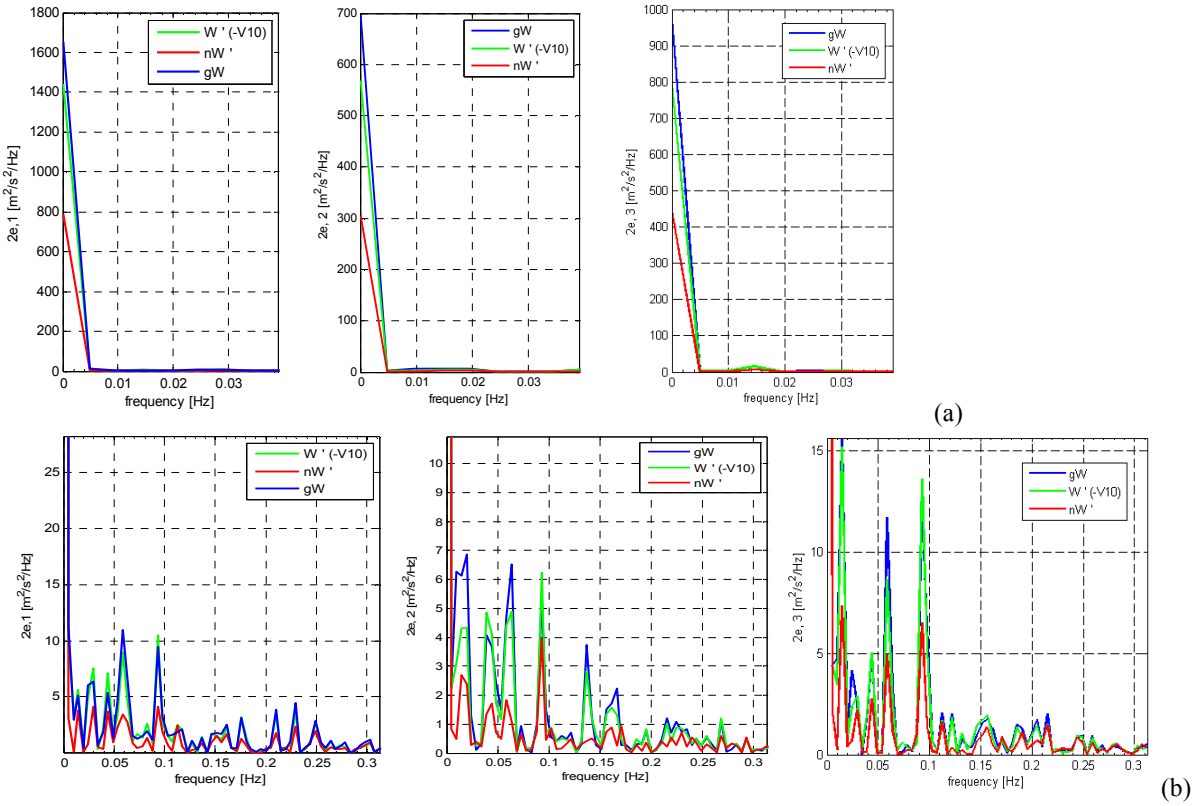

Figure 10. Sub-process n°6/12: 12h00 to 14h00: (a) PSD or 2e of USA 1, 2 and 3: detail of 0 Hz region of spectra; (b) PSD or 2e of USA 1, 2, and 3: detail of sub-Hertzian region of spectra. Each PSD contains three different signals transforms: gross wind (blue), turbulent wind (green), turbulent filtered wind (red).

Ergodicity assumption is also used to derive the PSD of the 12 sub-processes as the limit of the statistic mean:

$$\lim_{T\to\infty} E[\widetilde{PSD}_{\mathbf{gW-V_m}}(f)_T] = PSD_{\mathbf{gW-V_m}}(f) \tag{4}$$

where $\mathbf{gW - V_m}$ indicates the turbulent filtered signal. In fact, under the verified cyclostationary process assumption, one can take N days samples as N realizations, thus feeding equation (4) with:

$$\widetilde{PSD}_{\mathbf{gW}-\mathbf{V_m}}(f) = \frac{1}{N}\sum_{n=0}^{N-1}\frac{1}{T}\left|FFT\left(\mathbf{gW}-\mathbf{V_m}\right)_N\right|^2 \quad (5)$$

Pseudo spectral density of the absolute value of the turbulent wind vector can be seen as twice the relative TKE (see Equation 3). In Figure 10 are therefore presented the PSD or TKE of the single-lane anemometers set: detail is given to show both the 0 Hz and sub-Hertzian regions of the spectra containing energy. As the single vehicle passage has a main frequency widely above the sub-Hertzian region, the peak frequencies highlighted in Figure 10 can be typical of a certain regularity in the transit process, or to better say the slow separated wave of a column of trucks may be credited with.

6 CONCLUSIONS

It has been demonstrated that a 2D numerical approach is sufficiently accurate for a preliminary study of the drag coefficient and of the flow field related to the truck passing. Furthermore, flow structures above the truck have been successfully described. A direct link between the height of the separation bubble and the number of trucks has also been individuated both using CFD and experimental analysis.
In fact, results obtained from the motorway campaign have demonstrated good agreement with CFD simulations in reconstructing the wind velocity profiles for truck aerodynamic losses. In particular the contribute due to interaction between pressure wave, rear wake, and vehicles gap has proven to distinguish flow in high traffic density, and can be characterized by the proposed experimental set-up.

ABSTRACT: An accurate identification of the aerodynamic characteristics of vehicles and the corresponding bridge is the premise for the coupling vibration analysis of the wind-vehicle-bridge system. At present, the interaction of aerodynamic forces between the road vehicles and bridge is ignored in most researches. In the present study, an experimental setup was made to measure the aerodynamic characteristics of vehicles and the bridge for different cases in a wind tunnel considering the aerodynamic interference. The influence of the wind turbulence, the wind speed, the vehicle interference, and the distance of vehicle from the windward edge of the deck on the aerodynamic coefficients of vehicles, and the influence of vehicles on the static coefficients of the bridge were investigated based on the experimental results. The change reasons of the aerodynamic characteristics of vehicles and the bridge were attempted to be researched and the reliability of the measured results was validated according to the results of surface pressure of the vehicle and the bridge. The measured results showed that the wind turbulence, the vehicle interference, and the vehicle distance from the windward edge significantly affected the aerodynamic coefficients of vehicles. However, the influence of the wind speed on the aerodynamic coefficients of the studied vehicle is small. The static coefficients of the bridge were also significantly influenced by the presence of vehicles.

KEYWORDS: wind-vehicle-bridge system; cross winds; aerodynamic characteristics; aerodynamic interference; wind tunnel tests; numerical simulation.

1 INTRODUCTION

Economic and social developments increase tremendously the traffic volume over bridges and roads. Heavy road vehicles on bridges may significantly change the local dynamic behavior and affect the fatigue life of the bridge. On the other hand, the vibrations of the bridge under cross winds also in turn affect the safety of the road vehicles. These inevitably increase the potential risk of road vehicles moving on a bridge and subjected to strong winds. Thus, it is important to study the dynamic interaction between the bridge, road vehicles, and wind loads for ensuring the safety and normal working performance of both the road vehicles and bridge. Most existent research works focus on either wind action on vehicles running on roadway (Baker, 1986; 1987; 1988; 1991a,b), wind effect on the bridge without considering vehicles (Scanlan, 1990), or vehicle-bridge interaction analysis without considering wind effect (Yang, 1997; Pan, 2002).

For exactly estimating the response of a bridge and the safety of the vehicles moving on the bridge under cross winds, it is necessary to establish an analytical framework of vehicle-bridge-wind interaction. This problem has been noticed and studied by researchers in China and abroad. Xu et al. (2003) have investigated the coupled dynamic analysis of road vehicle and cable-stayed bridge system under turbulent wind. Cai et al. (2004) have built a framework for the vehicle-

bridge-wind aerodynamic analysis, which lays a very important foundation for road vehicle accident analysis based on dynamic analysis results and facilitates the aerodynamic analysis of bridges considering vehicle-bridge-wind interaction. Han and Chen (2007) also presented a state of the art three-dimensional dynamic model of the wind-vehicle-bridge coupling vibration. However, the aerodynamic forces on vehicles in previous studies were either built on the work undertaken by Baker [1991a,b] or obtained from wind tunnel tests, which did not consider the interaction of aerodynamic forces between the road vehicles and the bridge.

The aerodynamic force coefficients of vehicles under wind loads depend on not only the shapes of vehicles but also those of infrastructures, such as the bridge. On the other hand, the aerodynamic parameters of the bridge will be influenced by the vehicles on it. Therefore, in order to predict the performance of vehicle-bridge system under wind loads rationally, it is necessary to study the aerodynamic properties of road vehicles and bridges considering the interaction of aerodynamic forces between the road vehicles and the corresponding bridges. There is a wealth of data pertaining to the wind load coefficients for vehicles on standard 'open ground' scenario (Baker, 1991a; Quinn et al., 2007). However, the corresponding data for bridge decks with vehicles is sparse. Coleman and Baker (1990; 1994) measured the load coefficients of an articulated lorry positioned on the bridge deck model. Minoru Suzuki et al. (2003) carried out three kinds of wind tunnel tests to evaluate the aerodynamic characteristics of typical configurations of vehicles on typical configurations of infrastructures such as bridges and embankments. But the load coefficients of the bridge deck model were not presented. Li et al. (2004) developed a separation device, called the Cross Slot System, to measure the aerodynamic characteristics of the rail vehicle-bridge system taking aerodynamic interaction between the rail vehicle and the bridge into account. Diana and co-workers (Diana, 2004; 2006) undertaken much work on the aerodynamic effects of rail vehicles. Though these researches (Li, 2004; Diana, 2004; 2006) aimed at rail vehicles, the method is worth learning for road vehicles. Han et al. (2011) calculated the load coefficients for a car container running on the bridge and the load coefficients for the bridge were also investigated by numerical simulations (CFD).

This paper developed an experiment technique and carried out a series of wind tunnel experiments to examine the aerodynamic characteristics of vehicles and bridge in the HD-2 wind tunnel at Hunan University. All the measurements were undertaken in static conditions (i.e., with no vehicle movement) over a range of yaw angles from 0^o~90^o. The tests were carried out in both smooth flow and high turbulence flow simulated by a turbulence producing grid.

The experimental set-up adopted for the wind tunnel tests is outlined in Section 2, which illustrates the bridge deck and vehicle geometries and the instrumentation, test conditions and testing procedure, and the characteristics of the simulated wind. Section 3 reports and examines the values of the aerodynamic force/moment coefficients of the vehicle and the bridge corresponding to a variety of configurations tests. More specifically, the six studied cases are presented and compared. Finally, some conclusions are drawn in Section 4. It is found that the wind turbulence, the vehicle interference, and the vehicle distance from the windward edge significantly affected the aerodynamic coefficients of vehicles. However, the influence of the wind speed on the aerodynamic coefficients of the studied vehicle is small. The static coefficients of the bridge were also significantly influenced by vehicles.

2 WIND TUNNEL EXPERIMENTS

The experiment is carried out in the HD-2 wind tunnel of Hunan University that is a low-speed, one-close-circuit medium-sized boundary layer wind tunnel with two parallel test sections.

2.1 *Bridge deck and vehicle geometries*

The models are made with polymethylmethacrylate and the scale is 1:32. The bridge section model is divided into three parts. The intermediate part is the testing model with a length of 1.04 m. The two terminal parts are the compensation models with a length of 0.5 m, the role of which is to avoid the flow around the end and to improve the test precision. The distance between the intermediate part and the terminal part is 0.005 m. The details and dimensions of the bridge deck section and the vehicle are given in Figs. 1a and 1b. The distance between the bottom of the vehicle and the top surface of the bridge deck is 0.015 m. The distance of the vehicle from the bridge deck windward edge is defined by *d* with the values of 0.166 m and 0.547 m corresponding to the two different transverse positions of the vehicle on the bridge deck, windward and leeward, as shown in Fig. 1c. Three vehicles are made to investigate the aerodynamic interference between vehicles, which are laid on the bridge deck with an equal distance of 0.156 m between vehicles along the longitudinal direction, as shown in Fig. 1c. The middle vehicle model is the test vehicle and the terminal vehicle models are the interference vehicles.

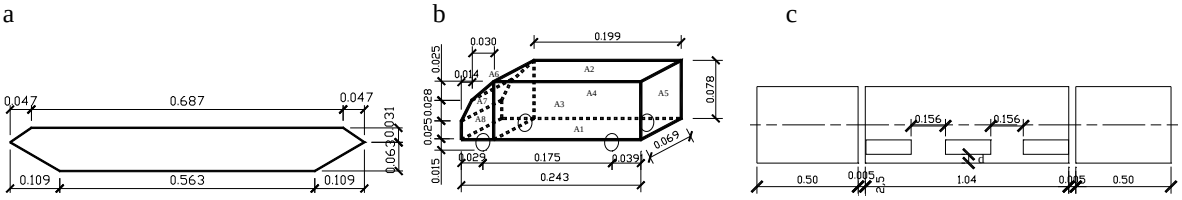

Fig.1 Model geometry and overall dimensions (Unit: m) (a: Bridge cross section model; b: Vehicle model; c: Layout plan of the model)

2.2 *Experimental set-up*

The experimental set-up is composed of three test frames, the middle test frame and the two end compensation frames, as shown in Fig. 2, each of which is composed of three parts, the upper, the middle, and lower parts. The upper part fixes the model to the test frame by using bolts. The middle part is the circular steel tube with a litter smaller diameter, of which the top is connected with the upper part by using bolts and the end is inserted into the circular steel tube of the lower part and fixed with the lantern ring. The lower part is the composite structure of the circular steel tube with a greater diameter and steel bar, which is connected with the rotating table in the wind tunnel by using bolts. In the experimental process, the test frames and the models are rotating with the table together to vary the wind yaw angle.

2.3 *Turbulence wind field simulation*

A passive turbulence generator was developed for generating homogeneous turbulence wind field, as shown in Fig. 3. The characteristics of the generated flow in the wind tunnel were measured by a TFI Series 100 cobra probes (Turbulent Flow Instrumentation). The turbulence intensity at the deck height was approximately 10% in the flow direction. The longitudinal integral scale for the streamwise velocity was 0.5 m which is well above the vehicle height (or length or width); thus ensuring that the turbulent structures are well correlated over the vehicles.

Fig. 4 indicates the power spectral density of the approaching streamwise velocity. To facilitate a comparison between the wind tunnel simulation and the target spectrum at full scale (i.e., the Von Karman Spectrum) both the axes in Fig. 4 have been non-dimensionalized. The horizontal axis represents the reduced frequency ($\overline{f} = f.L_u / U$) defined by the product of the frequency (*f*) and the turbulence length scale (L_u), divided by the reference mean wind speed. On the vertical axis the spectrum is multiplied by the frequency and divided by the mean velocity variance. The experimental and target spectra agree qualitatively well over a large proportion of the reduced frequency range, which suggests that the turbulence simulation is sufficient for the current purposes.

2.4 *Force measurements*

The forces on the bridge and the vehicle were determined by integrating the pressure of the pressure taps measured using electronically scanning pressure measurement system. The bridge model was installed with 329 pressure-taps, mounted flush with the surfaces of the bridge model and connected to the pressure transducers via flexible tubing. Seven pressure-tapped strips were located along the span of the bridge deck, as shown in Fig. 5a, to take into account the span-wise correlation of the aerodynamic forces. Each pressure-tapped strip has 47 pressure-taps representing the surface pressure distributions, as shown in Fig. 5b. The vehicle model was installed with 200 pressure-taps, as shown in Fig. 6. Figs. 7 and 8 outline the sign conventions for aerodynamic forces of the bridge and the vehicle, respectively.

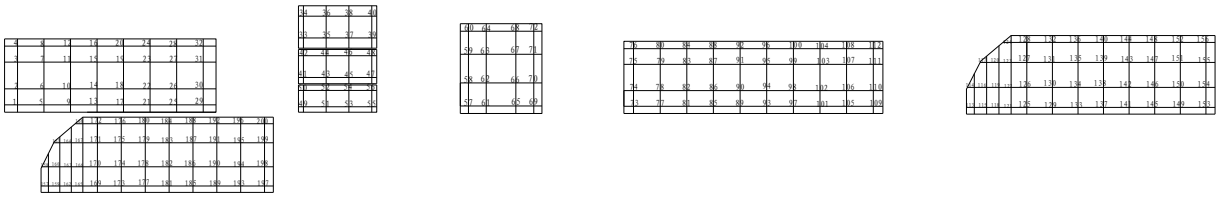

Fig. 6 The positions and notions of pressure-taps for each surface of the vehicle: (a) Top surface; (b) Frontal surface; (c) Back surface; (d) Bottom surface; (e) Left side surface; (f) Right side surface

The instantaneous fluctuating surface pressure at time t in a particular strip (j=1-7) were integrated independently over each of the seven pressure-tapped strips. The lift force $F_{Vj}(t)$, drag force $F_{Hj}(t)$ and the pitching moment $M_j(t)$ per unit span length of the bridge deck were calculated according to Equations (1a), (1b) and (1c), respectively, as:

$$F_{Vj}(t)=\sum_{i=1}^{47} p_{ij}(t)\Delta A_{ij}\cos(\alpha_{ij}) \qquad (1a)$$

$$F_{Hj}(t)=\sum_{i=1}^{47} p_{ij}(t)\Delta A_{ij}\sin(\alpha_{ij}) \qquad (1b)$$

$$M_j(t)=\sum_{i=1}^{47} p_{ij}(t)\Delta A_{ij}d_{Hij}\sin(\alpha_{ij})+\sum_{i=1}^{47} p_{ij}(t)\Delta A_{ij}d_{Vij}\cos(\alpha_{ij}) \qquad (1c)$$

where $p_{ij}(t)$ = the instantaneous fluctuating surface pressure of the bridge at time t; ΔA_{ij} = the tributary area of a pressure-tap of the bridge; α_{ij} = angle between the local (pressure-tap) and vertical axis; and d_{Hij}, d_{Vij} = pitching moment arms about the centre of the bridge deck.

The instantaneous fluctuating surface pressures at time t were integrated independently over each surface of the vehicle. The side force $F_S(t)$, lift force $F_L(t)$, drag force $F_D(t)$, pitching moment $F_P(t)$, yawing moment $F_R(t)$, and rolling moment $F_R(t)$ of the vehicle were calculated according to Equations (2a), (2b) and (2c), respectively, as:

$$F_S(t)=\sum_{i=1}^{200} p_i(t)\Delta A_i\Theta_{Si} \quad (2a) \qquad F_L(t)=\sum_{i=1}^{200} p_i(t)\Delta A_i\Theta_{Li} \quad (2b) \qquad F_D(t)=\sum_{i=1}^{200} p_i(t)\Delta A_i\Theta_{Di} \quad (2c)$$

$$F_P(t)=\sum_{i=1}^{200} p_i(t)\Delta A_i\Theta_{Li}d_{(L\text{-}S)i}+\sum_{i=1}^{200} p_i(t)\Delta A_i\Theta_{Di}d_{(D\text{-}S)i} \quad (2d)$$

$$F_Y(t)=\sum_{i=1}^{200} p_i(t)\Delta A_i\Theta_{Si}d_{(S\text{-}L)i}+\sum_{i=1}^{200} p_i(t)\Delta A_i\Theta_{Di}d_{(D\text{-}L)i} \quad (2e)$$

$$F_R(t)=\sum_{i=1}^{200} p_i(t)\Delta A_i\Theta_{Li}d_{(L\text{-}D)i}+\sum_{i=1}^{200} p_i(t)\Delta A_i\Theta_{Si}d_{(S\text{-}D)i} \quad (2f)$$

where $p_i(t)$ =the instantaneous fluctuating surface pressure of the vehicle at time t; $\Delta A_i(t)$ the tributary area of a pressure-tap of the vehicle; Θ_{Fi} ($F=S, L, D$)= the decomposition coefficients of surface pressure along the direction of side, lift, or drag force; $d_{(L\text{-}S)i}$ and $d_{(D\text{-}S)i}$ =horizontal moment arms of lift force and vertical moment arm of drag force contributing to the pitching moment, respectively; $d_{(S\text{-}L)i}$ and $d_{(D\text{-}L)i}$ = horizontal moment arms of side force and horizontal moment arm of drag force contributing to the yawing moment, respectively; $d_{(S\text{-}D)i}$ and $d_{(L\text{-}D)i}$.= vertical moment arm of side force and horizontal moment arms of lift force contributing to the rolling moment, respectively.

Based on the integrated lift force, drag force, and pitching moment, the corresponding force and moment coefficients of the bridge were determined according to Equations (3a), (3b) and (3c), respectively, as:

$$C_{F_H}=\frac{1}{7}\sum_{j=1}^{7}\frac{\bar{F}_{Hj}}{0.5\rho U^2B} \quad (3a) \qquad C_{F_V}=\frac{1}{7}\sum_{j=1}^{7}\frac{\bar{F}_{Vj}}{0.5\rho U^2B} \quad (3b) \qquad C_M=\frac{1}{7}\sum_{j=1}^{7}\frac{\bar{M}_j}{0.5\rho U^2B^2} \quad (3c)$$

where ρ = the air density; U = the mean wind speed on the elevation of the bridge; $\bar{F}_{Hj}$, $\bar{F}_{Vj}$ and $\bar{M}_j$ = the time averaged values of the lift force, drag force, and pitching moment in equations (1a), (1b) and (1c) over the required time period for Strip j; and B= the width of the bridge deck.

Based on the integrated side force, lift force, drag force, pitching moment, yawing moment, and rolling moment, the corresponding force and moment coefficients of the vehicle were determined according to Equations (4a)-(4f), respectively, as:

$$C_S(\psi)=\frac{\bar{F}_S}{0.5\rho V^2A} \quad (4a) \qquad C_L(\psi)=\frac{\bar{F}_L}{0.5\rho V^2A} \quad (4b) \qquad C_D(\psi)=\frac{\bar{F}_D}{0.5\rho V^2A} \quad (4c)$$

$$C_P(\psi)=\frac{\bar{F}_P}{0.5\rho V^2Ah} \quad (4d) \qquad C_Y(\psi)=\frac{\bar{F}_Y}{0.5\rho V^2Ah} \quad (4e) \qquad C_R(\psi)=\frac{\bar{F}_R}{0.5\rho V^2Ah} \quad (4f)$$

where $\bar{F}_S$, $\bar{F}_L$, $\bar{F}_D$, $\bar{F}_P$, $\bar{F}_Y$ and $\bar{F}_R$ = the time averaged values of the side force, lift force, drag force, pitching moment, yawing moment, and rolling moment in equations (2a)-(2f) over the required time period; A= frontal area of the vehicle; h is the distance from the gravity center of the vehicle to the road surface; and V is the relative wind speed to the vehicle, of which the specification is shown in Fig. 9.

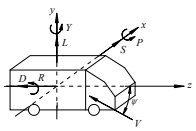

Fig. 8 Sign convention for aerodynamic forces of the bridge

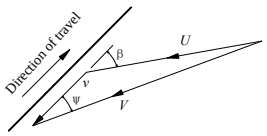

Fig. 9 Velocities and directions

In Fig. 9, v is the vehicle speed; ψ is the relative wind yaw angle to the vehicle; β is the angle between the wind direction and the vehicle direction of travel, and $\psi=\beta$ in this paper.

2.5 *Test configurations and experimental procedure*

Table 1 outlines the experimental configurations examined in the current work. In order to vary the yaw angle for the vehicle, the bridge and vehicle were simply rotated with respect to the oncoming wind together with the test frame and the rotating table in the wind tunnel. Seven yaw angles of 0^o, 15^o, 30^o, 45^o, 60^o, 75^o and 90^o were investigated. To investigate the influence of wind velocity, two velocities of 10 m/s and 20 m/s were adopted. Three vehicles were laid on the bridge deck with an equal distance of 0.156 m between the vehicles along the longitudinal direction to investigate the aerodynamic interference between the vehicles. The tests were carried out in smooth flow and turbulent flow with approximately 10% turbulence intensity described in Section 2.3. The local wind field of the surface of the bridge deck is expected to be modified as a result of the vehicle. Also, the local wind field of the vehicle is expected to be modified as a result of the bridge. Then, the vehicle model was positioned at two different locations corresponding to windward and leeward lanes.

Table 1 Measured cases in wind tunnel

Cases	Testing objects	Wind Velocity (m/s)	Wind field	Distance (d) of vehicle from the wind ward edge of the deck (m)	Wind yaw angle (^{o})
1	Bridge with one vehicle	10	Smooth	0.166	0, 15, 30, 45, 60, 75, 90
2	Bridge with one vehicle	20	Smooth	0.166	0, 15, 30, 45, 60, 75, 90
3	Bridge with one vehicle	10	Smooth	0.547	0, 15, 30, 45, 60, 75, 90
4	Bridge with one vehicle	10	Turbulent	0.166	0, 15, 30, 45, 60, 75, 90
5	Bridge with three vehicles	10	Smooth	0.166	0, 15, 30, 45, 60, 75, 90
6	Bridge with no vehicle	10	Smooth	0	0, 15, 30, 45, 60, 75, 90

3 EXPERIMENTAL RESULTS AND DISCUSSION

3.1 *Aerodynamic force coefficients*

Figure 10 illustrates the variation of force and moment coefficients of the vehicle with respect to the yaw angle ψ for cases 1and 5. It can be seen that for case 1, the side force coefficient C_S increases with the increase of the yaw angle ψ and reaches a maximum value at around 90^o yaw angle. But the increment between the yaw angles of 60-90 degrees is less significant. Such a trend is similar to that shown in the literature (Baker, 1991a; Coleman, 1990), although it is noted that the maximum values typically occur between yaw angles of 60-90 degrees. The lift force coefficient C_L increases and then decreases with the increase of the yaw angle ψ, and reaches a maximum value at around 30^o yaw angle, which is positive for $15^o<\psi<60^o$, and negative for other yaw angles. The positive values (sign convention shown in Fig. 8) of C_L are not good for traffic safety. The magnitude of the drag force coefficient C_D increases to a maximum at $\psi=30^o$ and then decreases to near zero for $\psi=90^o$, i.e. pure cross wind conditions, which seems reasonable. The aerodynamic moments reflect the trends of the aerodynamic forces. The yawing moment coefficient, determined mainly by the horizontal moment arm of the drag force, and to a lesser extent of that of the side force, shows similar variations to those observed in the drag force coefficient. The pitching moment and rolling moment results, relatively small, are changing irregularly, and are probably affected by some unknown experimental error.

In addition, from the comparison of the results for cases 1 and 5 (one vs. three vehicles in Fig. 10), it can be seen that the change trend of the aerodynamic coefficients is similar for the two cases, except for the pitching moment coefficient. The side force coefficient C_S in case 5

with three vehicles is obviously less than that in case 1 with one vehicle for $\psi<45^o$ because of the blocking effect of the frontal vehicle on the middle vehicle, i.e. the test vehicle. When the blocking effect is not obvious for $\psi>45^o$, the side force coefficient C_S for case 5 is slightly larger than that in case 1 due to the effect of the frontal and posterior vehicles on the surrounding flow field. There is a obvious difference in the lift force coefficient C_L between cases 1 and 5, especially for 30^o yaw angle, at which the lift force coefficient C_L for case 5 is obviously less than that in case 1, which means the effect of frontal and posterior vehicles is good for traffic safety. The frontal vehicle affects the drag force coefficient C_D greatly, which reduces the magnitude of the drag force coefficient C_D, especially for $\psi<60^o$. The magnitudes of the pitching moment coefficient C_P and the yawing moment coefficient C_Y for case 5 are less than those in case 1, while the rolling moment coefficient C_R is generally larger (in absolute values) due to the interference of frontal and posterior vehicles.

Figure 11 illustrates the variation of the aerodynamic force coefficients of the vehicle with respect to yaw angle ψ for cases 1and 4 (smooth vs. turbulent flow). It can be seen that the side force coefficient C_S for turbulent flow is smaller than that in the smooth flow and the difference increases with the increase of the yaw angle. The turbulence effects on the lift force coefficient C_L is not obviously for low yaw angles. For $\psi>40^o$, the lift force coefficient C_L in turbulent flow is significantly greater than that in the smooth flow case. The magnitude of the drag force coefficient C_D for the turbulent flow is smaller than that in the smooth flow for $\psi<45^o$, and slightly greater for $\psi>45^o$. The turbulence reduces the yawing moment basically and affects the pitching and rolling moment irregularly.

A further investigation on the influence of the distance of the vehicle from the windward edge of the deck on the aerodynamic force coefficients is illustrated in Figure 12 which shows the evolution of the aerodynamic coefficients with respect to the two distances (i.e., d=0.166 m and 0.547 m corresponding to cases 1 and 3). For $\psi<30^o$, there is a good agreement between the results of the side force coefficient C_S in the two cases. But the increase of the distance reduces C_S greatly for $\psi>30^o$. At zero degree yaw angle, the lift force coefficient C_S is not affected by the distance. But it decreases with the increase of distance d for $\psi<40^o$, and increases for $\psi>40^o$. The increase of the distance increases the magnitude of the rolling moment coefficient C_R for all yaw angles, except for 30 degree. The changing of the distance affects the drag force, pitching moment, and yawing moment coefficients insignificantly.

Figure 13 shows the variation of the aerodynamic force coefficients of the vehicle with respect to the yaw angle ψ for cases 1 and 2 (10 vs. 20 m/s wind velocity) to investigate the effect of the wind speed on the coefficients. It can be seen that three is very little difference between the results for all the aerodynamic force coefficients, which is perhaps not surprising since the vehicle model has sharp windward edges. As a result, the coefficients will be little affected by the Reynolds number (i.e. the wind velocity here).

Table 2 gives the static aerodynamic force coefficients of the bridge for cases 6, 1, 5 and 3 at the 90^o yaw angle. The results show that the aerodynamic force coefficients of the bridge are affected by the vehicles greatly, especially for lift force coefficient C_V, which increases significantly with the increase of the vehicle number. The drag force coefficient C_H with one vehicle is obviously greater than that with no vehicle, but little smaller than that with three vehicles, which indicates the drag force coefficient C_H is independent of the number of vehicles. The magnitude of the pitching moment coefficient C_M with three vehicles is significantly greater than that with one vehicle or with no vehicle, but there is little difference between the results with one vehicle and with no vehicle. The distance of the vehicle from the windward edge of the bridge deck affects the aerodynamic force coefficients of the bridge greatly. It not only affects the magnitude but also the direction.

3.2 *Pressure distribution*

A further investigation on the change reasons of the aerodynamic forces for the vehicle and the bridge is illustrated in the following figures, showing the surface pressure distribution of the vehicle and the bridge. Figure14 gives the pressure contour maps of the windward side surface of the vehicle at the 90^o yaw angle for cases 1, 4, 5 and 3. Figure 15 gives the pressure contour maps of the frontal surface of the vehicle at the 0^o yaw angle for cases 1 and 5. Figure 16 shows the pressure distribution of the top pressure taps of the middle strip of the bridge deck at the 90^o yaw angle for cases 1, 3, 5 and 6. It can be seen from these figures that there are no abnormal values for all pressure taps, demonstrating the accuracy and reliability of the experimental results.

From Figures 14(a) and 14(c), it can be seen that there is a good agreement between the pressure contour maps, which verifies that the effect of the frontal and posterior vehicles on the side force coefficient C_S is not obvious, just as shown in Figure 10(a). By comparing Figure 14(a) with Figure 14(b), it can be seen that the pressure for case 4 is obviously smaller than that in case 1, which explains the decrease of the side force coefficient C_S in turbulence flow at the 90^o yaw angle, as shown in Figure 11(a). Though the pressure in case 3 is not smaller than that in case 1, as illustrated in Figures 14(a) and 14(d), the high pressure area becomes small, which decreases the side force coefficient C_S at the 90^o yaw angle obviously, as shown in Figure 12(a).

As illustrated in Figures 15(a) and 15(b), the pressure in case 5 is obviously smaller that in case 1 for the blocking effect of the frontal vehicle, which is the main reason for the obvious decrease of the drag force coefficient C_D at the 0^o yaw angle, as shown in Figure 10(c).

From Figure 16, it is observed that for case 6 (with no vehicle), the pressure is negative, that is, the measured point is subjected to a tensile force with an upward direction (i.e. the positive direction of life force). The pressure increases (the absolute value decreases) with the increase of the distance from the windward edge and then basically remains unchanged after the

distance is up to a certain value. For case 1 (one vehicle with d=0.166m), the pressure of the measured point located in front of the vehicle on the windward side increases sharply with the increase of the distance due to the blockage effect of the vehicle, changing from negative to positive. The pressure turns to be negative when the measured point is located under the vehicle and approaches to the value like that in case 6. The magnitude of the pressure for case 1 is larger than that in case 6 with the direction upward, which leads to the lift force coefficient C_V to change correspondingly. For case 5 (with three vehicles), the variation of the pressure is similar to that in case 1, except for the pressure taps in front of the windward side of the vehicle. Since there are three strips of the bridge deck (as shown in Figure 3(a)) affected by the vehicles, the lift force coefficient C_V in case 5 is obviously higher than that in case 1. For case 3 (one vehicle with d=0.547m), the pressure increases with the increasing of the distance, turns from negative to positive, but decreases sharply near the vehicle and becomes negative. There are half measured points that have positive pressure values with a downward direction. As a result, the lift force coefficient C_V in case 3 is negative and is lower than that in case 6. From the above analysis, it is not hard to understand the change reason of the lift force coefficients presented in table 2.

4 CONCLUSIONS

The present work has investigated the aerodynamic force coefficients of the vehicle and the bridge by carrying out six experimental tests in wind tunnel. Based on the experimental results, the following conclusions can be drawn:

(1) The analysis of surface pressure distributions of the vehicle and bridge proves that experimental results in this paper are accurate and reliable.

(2) The aerodynamic coefficient is obviously a function of the yaw angle. The side force coefficient C_S increases with the increase of the yaw angle ψ, the lift force coefficient C_L increases and then decreases with the increase of the yaw angle ψ, the drag force coefficient C_D increases and then decreases with the increase of the yaw angle ψ, the yawing moment coefficient shows similar variations to those observed in the drag force coefficient, and the pitching moment and rolling moment results are relatively small.

(3) The interference of vehicles, the flow turbulence, and the cross position of vehicles largely affect the aerodynamic force coefficients of vehicles, but the wind velocity basically has no influence on these coefficients. The effects of the number of vehicles and the distance of vehicles from the windward edge on the aerodynamic force coefficients of bridges are strong. When there is a vehicle or no vehicle on the bridge, the aerodynamic force coefficients of the bridge is largely affected, just as do the number of vehicles and the distance of vehicles from the windward edge.

(4) There are still many factors that may affect the aerodynamic force coefficients of the vehicle, such as the configuration of the bridge cross section, the vehicle type, and the running environment (on bridge, embankment, or ground). These factors should be studied to develop empirical formulas to calculate the aerodynamic forces for typical vehicles.

(5) It is known that vehicles on bridges have significant effect on the static aerodynamic forces of the bridge. How much effect of the vehicle on other aerodynamic forces of the bridge, such as the self-excited force and buffeting force, and on the wind-induced vibrations of the bridge is worth a further study.

Control of the aerodynamic drag of Ahmed model with slot jet

Wang Hanfeng [a], Xu Mengxia [a]

[a]*National engineering laboratory for high-speed railway construction, Central South University, Changsha, China*

ABSTRACT: The effects of a slot jet on the aerodynamic drag of an Ahmed model with the slant angle of 25º is investigated using LES technique. Three jet directions are considered, i.e. along slant surface (case 1), backwards horizontally (case 2) and 30º inclined upward (case 3). There is a pair of symmetrical streamwise tail vortices, which accounts for a major part of the aerodynamic drag. The slot jet has significant effects on the near wake and aerodynamic drag. For case 1, the tail vortices are enhanced and the drag is increased by about 0.91%. While for cases 2 and 3, the application of slot jet extends the reverse flow zone and suppresses the tail vortices. The total aerodynamic drag reduces by 7.88% and 3.64% for these two cases, respectively.

KEYWORDS: Ahmed model, Tail vortex, Flow control, Drag reduction, LES.

1 INTRODUCTION

Control of the aerodynamic drag of a road vehicle is one of the most important research problems about vehicle aerodynamics, which is directly related to the fuel efficiency. Generally, the drag of a vehicle is proportion to the square of its speed. The aerodynamic drag on a road vehicle typically accounts for about 70% of its total resistance when its speed reaches 90 Km/h. The control of aerodynamic drag becomes widely concerned because of the skyrocketing fuel cost and increasing environmental burden from fossil fuels.

The geometrical figure of road vehicle is usually a three-dimensional (3D) bluff body. The aerodynamic drag on a bluff body is largely determined by the pressure difference between its front and rear end[1, 2], and closely related to the flow separation near the rear end[1]. The flow in the near wake of this 3D bluff body is highly complex, unsteady. To facilitate the comparative aerodynamic studies, Ahmed[3] proposed a generic vehicle configuration, named "Ahmed model". Despite that the Ahmed model has been proposed for nearly three decades, it is still frequently used for the investigation of the 3D wake flow and aerodynamic performance for road vehicles[4-7]. The near wake structure and consequently the aerodynamic drag of Ahmed model strongly depend on the rear slant angle[2, 3]. For the slant angle of approximately 25º to 30º, large longitudinal vortex structures occur in the near wake, which lead to a considerable increase in aerodynamic drag.

Recently, the flow control techniques have been more and more studied for drag reduction, with the Ahmed model as a benchmark[7]. Some passive control methods, such as: tail clapboards[8], flaps near the flow separation point[9] and deflector[10] etc., have been successfully used for drag reduction. However, most of these passive control techniques introduce quite unsightly appendages on the body, which is in contradiction with design constraints[7]. This fact makes active control by jet and/or suction very attractive. For Ahmed model with the slant angle of 25º, Roumeas *et al.*[11] used steady aspiration on the top edge of the slant and obtained about 17% drag reduction. Krajnovic *et al.*[12] made numerical simulations of the same case and obtained a little bit more than 7% reduction using steady blowing and suction at the slant top edge.

In the present paper, the flow around and the aerodynamic drag on an Ahmed model with a slant angle of 25º are investigated using large eddy simulation (LES) technique. A slot jet at

slant top edge is employed to control the flow. Three jet directions are presently studied to examine the effects of jet direction on the near wake flow structure and aerodynamic drag.

2 LES & CONTROL CASES

2.1 *LES method*

The governing equations of LES are the incompressible Navier-Stokes and the continuity equations filtered with the implicit spatial filter of characteristic width Δ, which is the grid resolution. The goal of this filtering is to decompose the fluid motion into a large-scale component that is resolved directly, and the small subgrid scale (SGS) which is modeled using SGS model. The filtered LES equations are shown in Eqs. (1 & 2), where the overbar denotes the filtered variable, ρ and ν are the density and kinematics viscosity of fluid, respectively.

$$\frac{\partial \overline{u}_i}{\partial x_i} = 0 \tag{1}$$

$$\frac{\partial \overline{u}_i}{\partial t} + \frac{\partial \overline{u}_i \overline{u}_j}{\partial x_j} = -\frac{1}{\rho}\frac{\partial p}{\partial x_i} + \nu \frac{\partial^2 \overline{u}_i}{\partial x_i \partial x_j} - \frac{\partial \tau_{ij}}{\partial x_j} \tag{2}$$

The influence of the small scale turbulence on the large energy carrying scales in Eq. (2) appears in the SGS tensor, $\tau_{ij} = \overline{u_i u_j} - \overline{u}_i \overline{u}_j$ [4]. The algebraic eddy viscosity model proposed by Smagorinsky[13], shown in Eq. (3), is presently used for its simplicity and low computational cost, where the SGS viscosity $\nu_t = (C_s \Delta)^2 \left|\overline{S}\right|$. $\left|\overline{S}\right|$ is the resolved rate-of-strain tensor, and $\left|\overline{S}\right| = (2\overline{S}_{ij}\overline{S}_{ij})^{0.5}$, where $S_{ij} = \frac{1}{2}(\frac{\partial \overline{u}_i}{\partial x_j} + \frac{\partial \overline{u}_j}{\partial x_i})$. The filter width Δ is defined as $\Delta = (\Delta_x \Delta_y \Delta_z)^{1/3}$, where Δ_i are the computational cell sizes in three coordination directions. Readers may refer to Krajnovic & Davidson[4] for detailed description of the LES method presently used.

$$\tau_{ij} = \overline{u_i u_j} - \overline{u}_i \overline{u}_j = -2\nu_t \overline{S}_{ij} + \frac{\tau_{kk}\delta_{ij}}{3} \tag{3}$$

2.2 *Generic vehicle mode and numerical details*

An Ahmed model with the slant angle of 25º is presently investigated. The dimensions are shown in figure 1(a), the length (l), width (w) and height (h) are 1044 mm, 389 mm and 288 mm, respectively. The computational domain is 8l in length, 10w in width and 5h in height. The model is 2l from the inlet and 50mm above the bottom wall. The blockage ratio is 2%. Definition of the coordinate system is shown in figure 1(b).

The computational domain is meshed into hexahedrons. The grid size reduces gradually with the wall approached, so that most of the grids concentrate around the Ahmed model. The total number of grid is about 180 million. The y^+ on the model surface ranges from 0.7 to 33, which is considered enough to capture the larger scale flow structure.

A uniform velocity U_∞ of 25m/s is used as the inlet boundary layer condition in present LES. Corresponding Reynolds number, based on U_∞ and l, is 1.75×10^6. Pressure boundary condition is used at the exit of computation domain. The lateral and ceiling surfaces of the computa-

tional domain are treated as slip surfaces using symmetry condition. No slip boundary layer conditions are used on the surfaces of Ahmed model and ground wall.

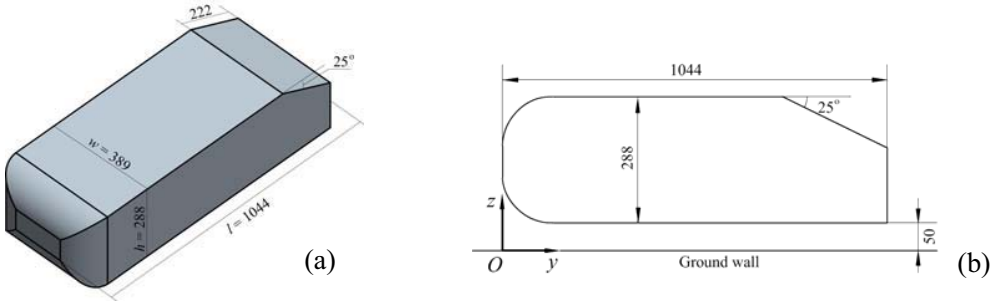

Figure 1. Generic vehicle model and control cases: (a) dimension of Ahmed model, (b) definition of the coordinate system. All dimensions are in mm.

2.3 *Control cases*

To manipulate the near wake flow and subsequently the aerodynamic drag on the Ahmed model, a slot jet at the top edge of the slant surface was used. Three different jet directions were tested. For case 1, the direction of the slot jet is along the slant surface, for case 2, the jet is horizontally backwards, while for case 3, the jet direction is inclined upwards with an angle of 30º, as shown in figure 2. To provide a benchmark, the case without control was taken as case 0. The length of the slot was equal to the width of the model, and the width of slot is 11 mm, 5% of the slant length. The slot jet velocity (U_J) is 9 m/s for the three cases, corresponding to a jet intensity c_μ = 5×10^{-3}. c_μ is defined by Eq. (4)[14], in which A_J and A_B are the projected area of the slot jet and the Ahmed body in flow direction, respectively.

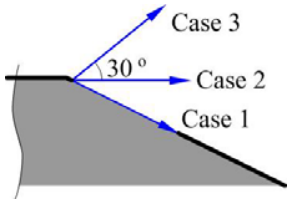

Figure 2. Configuration of control cases.

$$c_\mu = \frac{A_J}{A_B} \cdot \frac{U_j^{\,2}}{U_\infty^{\,2}} \tag{4}$$

3 RESULTS & DISCUSSIONS

3.1 *The new wake flow structures*

Figure 3 presents the isosurfaces of instantaneous streamwise vorticity, i.e., ω_y^*. In present paper, the superscript asterisk represents the normalization with U_∞ and/or l. Obviously, the near wake is highly complex and 3D. A pair of streamwise tail vortices occurs near the side edges of slant face (as shown in figure 3), similar to that observed by Vino *et al.*[15] with smoke visualization technique. The time-averaged near wake structure is shown in figure 4, together with the schematic near wake structure proposed by Ahmed *et al.*[3] for comparison. The shear layers from the ceiling and bottom surfaces form a recirculation zone downstream the body. A pair of symmetrical tail vortices dominates the near wake, which is responsible for a significant part of

the lift and drag[16]. The time averaged flow structure of present LES, as shown in figure 4(b), corresponds well with the proposed flow model, which validates the present results. For an Ahmed model with the slant angle of 25º, the reported drag coefficient (C_D) was scattered for different techniques, e.g. 0.30 by Ahmed et al.[3] and 0.32 by Vino et al.[15] The present C_D for case 0 is 0.33, which will be used as a benchmark to evaluate the effectiveness of the slot jet on drag reduction.

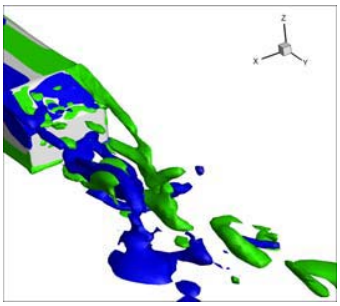

Figure 3. Isosurfaces of instantaneous streamwise vorticity, $\left|\omega_y^*\right| = \pm 6$.

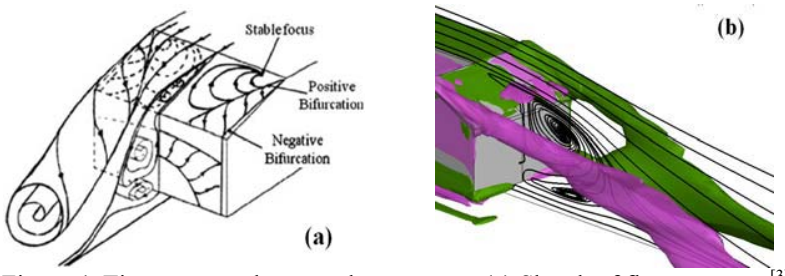

Figure 4. Time-averaged near wake structure: (a) Sketch of flow structure[3], (b) Present LES result.

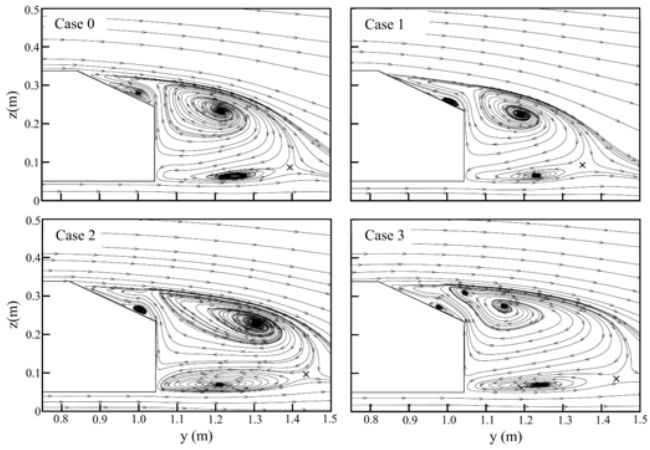

Figure 5. Time-averaged sectional streamlines in the central symmetry plane for different cases.

The time-averaged sectional streamlines in the central symmetry plan are shown in figure 5 for the four cases. The shear layers from the top and bottom surfaces of the model form a reverse flow zone. Under the effects of the negative pressure on slant and rear end, the upper shear layer exhibits a strong downwash and forms a saddle point, denoted by "×", with the lower shear layer. The streamwise position of this saddle point can represent the length of the reverse flow zone. For case 1, the downwash becomes more remarkable and the saddle point shifts upstream to the model, which suggests that the reverse flow zone shrinks in case 1. Contrarily, the down-

wash flow becomes weaker and the streamwise extent of reverse flow zone enlarges in cases 2 and 3. For a 2D bluff body, the length of reverse flow zone is in contrast with the aerodynamic drag[17]. In view of the extended reverse flow zone in cases 2 and 3, the corresponding aerodynamic drag may reduces, which will be discussed in detail later.

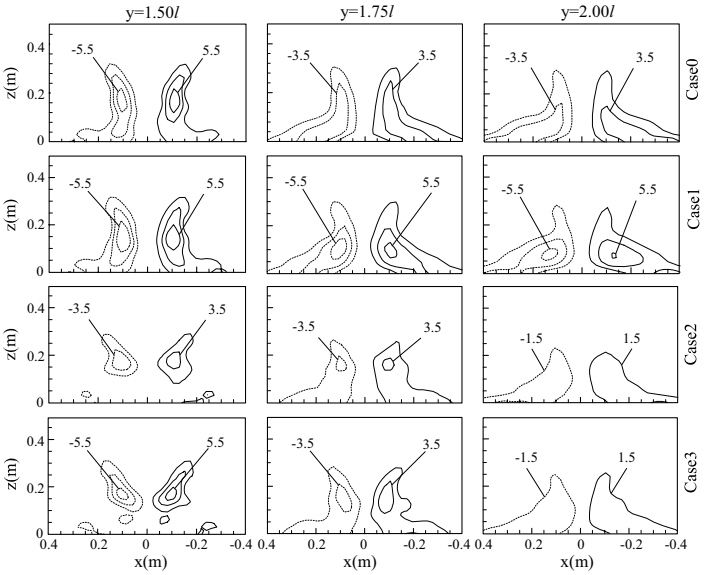

Figure 6. Time-averaged normalized streamwise vorticity ω_y^* for different cases (contour interval=2.0).

Figure 6 presents the time-averaged ω_y^* contours at different downstream positions for the four cases. For case 0, i.e. without control, there is a pair of symmetrical streamwise vortices, which decays monotonously as moving downstream for the three y positions as shown in figure 6. Obviously, this pair of tail vortices is associated with the downwash flow from the slant, as shown in figure 4. Although, the intensity of tail vortices is the same for case 0 and case 1 at y = 1.5l, the size of these vortices is slightly larger for the later. For case 1, the vortex intensity does not diminish with increasing y. This observation may be ascribed to the effects of the slot jet along slant surface. The slot jet in case 1 enhances the downwash flow (as shown in figure 5) and subsequently the associated tail vortices. For cases 2 and 3, the application of slot jet noticeably suppresses the tail vortices, especially for the former. For example, at y = 1.5l, the maximum of ω_y^* is 3.5, about 64% of that for case 0. The application of slot jet in cases 2 and 3 increases the decaying rate of tail vortices. At y = 2.0l, the maximum of ω_y^* is 1.5, about 43% of that for case 0. Since the tail vortices are responsible for a significant part of the aerodynamic drag[16], the variation of tail vortices as shown in figure 6 suggests that the slot jet has significant effects on the aerodynamic drag.

3.2 *Pressure distribution and aerodynamic drag*

Pressure coefficients (C_p) on the slant and rear end are presented in figure 7 for the four cases, which is defined as $C_p = 2(p - p_\infty)/\rho U_\infty^2$, where p_∞ is the static pressure of oncoming flow, ρ is the density of air. For case 0, the pressure gradient is remarkable near the top and side edges of the slant surface, suggesting strong flow separation there which forms the tail vortices. For case 1, the slot jet is along the slant, which reinforces the momentum of shear flow and may postpone the flow separation. Consequently, the absolute value of C_p on the slant is slightly smaller for

case 1 than for case 0. However, the absolute value of C_p on rear end for case 1 is larger than that for case 0. That is, the slot jet at the top edge of slant changes not only the pressure distribution on the slant surface, but also alters the whole wake flow. For cases 2 and 3, the extremum of C_p on the slant is -0.25, slightly higher than -0.3 for case 0. On the rear end, although the extremum of C_p for case 2 is the same with case 0, the range of the contour of -0.2 is obviously larger for the former. For case 3, the extremum of C_p is -0.2 one the rear end, slightly smaller than the corresponding value of -0.15 for case 0.

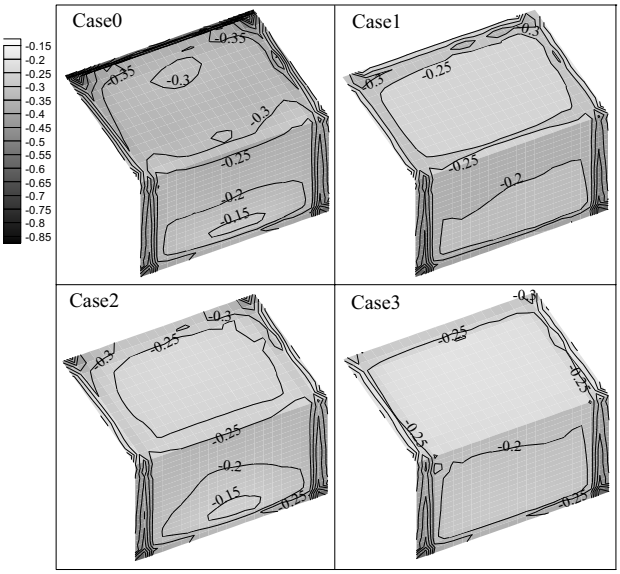

Figure 7. Pressure coefficient on the slant and rear end (contour interval=0.05).

Table 1. Drag coefficients of the model and its different parts.

	Case0	Case1	Case2	Case3
Drag from the front end, C_{D_front}	0.020	0.020	0.020	0.022
Drag from the side walls, $C_{D\_sidewall}$	0.043	0.043	0.042	0.042
Drag from the slant, C_{D_slant}	0.103	0.099	0.084	0.091
Drag from the rear end, C_{D_back}	0.164	0.171	0.158	0.163
C_D	0.330	0.333	0.304	0.318
Drag reduction efficiency	---	-0.91%	7.88%	3.64%

To highlight the effects of slot jet on the aerodynamic drag, table 1 lists the overall drag coefficients C_D and its components from different parts of the Ahmed model. For all cases, the drag from the front end of the model is almost unchanged, suggesting that the application of slot jet does not noticeably change the flow near the head. The drag from side walls is largely dominated by the turbulence friction on side walls, which is related to the Reynolds number, wall roughness etc. The present slot jet does not change $C_{D\_sidewall}$, similar to that observed for C_{D_front}. Both C_{D_front} and $C_{D\_sidewall}$ account for a small portion of total aerodynamic drag. As listed in table 1, most C_D results from the negative pressure distribution on the slant and rear end, consistent with that proposed by Drouin *et al.*[16]. For case 1, although the application of slot jet reduces slightly the drag on slant, C_{D_back} is increased by about 4.3%, which is consistent with the pressure distribution shown in figure 7. The total drag reduction for case 1 is -0.91%, i.e., C_D for case 1 is slightly bigger than that for case 0. Cases 2 and 3 reduce C_D by 7.88% and 3.64%, respectively.

Considering the effects of slot jet on the near wake structure, following observations can be made. Firstly, C_D is inversely correlated with the length of reverse flow zone, i.e. a smaller

length corresponds to a larger C_D. Secondly, C_D is inversely correlated with the strength of tail vortices. A horizontal slot jet, i.e. case 2, suppresses the tail vortices significantly and results in the smallest C_D for present invested cases. While for case 1, the tail vortices are enhanced and the corresponding C_D is slightly bigger than that without control. Finally, the application of slot jet at the top edge of slant modifies not only the pressure distribution on the slant, but also changes that on the rear end. The total C_D largely comes from the slant and rear end. To evaluate the over all drag reduction efficiency, the combined effects on both slant and rear end should be considered.

4 CONCLUSIONS

A steady slot jet at the top edge of the slant of an Ahmed model is used to control the aerodynamic drag. The slant angle is 25º. Three slot jet directions are investigated using LES technique. For case 1, the slot jet is along the slant surface; for case 2, it is horizontally backwards; and for case 3, it is inclined upwards by 30º relative to the horizontal direction. Based on the simulation results, the following conclusions can be drawn:

(1) There is a pair of symmetrical streamwise tail vortices in the near wake, which is responsible for the negative pressure distribution on the slant and rear end. This negative pressure on slant and rear end accounts for about 80% of the total aerodynamic drag.

(2) The aerodynamic drag is inversely correlated with the length of reverse flow zone and the strength of tail vortices.

(3) The slot jet has strong effects on the near wake and subsequently the aerodynamic drag. For case 1, the length of reverse flow zone shrinks significantly and the tail vortices are enhanced, the corresponding C_D is about 0.91% larger than that without control. While, for cases 2 and 3, the application of slot jet enlarges the reverse flow zone and suppress the tail vortices. The corresponding drag reduction is about 7.88% and 3.64%, respectively.

Flow measurement of vortex-induced vibration of parallel bridge girders by PIV

Jin Park [a], Ho-Kyung Kim [a], Sun-Joong Kim [a]

[a] *Seoul National University, 599 Gwanak-ro, Gwanak-gu, Seoul, Korea*

ABSTRACT: A vortex-induced vibration has been observed in a parallel cable-stayed bridge. In order to understand the aerodynamic behavior of the bridge, a series of wind tunnel tests was performed. The flow around the decks is investigated with the help of a Particle Image Velocimetry.

KEYWORDS: parallel bridge, vortex-induced vibration (VIV), particle image velocimetry (PIV), wind tunnel test, flow measurement

1 INTRODUCTION

A vortex-induced vibration (VIV) has been observed in a parallel cable-stayed bridge. The maximum single amplitude was found to be almost 20 cm at the center of the main span. The bridge is composed of a streamlined steel box deck with 344 m in span length. Both the decks are equipped with guide vanes to mitigate the VIV. The performance of the guide vanes were satisfied with the design allowance for the case of single location. However, the parallel disposition seems to promote the VIV currently observed. The two bridges are very closely disposed, and the clear distance between each deck is shorter than a deck width (see Fig. 1). The center to center gap distance X is 22.25 m and the deck widths of investigated and proximate bridges are, respectively, 12.69 m and 11.86 m, then the ratio X / B is 1.75 ~ 1.88.

This kind of aerodynamic interference has been reported between closely spaced two decks (Honda et al., 1993; Larsen et al., 2000; Kimura et al., 2008). If the two bridge decks are close to each other, the behavior of VIV of one bridge deck will be affected by another deck. This parallel effect is sensitive to the ratio X / B, and it is even serious with the ratio as much as 8 (Kimura et al., 2008).

Most of the previous researches concentrated on the aerodynamic performances of the parallel decks, and introduced interesting results. However it did not derive any general conclusion for parallel bridge behaviors. In order to confirm that the vibration of investigated bridge is originated from the parallel disposition of the decks, the flow field is observed in 2D wind tunnel with Particle Image Velocimetry (PIV).

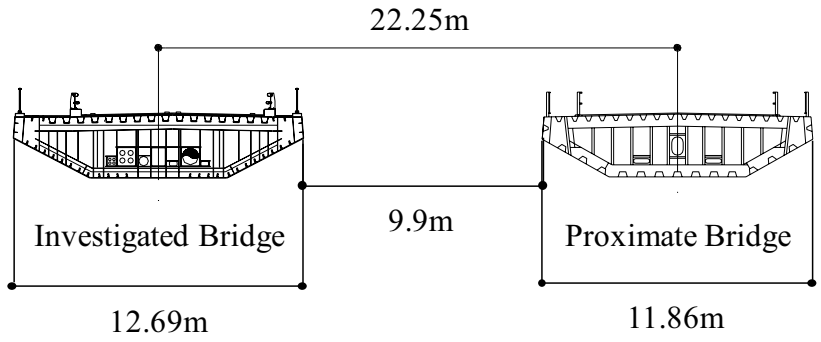

Figure 1. Girder section configuration (Guide vanes are not included)

2 VIV OF PARALLEL BRIDGE DECKS

A series of 2D wind tunnel tests was performed with 1/36 scaled section models. The dimensions including the gap distance and dynamic properties of the real bridges were reflected in section model by the law of similitude. Table 1 shows dynamic parameters for the model setup.

The tests are mainly performed for 3 cases. In Case 1, the investigated bridge is tested alone. In Case 2, the investigated bridge is placed at windward while the proximate bridge is located at leeward. This case has the same wind direction as the VIV occurred for the actual bridge. In Case 3, the test is performed for the opposite wind direction. Thus the investigated and proximate bridges are set at the leeward and windward, respectively. All cases are performed in smooth flow. The test section of the wind tunnel is 1.0 m in width and 1.5 m in height.

Tests results are shown in Figure 2 with a prototype scale. The damping ratios are under-tuned in the experiments in order to emphasize the vibrations of decks. In Cases 2 and 3, the maximum amplitudes of the investigated bridge are respectively 4.7~6.2 times larger than Case 1 in the vertical VIV. In Case 2, especially, VIV occurs at wind velocity of 12~14 m/s and that is similar to wind velocity for VIV of real bridge, 13~15 m/s. For the torsional VIV, parallel effect increases the displacement for Case 3, while decreases for Case 2.

Table 1. Dynamic parameters of the investigated and proximate bridges

Parameters	Investigated brdige			Proximate bridge		
	Proto	Model design	Model measured	Proto	Model design	Model measured
Length (m)	32.4	0.9	0.9	32.4	0.9	0.9
Width (m)	12.69	0.353	0.353	11.86	0.329	0.329
Mass (kg/m)	8978	6.927	6.697	6950	5.363	5.304
Mass moment of inertia (kg·m^2/m)	152836	0.091	0.090	84030	0.050	0.052
Vertical natural frequency (Hz)	0.436	2.180	2.180	0.513	2.561	2.550
Torsional natural frequency (Hz)	1.834	9.165	8.867	1.490	7.444	7.533

3 FLOW MEASUREMENT BY PIV

There is no doubt that the aerodynamic characterastics of the bridge decks are influenced by aerodynamic interference due to parallel disposition of two bridge decks. In order to interpret the VIV mechanism observed in the wind tunnel tests, flow visualization is required.

There was an attempt to show the flow patterns around the decks with CFD analysis (Meng et al., 2011). The research compares the flow patterns of two types of single deck which are, respectively, semi-closed box deck and single full-closed box deck with that of double semi-closed box decks. It says that the flow around double decks is significantly different from that of single deck. According to the CFD results, the paper anticipates that the VIV resonances of bridges, especially for leeward one, would be magnified if the both bridges have same aerodynamic configuration and natural frequencies, but if not, in contrast, the VIV resonances would be non-synchronous and weakened. The investigated bridge and proximate bridge have similar shapes and frequencies and, as a result, the VIV is anticipated as was observed.

The PIV images could cover sufficient area for analysis at one time as long as the system is consisted of a laser with light intensity of 135 mJ at 15 Hz and a digital CCD camera with 2M pixel resolution at 15 fps (a maximum frame rate of 32). The sampling rate is not high enough to get the very clear procedure of VIV formation. This problem may be enhanced in further study with a triggering technique for a series of divided target phases.

Figure 3 shows the flow around the single bridge deck. The contour represents the magnitude of velocity vector and the white lines denote the streamlines. It can be seen that the flow separation occurs alternately from the top and bottom of the deck, and then moves to leeward for a certain distance, converging into one flow. For this reason, a triangular area is obviously observed right behind the deck where the flow velocity is nearly zero.

Figure 4 shows the flow around the double decks with the contour and streamlines. It can be seen that the flows suddenly converge right behind the windward deck, and stirs up the gap space then moves to leeward side. In this situation, additional large eddies are generated in the gap space. The rotational direction of eddies keep changing periodically, and accordingly, the direction of flow streams changes up and down alternately. This will be the source of VIV excitation.

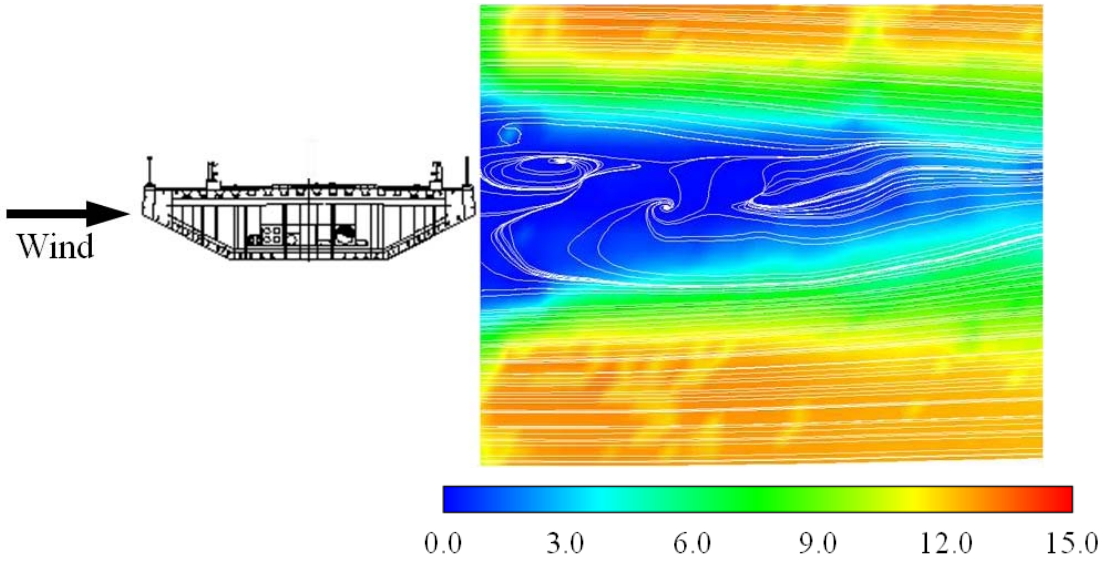

Figure 3. Flow around the investigated deck

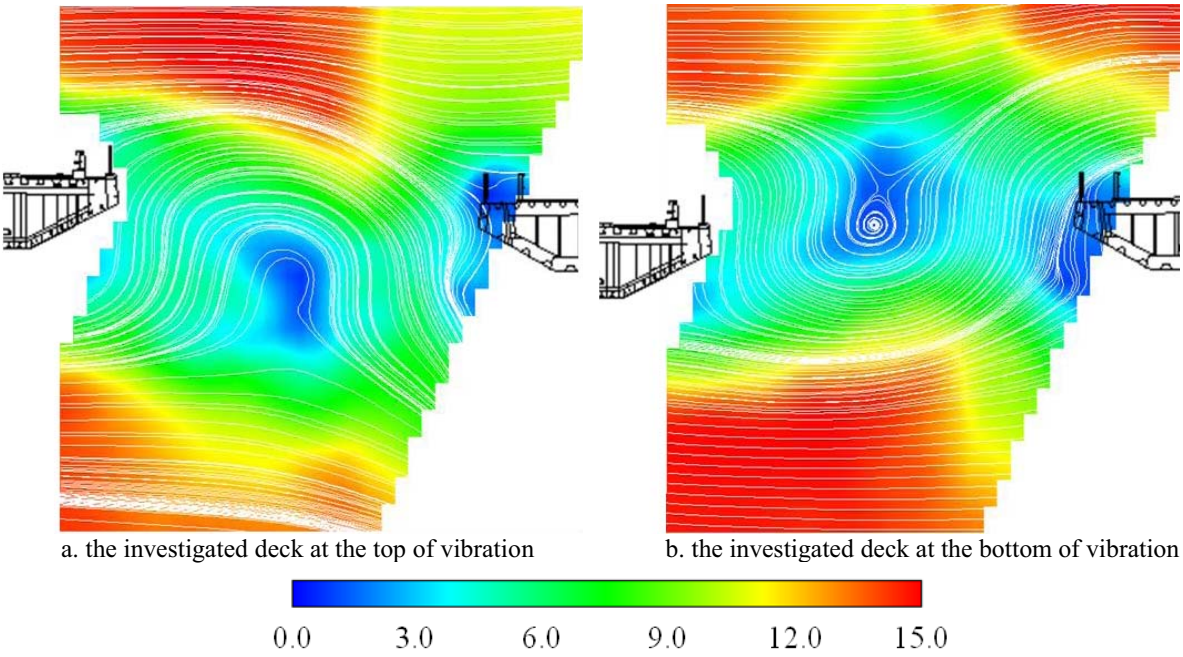

Figure 4. Flow around parallel decks

4 CONCLUSION

The VIV for a parallel cable-stayed bridge is realized in a wind tunnel test. In order to confirm the resource of the VIV, three cases of comparative tests were performed. The simulated tests successfully demonstrated the VIV characteristices for the parallel bridges. The flow field is traced with a PIV test. The large eddies is confirmed at the gap between two bridge decks. This alternating vortex maybe the source of the VIV observed in the field monitoring.

Simultaneous PIV/pressure measurements of the flow around elongated bluff bodies

Zachary J. Taylor [a], Roi Gurka [a, b], Gregory A. Kopp [a]

[a]*Boundary Layer Wind Tunnel Laboratory, Faculty of Engineering, University of Western Ontario, London, Canada*
[b]*Department of Chemical Engineering, Ben-Gurion University, Beer-Sheva, Israel*

ABSTRACT: Synchronized pressure and Particle Image Velocimetry (PIV) data are presented from experiments on 6 elongated bluff bodies of varying leading edge geometry and constant chord-to-thickness ratio of 7. The experiments spanned a range of Reynolds numbers of order 10^4, and the results show marked differences from previous results at lower Reynolds numbers. The surface pressure data show a gradual transition between two extremes. One extreme shows characteristics of being dominated by the separating-reattaching flow at the leading edge while the other shows that the trailing edge is dominant. The transition between these two extremes is observed to be continuous. The PIV data have been phase averaged, and a relationship is proposed to account for the observed shedding frequency variation which suggests that the leading edge geometry is a form of passive flow control.

KEYWORDS: Elongated bluff bodies, shedding frequency, vortex shedding, separation, reattachment, flow control

1 INTRODUCTION

Elongated bluff bodies contrast with shorter vortex shedding bluff bodies by the addition of leading edge separation-reattachment. The most common engineering application for these bodies is the case of suspension bridges. The geometry of the deck of a suspension bridge causes the flow to separate at the leading edge and reattach along the body before separating at the trailing edge, which initiates the vortex shedding process. Vortex shedding induced resonance is an issue for long-span suspension bridges whose design and construction makes them relatively flexible. A recent high profile example of vortex-induced vibrations on a full scale bridge structure was the Great East Belt Bridge in Denmark (Larsen et al., 2000).

Previous studies on elongated bluff bodies are few and typically limited to lower Reynolds numbers ($Re < 2000$); however, these works place the studies at higher Reynolds numbers in better context. The first indication that elongated bluff bodies are distinct from shorter bluff bodies was found in the splitter plate experiments of Nakamura and Nakashima (1986). In these experiments, a vortex street-like arrangement of vortices was observed even with the presence of a splitter plate in the wake. This result was surprising because the splitter plate negated the reliance on shear layer interaction in the recirculation region suggested by Gerrard (1966) to be crucial to the development of the vortex street for a circular cylinder. Nakamura and Nakashima (1986) realized that the vortex street-like arrangement was the result of an instability of the leading edge flow. Naudascher and Wang (1993) referred to this instability as the Impinging Leading Edge Vortex (ILEV) instability realizing that it was the leading edge vortices passing the trailing edge corner which completed the feedback loop to the leading edge vortex shedding. Thus, the vortex street-like arrangement of Nakamura and Nakashima (1986) was the observation of staggered leading edge vortices not trailing edge vortices observed in the wake

of circular cylinders. Hourigan et al. (2001) have discussed the relative importance between leading edge vortex shedding and trailing edge vortex shedding for elongated bluff bodies at low Reynolds numbers. They show that the preferred shedding frequency of leading edge vortices is determined by the natural trailing edge vortex shedding. Likewise, Mills et al. (2002) use external forcing at higher Reynolds numbers, and they show that the strongest shedding occurs when the external forcing is close to the trailing edge vortex shedding frequency. Similarly, the majority of the previous studies at higher Reynolds numbers are focused on external forcing (e.g., Stokes and Welsh, 1986; Parker and Welsh, 1983).

One of the most important studies of elongated bluff bodies at higher Reynolds numbers is that of Parker and Welsh (1983). Although the focus of their study was on acoustic forcing of the wake, they performed experiments over an extensive range of elongation, or chord-to-thickness, ratios up to $c/t = 52$. Within the range of elongation ratios there was a broad range ($7.6 < c/t < 25$) where the hot-wire anemometer in the wake did not detect any periodicity. This result suggests that periodic vortex shedding in the wake is suppressed over this elongation ratio range – a surprising result due to the persistence of vortex shedding for shorter bluff bodies. Roshko (1993) has shown that vortex shedding occurs for Reynolds numbers over at least 6 orders of magnitude even though its nature changes substantially. Others (e.g., Pastoor et al., 2008) have attempted to destroy vortex shedding as a form of drag reduction. However, vortex shedding has proven to be a persistent aerodynamic phenomenon, which is why its suppression over a wide range of elongation ratios for rectangular cylinders demonstrates the distinction between shorter bluff bodies and elongated bluff bodies at higher Reynolds numbers.

Recently, in Taylor et al., (2011), we showed that several key trends related to shorter bluff bodies do not hold for elongated bluff bodies. The trends to which we refer were established primarily by Roshko (1954) who related base pressure, the scale of the recirculation region and the shedding frequency to each other. One of the reasons, which we offered in Taylor et al. (2011), to explain the departure from these established trends was a noticeable change in the dynamics of the formation process in the recirculation region using a force balance on the time-averaged recirculation region of three elongated bluff bodies of differing geometries. The force balance method allows for an assessment of three key forces in closing the recirculation region. These three forces are the surface integrals of the Reynolds shear stress, the streamwise Reynolds normal stress and the pressure, along the boundary of the recirculation region. As the scale of the leading edge separation-reattachment zone grew, it was observed that the dominance of the force due to the pressure decreased while the scale of the near wake recirculation region remained largely unaffected. Thus, it was suggested that the leading edge plays a critical role in the formation process of the near wake. However, it remains unclear the extent to which the leading edge geometry affects the wake shedding frequency at higher Reynolds numbers.

2 EXPERIMENTAL SETUP

2.1 *Wind tunnel tests*

The experiments were performed in Boundary Layer Wind Tunnel II at the University of Western Ontario. This wind tunnel is of closed circuit design consisting of a high-speed test section with a cross-section 3.35 m wide by 1.83 m high. In this case, we have utilized the smooth flow at the upstream end of the 39 m long test section which is measured to be uniform to within 1% away from the walls and to have turbulence intensity less than 1%.

2.2 *Model details*

The wind tunnel model was designed to accommodate different forebodies (i.e., attachments to the leading edge). The basic model was of rectangular cross-section with a chord (defined as the streamwise dimension) of 533.4 mm and a thickness of 76.2 mm giving an elongation ratio, or chord-to-thickness ratio, of $c/t = 7$. In this study, we used a combination of the base model and five forebodies which are shown in Figure 1. The leading edge separation angles are marked in Figure 1 and referred to in the text by θ. The leading edge separation angles have not been measured but are assumed to be tangent to the leading edge forebody at the fixed separation points. The validity of this assumption was confirmed in our previous study on elongated bluff bodies (Taylor et al., 2011). The shapes used in the current study allow us to capture both extremes at the leading edge: the case of no separation ($\theta = 0°$), a blunt leading edge ($\theta = 90°$), and a range in between.

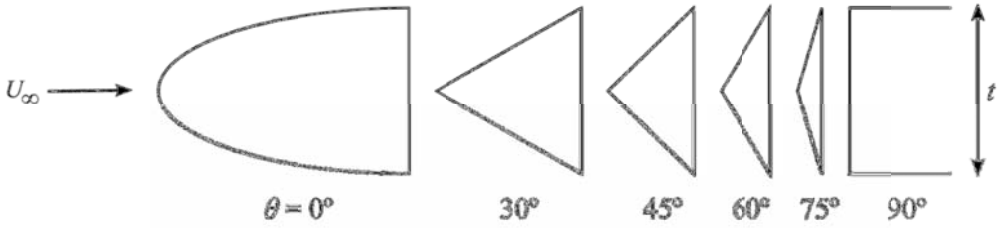

Figure 1. The five different forebodies and the leading edge of the base model (far right) are shown. Angles refer to the assumed leading edge separation angle, t is the thickness of the model and U_∞ the free stream speed.

2.3 *Pressure measurements*

Surface pressure measurements have been performed at 512 tap locations around the body (see Figure 2). The location of the taps yields three rings of sectional data in addition to five rows of spanwise data. The combination of tube length and restrictor size is one of the standard ones used at the BLWTL which has been repeatedly tested to ensure the frequency response is flat until approximately 200 Hz. We have sampled data from all 512 pressure taps near-simultaneously at a sampling frequency of 500 Hz and the data have been low pass filtered at 180 Hz to remove any effects of tube resonance. Multiplexed pressure scanners are used to sequentially scan up to 16 taps at each 0.002 s (corresponding to the 500 Hz sampling frequency). These measurements are interpolated in time to yield data which are essentially sampled simultaneously at all 512 pressure taps at 500 Hz. Phase lag tests have been performed to ensure that there are no errors from this procedure. The reader is referred to Ho et al. (1999) for more details on the pressure scanning system used in the current study.

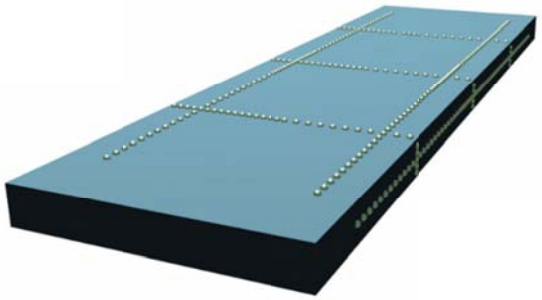

Figure 2. Gray markers represent the location of the surface pressure taps around the body. The camera in this figure is pointed at the trailing edge and top surfaces of the model.

2.4 *Particle Image Velocimetry measurements*

The Particle Image Velocimetry data were obtained using a custom long-duration time-resolved system developed at the University of Western Ontario. Development of the system is described in detail in Taylor et al. (2010). The camera has a 1024x1024 pixels^2 CMOS sensor with a 10-bit dynamic range. The innovation in the system comes from the streaming capability provided by IO Industries where the full resolution data can be streamed from the camera at 1000 frames per second for more than 20 minutes. In these experiments, the data are sampled simultaneously with the pressure data for 64 sec.

The large scale flow facility is seeded with atomized olive oil with a mean particle size of 1 μm (Echols and Young, 1963). Illumination is provided by the Quantronix Darwin Duo laser which is a double-head Nd:YLF laser operating with a wavelength of 527 nm. Due to the repetition rate required by the cameras, the laser has to have substantial power and this laser can produce 80W of light power. Operating at 1000 Hz, the laser provides 22 mJ of light in each half of a PIV interrogation pair.

To limit the reflection that makes measurements near the body difficult, the camera was placed so that the center of the field of view coincided with the lower trailing edge corner of the body (Figure 3). Using this technique, the amount of reflected light from surface reflections entering the camera is significantly reduced without the use of expensive coatings. Because of the large scale nature of the wind tunnel, getting a sufficient combination of seeding and illumination proved to be the most challenging experimental aspect of the work. However, by focusing the available illumination power on the near wake, suitable signal-to-noise ratios were obtained over a region 1.6*t* x 1.2*t* and velocity data were sampled encompassing the entire recirculation region (Figure 3).

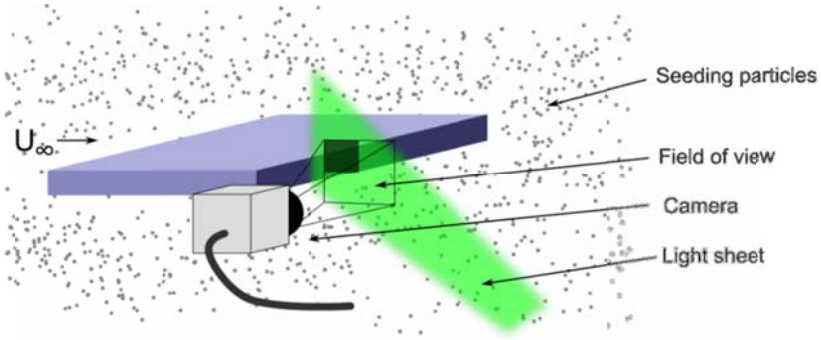

Figure 3. Schematic of the PIV setup.

2.5 *Phase averaging procedure*

All of the data have been phase averaged based on the time signal of a pressure tap in the recirculation region. Two examples of the pressure time series at this location are shown in Figure 4. Figure 4(a) shows the data for $\theta = 0°$ where the signal is distinctly periodic even though the amplitude of the signal changes continuously in time. In contrast, Figure 4(b) shows the data for $\theta = 90°$ where the signal is noticeably noisier, yet a distinct periodicity is still observed. The fitted data in Figure 4 is computed using the coefficients of the dominant frequencies from a FFT performed on 2 sec. long windows. The fitted data were used to perform the phase average.

Phase averaging of the data is performed following the approach of Reynolds and Hussain (1972). In this approach the data are decomposed as follows (note that in our example we decompose the pressure, but the same is done for each component of velocity as well),

$$p = \langle p \rangle + \tilde{p} + p' \tag{1}$$

In Eq. 1, p is the instantaneous value of pressure, $\langle p \rangle$ is the global time averaged pressure, $\tilde{p}$ is the periodic component and p' is the fluctuation from the global time average and the periodic component. This fluctuating term is often referred to as the 'incoherent' part of the flow associated with turbulent motion whereas the periodic component is responsible for fluctuations from the global time average, but is a 'coherent', or organized, fluctuation.

Taking the reconstructed time signal, as described above, and dividing each cycle into 16 bins we obtain an expression for each bin n,

$$\tilde{p}_n = \frac{1}{N_n}\sum_{i=1}^{N_n} p(\tau_i) \times M \qquad \text{where, } M = \begin{cases} 1, & \text{for } \dfrac{(n-1)}{16 f_s} \le \tau_i < \dfrac{n}{16 f_s} \\ 0, & \text{otherwise} \end{cases} \tag{2}$$

where τ_i is the time (starting from $\tau = 0$) of a discrete sample and f_s is the vortex shedding frequency of the wake for each body.

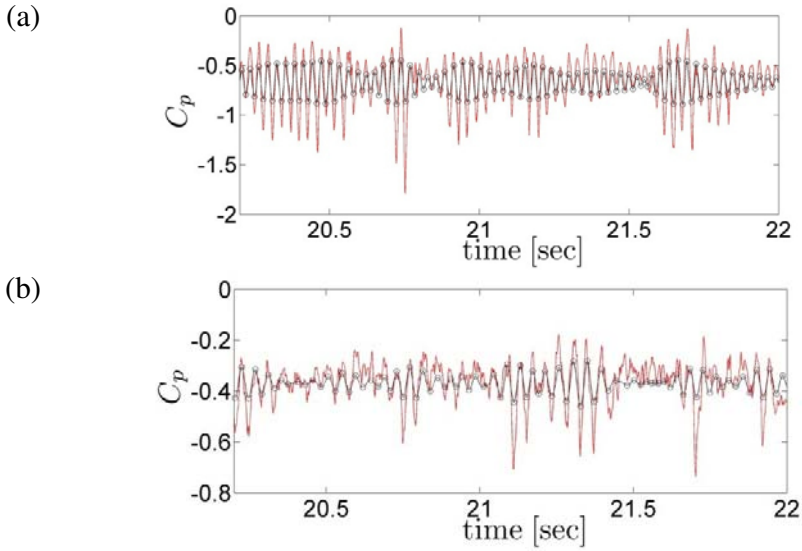

Figure 4. Example of the time signals from which the phase averages are constructed. (a) θ = 0°, (b) θ = 90°.

3 RESULTS

3.1 *Shedding frequency*

The most important aerodynamic feature in application to bridge structures is the shedding frequency since it is the shedding frequency which dictates when vortex-induced resonance will begin. We have measured the shedding frequency by calculating the time series of the sectional lift force, which is computed at each time step by integrating the surface pressures around each streamwise loop of pressure taps. The shedding frequency is normalized using the Strouhal number based on the model thickness as $St = ft/U_\infty$, where f is the shedding frequency in Hz, t is the model thickness and U_∞ the free stream speed.

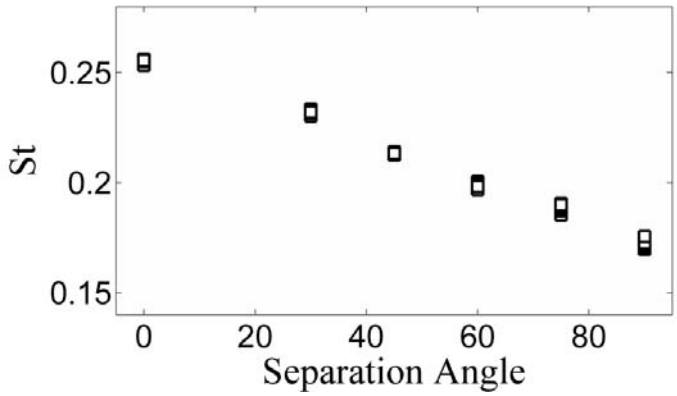

Figure 5. Thickness-based Strouhal number variation with leading edge separation angle. Each square marker represents a separate Reynolds number between 4-7.5x10^4.

3.2 *Leading edge separation bubble*

The size of the mean leading edge separation bubble is x_r and is estimated by the fluctuating pressures along the surface. Roshko and Lau (1965) showed that the mean pressures underneath separation bubbles collapse when the streamwise dimension is scaled by x_r. Their observation was true for a wide variety of leading edge geometries. Additionally, Ram and Arakeri (1990) observed that the maximum fluctuating pressures occur at the same streamwise location when scaled by x_r and that these maxima occur at approximately $0.95x_r$. Thus, we define the leading edge reattachment length by $x_r = x|_{max(Cp')}/0.95$ and mark the potential errors due to the spatial resolution of the pressure taps in Figure 6.

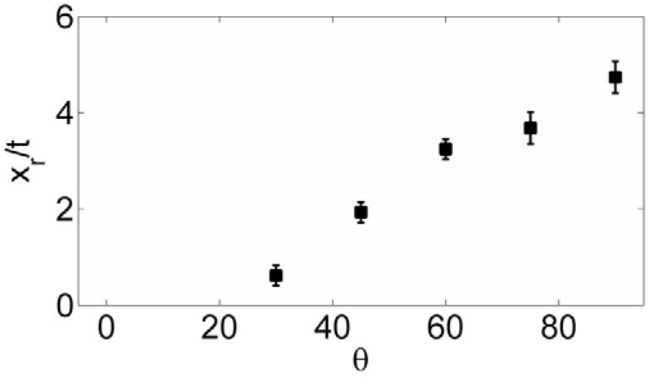

Figure 6. Leading edge mean reattachment length x_r is normalized by the thickness, t, and plotted against the leading edge separation angle, θ. Error bars mark uncertainty in the estimate arising from the spatial resolution of the pressure taps.

Another method to quantify the leading edge separation bubble is to study the vortices which are shed from this location. It should be noted that there is no periodicity to the shedding of vortices from the leading edge at the Reynolds numbers of the present study. This result is anticipated from Cherry et al. (1984) who also characterize leading edge vortices shed from a blunt-nosed semi-infinite plate using autocorrelations. In Figure 7, we present contours of the autocorrelation coefficient defined as,

$$R(\Delta x, \mathrm{T}) = \frac{\langle p_1'(x_0,\tau) p_2'(x_0+\Delta \mathrm{x},\tau+\mathrm{T})\rangle}{\sigma_{p_1}\sigma_{p_2}} \tag{3}$$

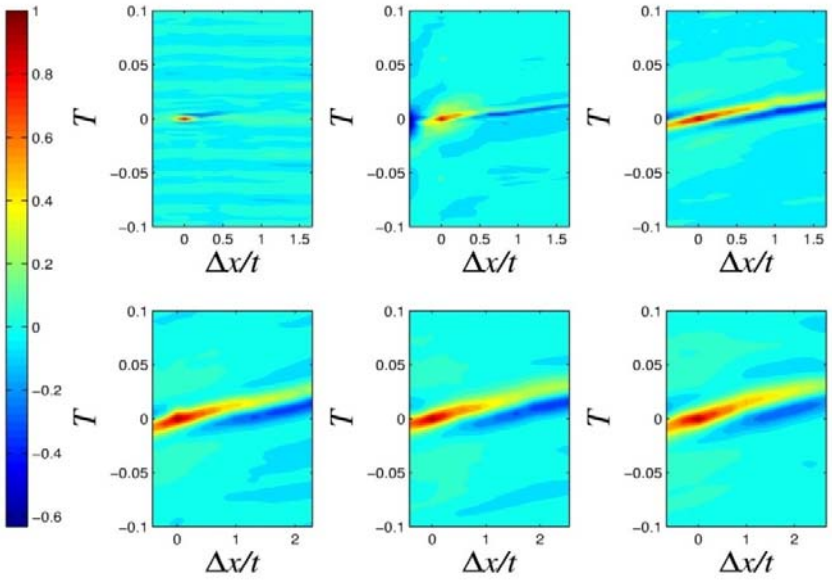

Figure 7. Contours of the correlation coefficient defined by Eq. 3 with $x_0 = x|_{max(Cp')}$. From top left to bottom right: θ = 0°, 30°, 45°, 60°, 75°, 90°. Color map applies to all θ.

where x_0 is a reference streamwise location; τ is time; Δx and T are the spatial and time lags, respectively; a prime marks a fluctuation from the mean; angle brackets represent the time-average of the entire time series; and, σ is the standard deviation. In Figure 7, we define the reference streamwise location, x_0, as $x_0 = x|_{max(Cp')}$ which is just upstream of the mean reattachment length.

The ridge of high correlation observed in Figure 7 was suggested by Cherry et al. (1984) to correspond to a 'footprint' of a leading edge vortex, and by calculating the slope of this ridge one obtains an approximation to the convection speed of a vortex traveling along the surface. For all cases with leading edge separation (i.e., all but θ = 0°) the range of estimated convection speeds is 0.5-0.55U_∞.

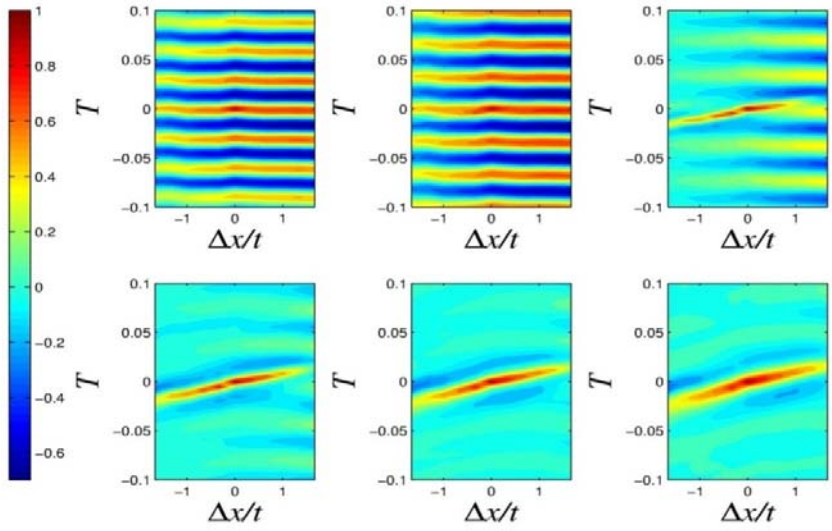

Figure 8. Contours of the correlation coefficient defined by Eq. 3 with $x_0 = 5.5t$. From top left to bottom right: θ = 0°, 30°, 45°, 60°, 75°, 90°. Color map applies to all θ.

Having used the autocorrelation in space and time to characterize the leading edge vortices, we perform a similar analysis near the trailing edge. This type of analysis allows us to explore the state of the leading edge vortices when they approach the trailing edge. In Figure 8 we once again show contours of the correlation coefficient defined by Eq. 3, but the reference streamwise value has changed to $x_0 = 5.5t$. It is observed from Figure 8 that for $\theta = 75°$ and 90° little has changed between the autocorrelation map at this location and that shown near the leading edge in Figure 7. However, this is in contrast to the case of $\theta = 0°$ and 30° where the autocorrelation map is dominated by a strong periodic feature in time whose wavelength matches that of the wake vortex shedding. Therefore, we have cases which can be labeled as 'trailing edge dominated' ($\theta = 0°$ and 30°) and cases which can be labeled as 'leading edge dominated' ($\theta = 75°$ and 90°), yet the most striking feature of Figure 8 is the apparent continual transition between these two extremes. The transition is apparent from the autocorrelation maps of $\theta = 45°$ and 60° because characteristics of both leading and trailing edge features are observed.

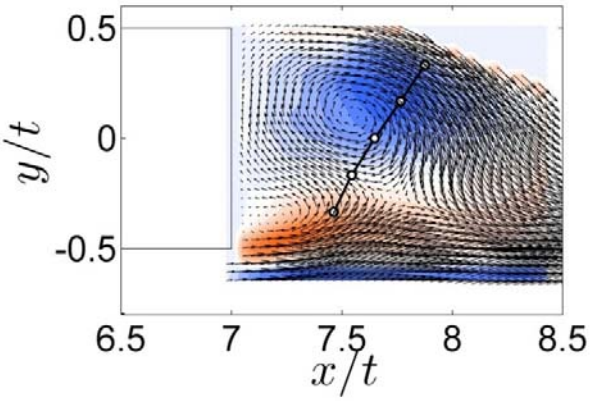

Figure 9. Phase averaged velocity vectors and vorticity contours (red: positive, blue: negative). Line is phase averaged pressure where distance from the surface is representative of suction at that location.

3.3 *Results of the phase average*

The phase averaging procedure is discussed in detail in §2.5 and an example of the result is shown in Figure 9. From Figure 9 it is observed that we can estimate features of the vortices in the near wake region with data that are spatially well resolved.

Although various features of the vortices in the near wake region can be computed, we focus on the convection speed. We suggest that the convection speed during the growth process and the shedding frequency are closely related. This notion is somewhat intuitive because if a vortex leaves the recirculation faster, then the next vortex can form sooner. Gerrard (1966) used a similar argument in his hypothesis regarding the effects of free stream turbulence on the shedding frequency of a circular cylinder. Using the phase averaged data in the recirculation region, we estimate the convection speed of a clockwise vortex (i.e., $y < 0$) through the vortex shedding cycle; these data are plotted in Figure 10. Agreeing with our hypothesis, it is observed that when the shedding frequency is higher the vortices have greater convection speeds through the recirculation region.

4 DISCUSSION & CONCLUSIONS

Based on the data presented, it is apparent that there is a gradual transition between bodies which are dominated by the leading edge flow and those which are dominated by the near wake. No-

where is this transition more evident than in Figure 8. As we have previously discussed, from this figure there are clear cases (θ = 75° and 90°) that are 'leading edge dominated' and other cases (θ = 0° and 30°) that are 'trailing edge dominated'. The transition between these two extremes appears to be gradual suggesting a continuous, rather than discontinuous, influence of the leading edge separating-reattaching flow on the near wake vortex shedding.

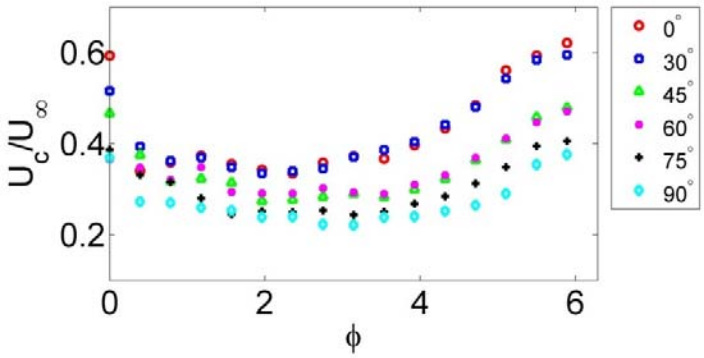

Figure 10. Phase averaged convection speed of a vortex ($y < 0$) through all phases $\phi \in [0,2\pi]$. Values in the legend correspond to the leading edge separation angle, θ.

We have not shown the frequency content of the leading edge separation bubble, but we could not detect any peaks in the spectra of the surface pressure data near the leading edge which confirms the suppression of the ILEV instability for all of these bodies at Reynolds number $O(10^4)$. Therefore, the determination of the shedding frequency at these Reynolds numbers must be a different mechanism than the feedback instability at lower Reynolds numbers.

A larger leading edge reattachment length corresponds to stronger separation, and it is expected that turbulence of larger scale is also produced. Therefore, we suggest that the leading edge flow is still significant in the determination of the shedding frequency; however, at higher Reynolds numbers it is no longer through a feedback mechanism. Returning to the hypothesis that faster moving vortices in the recirculation region (Figure 10) accompany higher shedding frequency, the turbulence created at the leading edge is suggested to slow down the growing vortices, which lowers the shedding frequency.

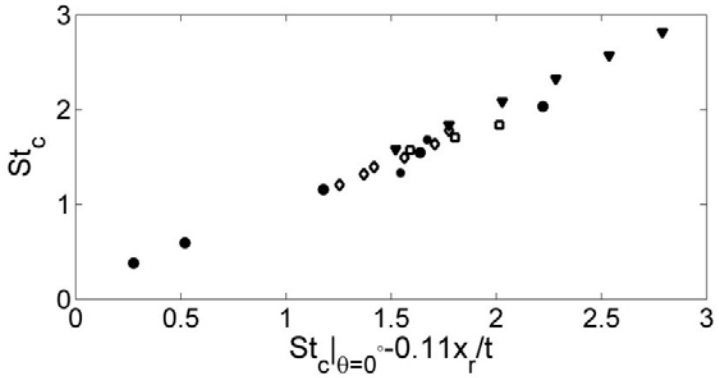

Figure 11. Plot of the modified chord-based Strouhal. Legend: Naudascher & Wang (1993): □ – Rectangular cylinder, ● – Semi-circular leading edge; ▼ - Elliptical leading edge from Mills et al. (2005); * – from Taylor et al. (2011); ◊ – Present data.

Extending this hypothesis to other elongated bluff bodies, we propose that the chord-based Strouhal number be modified by,

$$St_c = St_c|_{\theta=0} - g(x_r) \quad (4)$$

where, $g(x_r)$ is some function based on the reattachment length. Combining the data from Figure 5 and Figure 6 we obtain,

$$St_c|_{c/t=7} = St_c|_{c/t=7,\theta=0^\circ} - 0.11x_r \ . \quad (5)$$

We extend this relationship established for *c/t* = 7 to other bodies using data available in the literature (Figure 11). From Figure 11 it appears that this relationship yields a reasonable collapse of the data. Therefore, it appears that the leading edge offers a type of flow control through the level of turbulence rather than synchronization through feedback as it does at lower Reynolds numbers. Further studies are underway to examine how the turbulence created at the leading edge is connected to the vortex convection speed in the recirculation region.

ABSTRACT: Particle Image Velocimetry (PIV) and pressure measurements were performed on a high-rise model with a height (H) of 0.48 m and a width (B) of 0.12 m in a turbulent atmospheric boundary layer. Experiments were carried out for an isolated model and four tandem configurations with varying separation distance (S) between the models. Mean and standard deviation were determined for the PIV and the pressure dataset. Both velocity fields and pressure coefficient distributions show an increase in mean and fluctuating components near the entrance of the passage with decreasing separation distance. Proper Orthogonal Decomposition (POD) was performed on the PIV data to determine the most energetic modes. These modes were compared with observations from literature for tandem configurations in a laminar boundary layer. Similar modes were found (single, gap and coupled mode). In the current study it was found that the modes can occur simultaneously. Also the dominant mode differs from previous results described in literature for the investigated setup ranges.

KEYWORDS: High-rise buildings, wind interference, tandem arrangement, Particle Image Velocimetry

1 INTRODUCTION

Wind flow around a single isolated building has been studied extensively. Typical flow phenomena, such as the separation bubble and vortex shedding are quite well understood. There is less understanding on the changes of existing phenomena or the emergence of new phenomena when two or more high-rise buildings are in close proximity. A typical case is the tandem configuration, in which the wind approaches the buildings parallel to the intermediate passage. This configuration is known for particularly large mean velocities in the passage (e.g. Blocken et al, 2007) and large negative mean (Bronkhorst et al, 2011) and peak (Kim et al, 2010) pressures on the passage facades.

Yen and Liu (2010) performed pressure and visualization measurements using the smoke-streak technique on two square cylinders in side-by-side arrangement in quasi two-dimensional laminar flow. They found a change in flow patterns and vortex shedding frequency with increasing separation distance and classified three vortex shedding modes: the single mode ($S/B < 0.1$), the gap-flow mode ($0.1 < S/B < 5.5$) and the coupled vortex-shedding mode ($S/B > 5.5$). The gap-flow mode exhibits anti-phase vortex shedding; the vortex streets behind both models are symmetric with respect to the gap centre line. The coupled vortex-shedding mode has in-phase vortex shedding: the vortex streets behind both models are the same as the vortex street behind a single building, the interaction is observed in the in-phase rhythm of the vortex shedding. These flow characteristics of the tandem configuration defined by Yen and Liu (2010) for laminar flow were, to the author's knowledge, never investigated in an atmospheric turbulent boundary layer.

The goal of this paper is to obtain a better understanding of the flow phenomena and related pressure effects encountered in a tandem configuration of high-rise models in an atmospheric boundary layer. Particle Image Velocimetry (PIV) measurements were performed to obtain ve-

locity vector fields in the horizontal plane around the models. Separate pressure measurements in the same plane gave data on the local pressure distribution. This work describes the set up of the experiments and discusses results and findings.

2 MATERIALS AND METHODS

Wind tunnel experiments were carried out in the open circuit atmospheric boundary layer (ABL) wind tunnel of TNO in the Netherlands. It has a working section of approximately 13.5 m in length; the test section has a 3 m width and 2 m height. The boundary layer applied in this study had an aerodynamic roughness length z_0 = 3.2 mm. A detailed description of the flow field is given in Bronkhorst et al (2011).

2.1 *Pressure measurements*

The reference model is a wooden square cylinder with a height of H = 0.48 m and width B = 0.12 m. The pressure tap distribution on the faces is illustrated in Figure 1(a). The interfering model has the same dimensions as the reference model. Measurements were performed on the isolated configuration and four tandem configurations [as illustrated in Figure 1(b)]. The reference model was instrumented with pressure taps at 38 locations on each face. The current study only uses the data obtained at 0.32 m height (row i = 4), which is 2/3H. The pressures were measured with a sampling rate of 400 Hz for a period of approximately 20.5 seconds. During pressure measurements the undisturbed static and dynamic pressure were measured with a pitot-static tube positioned at model roof height (H = 0.48 m). The mean velocity at this height, U_H = 14.2 m/s, corresponds with a width-based Reynolds number of $Re = U_H B/\nu \approx 1.1 \times 10^5$.

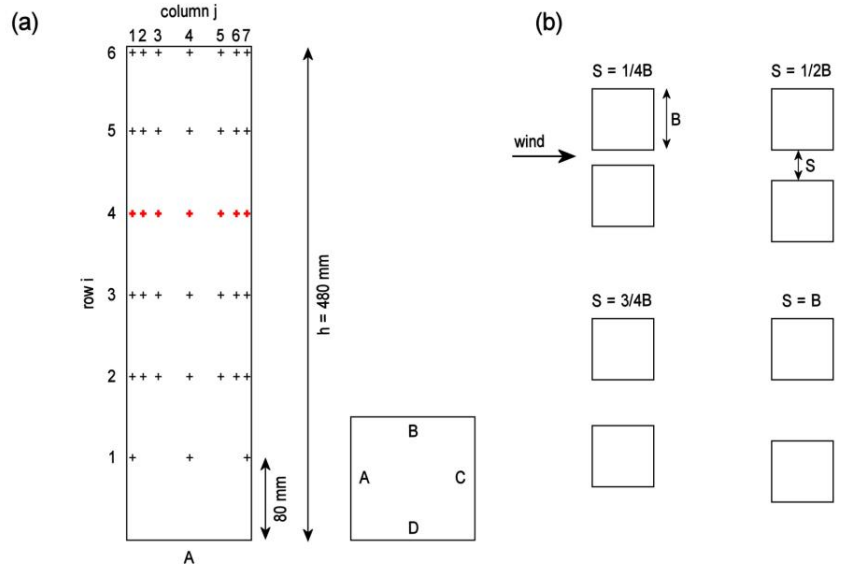

Figure 1. (a) pressure tap distribution on face A, the same distribution is found on face B, C and D, this study only uses the data obtained in row i = 4; (b) investigated tandem configurations.

2.2 *PIV measurements*

The tandem configuration consists of two wooden square cylinders with a height H = 0.48 m and width B = 0.12 m. Measurements were performed with a mean velocity at model height,

U_H = 14.2 m/s. The isolated configuration and four tandem configurations, illustrated in Figure 1(b), were investigated.

In order to evaluate the flow around the tandem square cylinders, two-component particle image velocimetry (PIV) is employed. The PIV measurements provide a velocity vector field with 2 velocity components in horizontal streamwise and spanwise x- and y-direction (u_x and u_y) at a height of z = 0.32 m from the ground. The PIV field of view (FOV) of approximately 600 by 460 mm is indicated in Figure 2(a), and is chosen to encompass the flow around both cylinders, the intermediate passage and a large portion of the cylinder wakes.

The illumination over the field of view is provided by a Quantel Evergreen 200 Nd:YAG double puls laser with 200 mJ maximum puls energy. The light sheet is generated downstream of the object of investigation. A LaVision Imager Intense CCD camera is placed above at a 90° angle with respect to the illumination sheet, and captures 1376 x 1040 pixel images, illustrated in Figure 2(b). The illumination and recording devices were synchronized and controlled by a LaVision Programmable timing unit controlled by Davis (Version 8, 64 bit) Software. Each test consisted of 200 image pairs at a recording frequency of 10 Hz. The double pulse interval was 250 microseconds. The chosen magnification yields a typical digital resolution of 2.3 pixels/mm. The images were analyzed with the Davis software; reflections in the raw images were corrected for through subtraction of the minimum pixel values over the 200 images, resulting in images as illustrated in Figure 2(c). Velocity vector fields were obtained through a multi-stereo cross-correlation with a final interrogation window of 16 x 16 pixels with 75% overlap.

The instantaneous velocity magnitudes are computed using $u(t) = [u_x(t)^2 + u_y(t)^2]^{1/2}$. The time-averaged mean and standard deviation velocity magnitudes, U and u_{std} respectively, were computed from the velocity magnitude time series. The results are presented non-dimensionally, referenced to the mean velocity at model height, U_H.

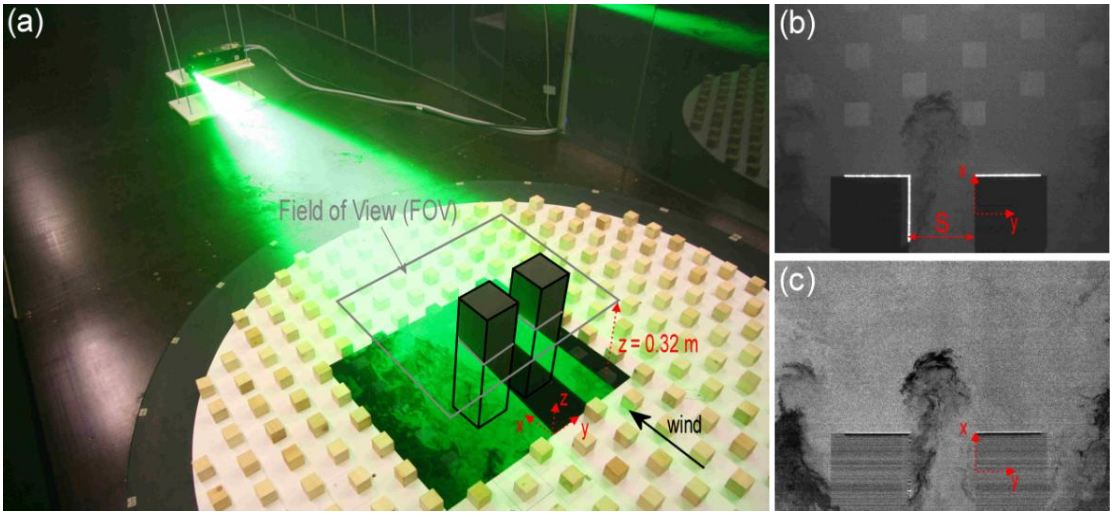

Figure 2. PIV measurements: (a) experimental set up, (b) raw image, (c) image after manipulation to correct for reflections.

3 RESULTS AND DISCUSSION

3.1 *Mean and standard deviation velocity field and pressure coefficient distribution*

The mean velocity field around the single isolated building at $z = 2/3H$ is illustrated in Figure 3(a). Flow phenomena such as the separation on the side face and the counter rotating mean wake structure behind the model are visible in the vector field. These flow features change significantly when two models are placed in tandem arrangement. First of all, for the studied configurations, the vector fields indicate that mean separation and recirculation are not present in the passage. Instead an increase is observed in the passage and low forward velocity around the side walls. Secondly, the strength of the jet at the exit of the passage has a large influence on the mean wake structure behind the models.

Blocken et al (2007) performed a tandem configuration study on building models with full scale dimensions B x D x H = 40 m x 20 m x 20 m. They determined an increase in mean velocity at pedestrian level (2 m). However, at larger heights (approximately $\frac{1}{2}H$) they found a decrease in mean longitudinal velocity of 10-25%. Blocken et al related this effect to an upward flux through the top of the passage caused by the overpressure region in front of the buildings near the ground. This effect reduced the longitudinal velocity through the passage at larger heights. The current study shows that the height of the buildings has a large influence on the flux through the passage, as there is a large velocity increase in the passage. In case of high-rise buildings, the high pressure region is not near the ground, resulting in a downward flux below approximately $2/3H$ (i.e. the stagnation point of buildings is in the region of $2/3H$) and an upward flux above $2/3H$.

Figure 3(b) shows the mean pressure coefficient distribution. On face A, the mean pressure coefficient increases with decreasing separation distance. This increase is particularly large near the passage entrance, where an increase is observed from $C_{p,mean} = 0.3$ (isolated case) to $C_{p,mean} = 0.6$ ($S/B = \frac{1}{4}$). This increase indicates the merging of the overpressure regions in front of the two buildings. The mean pressure distribution on face B is severely influenced by the neighbouring model. Near the entrance, the mean pressure coefficient increases with decreasing separation distance, from $C_{p,mean} = -0.7$ in the isolated case to $C_{p,mean} = -1.6$ for $S/B = \frac{1}{4}$. Near the passage exit, the mean pressure coefficients decrease towards the coefficients observed on face C. The influence of the adjacent model on the mean pressure coefficient distribution on face C and D is small.

Figure 4(a) shows the standard deviation velocity fields with decreasing separation distance. The high velocities near the sides are characteristic for the shear layer. In the tandem configuration, an increase is observed in the shear layers near the faces on the outside. In the passage, large values are found closer to the building face than on the outside faces. With decreasing separation distance, the large standard deviation velocities are concentrated near the entrance of the passage.

Figure 4(b) illustrates the standard deviation pressure coefficient distribution. On face A, a small increase is found which is largest at a separation distance of $S/B = \frac{1}{2}$. Large effects are observed on the distribution of face B in the passage. In the isolated case, the largest coefficients are observed near the trailing edge. This increase is a well-known effect caused by reattachment (e.g. Surry and Djakovich, 1995). The movement of the zone of reattachment results in a change in inclination with which the fluid approaches the surface which is responsible for an increased variation in pressure. Because the velocity magnitude varies little, no large standard deviation values are observed in this region.

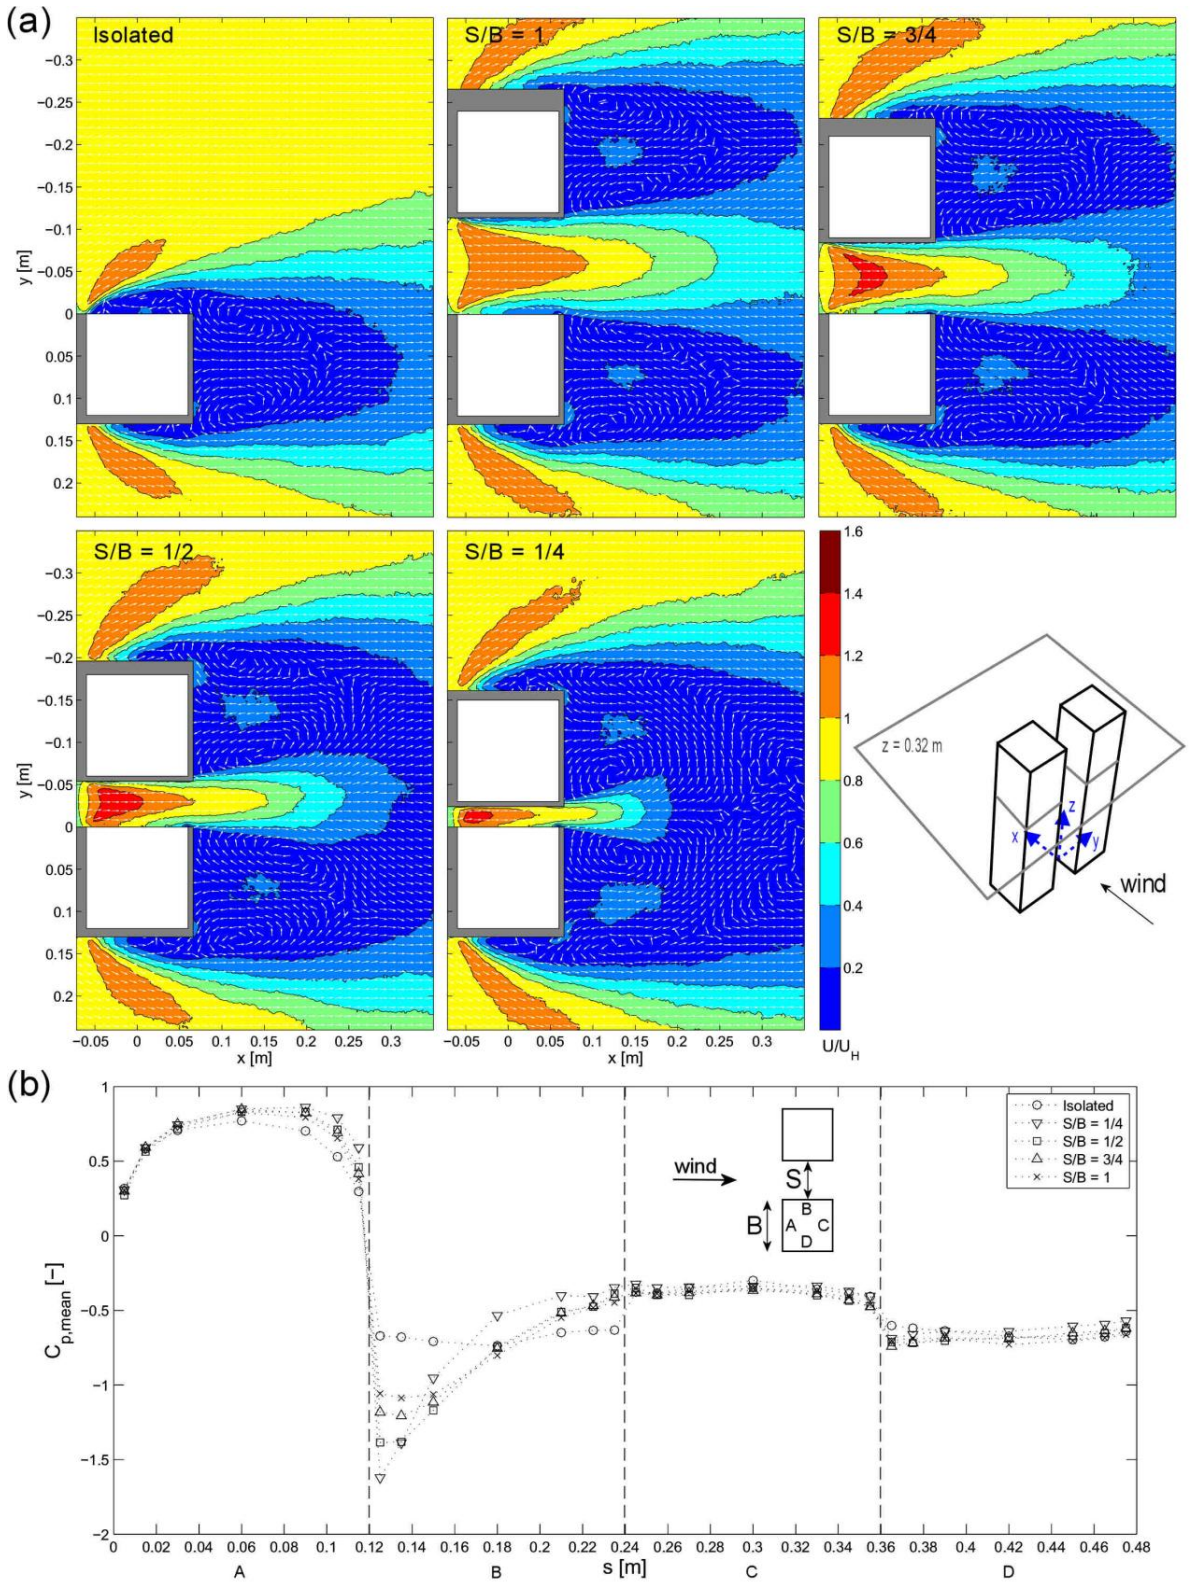

Figure 3. (a) Variation of the mean velocity field with increasing separation distance between the buildings at 2/3*H*: isolated building; *S/B* = 1; *S/B* = ¾; *S/B* = ½; *S/B* = ¼. (b) Influence of the separation distance on the mean pressure coefficient distribution at 2/3*H*.

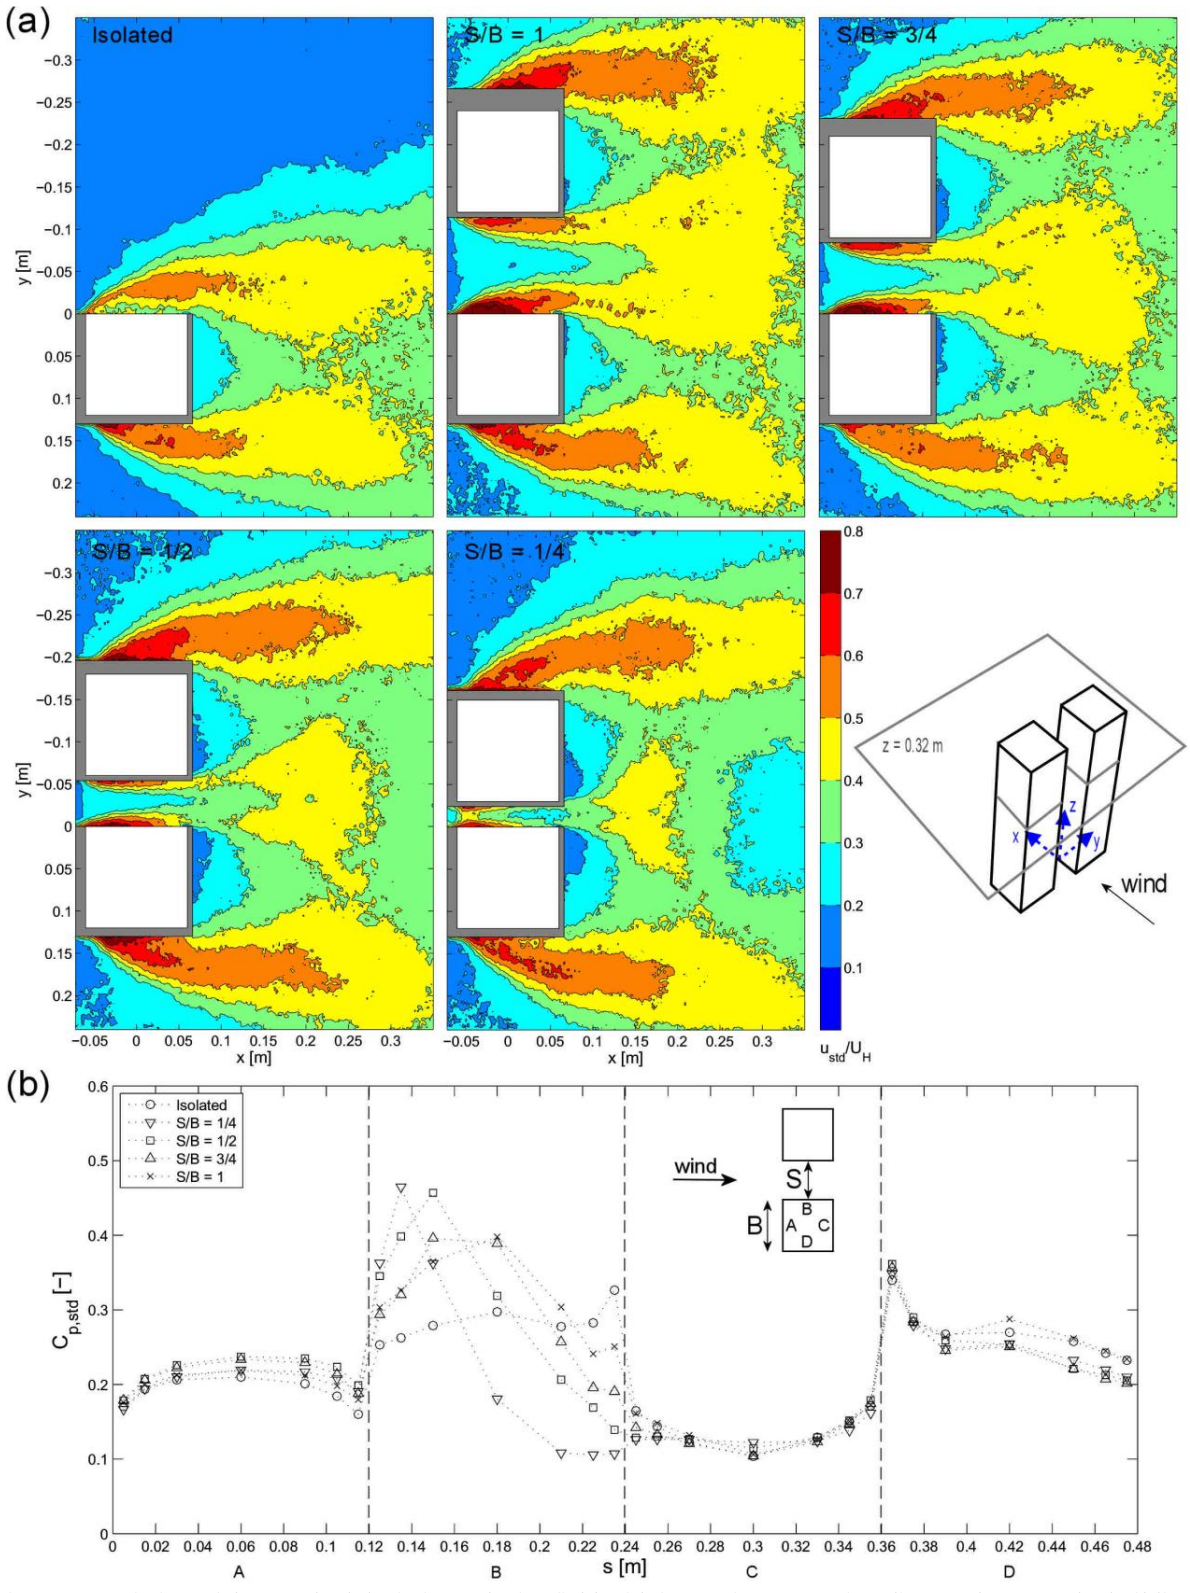

Figure 4. Variation of the standard deviation velocity field with increasing separation distance between the buildings at 2/3*H*: isolated building; *S*/*B* = 1; *S*/*B* = ¾; *S*/*B* = ½; *S*/*B* = ¼. (b) Influence of the separation distance on the standard deviation pressure coefficient distribution at 2/3*H*.

The standard deviation pressure coefficients near the entrance of the passage increase with decreasing separation distance. This is in agreement with the increase in velocity fluctuations in this region. Near the exit of the passage, there is a reduction in standard deviation pressure coefficient. The standard deviation velocities also show a decrease in this region. Small effects are observed on face C and D.

3.2 *Instantaneous and POD analysis of the velocity field*

Figure 4 shows three sequential snapshots of the *S/B* = ¾ configuration. Large differences compared to the mean flow results of figure 2 can be observed. Where the mean velocity field of figure 2 indicated no separated flow in the inner passage, the instantaneous velocity fields show separation does occur, either on left or right side or simultaneously on both sides. These observations are in agreement with the standard deviation visualizations observed in Figure 4.

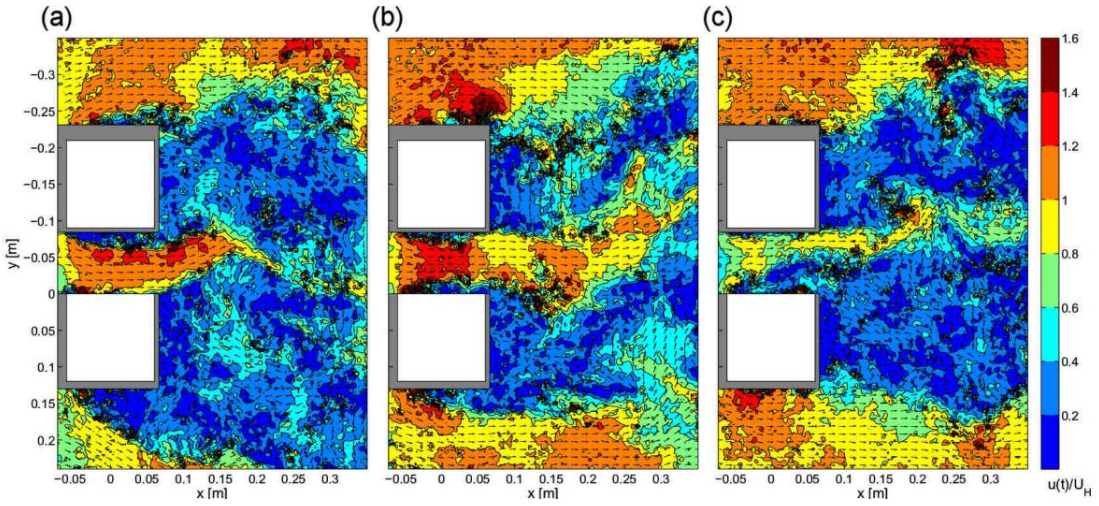

Figure 5. Instantaneous velocity fields illustrating the alternating behavior of the separation zones in the passage: (a) separated zone on right side, (b) separated zone on both sides, (c) separated zone on left side.

In order to obtain a better understanding of the underlying patterns in the turbulent flow, proper orthogonal decomposition (POD) was employed on each dataset of 200 vector fields. POD is a mathematical procedure that uses an orthogonal transformation to convert a set of observations of possibly correlated variables into a set of values of linearly uncorrelated variables. The transformation is defined in such a way that the first principal component has the largest possible variance and each succeeding component in turn has the highest variance possible under the constraint that it be orthogonal to (i.e., uncorrelated with) the preceding components. For velocity fields, the largest variance corresponds to the highest fluctuation kinetic energy. The two most energetic modes for *S/B* = ¾ and the most energetic mode for *S/B* = ¼ are depicted in Figure 6. On the left of the figure, the modified fluctuation velocity magnitude $\mathrm{sgn}(u_y) \bullet U_i$ for the 1st and 2nd mode is depicted. The $\mathrm{sgn}(u_y)$ term is added to indicate the relative direction in the mode shape. On the right of the figure, the mode velocity field is added to and subtracted from the mean velocity field to show the influence of the mode on the velocity field.

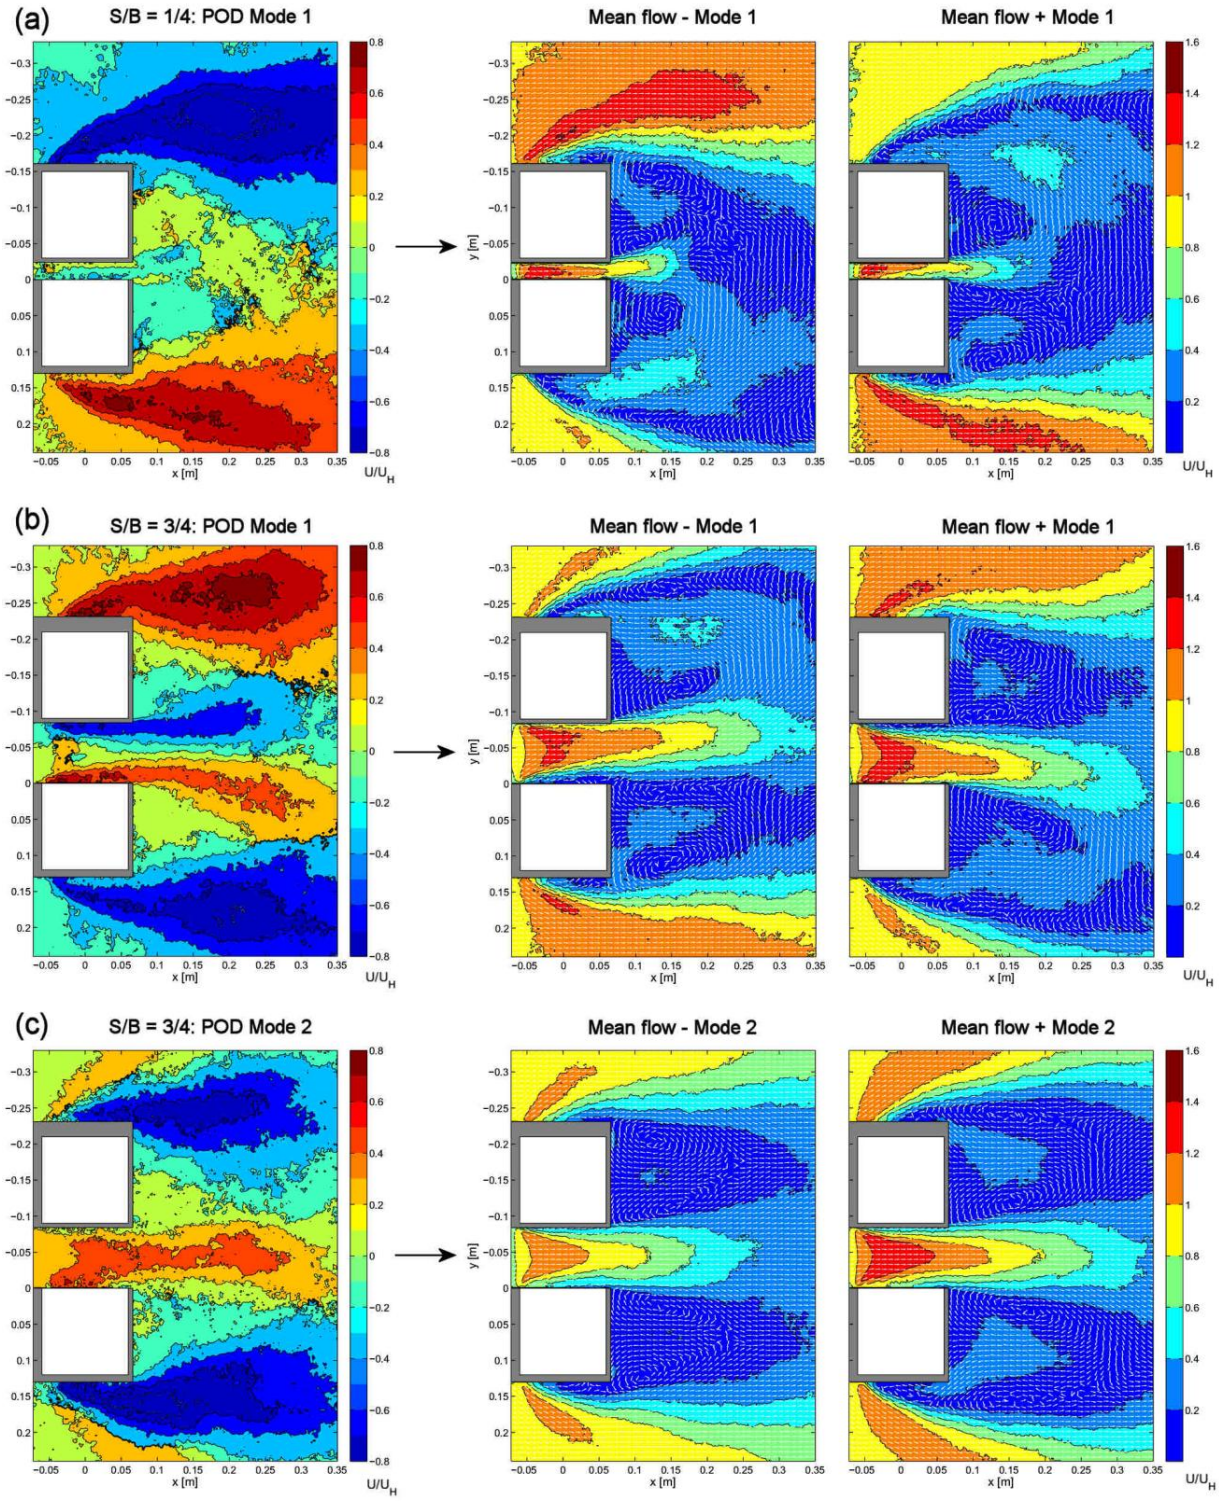

Figure 6. POD modes and effect in the flow field for: (a) Mode 2 (S/B = ¼), (b) Mode 1 (S/B = ¾) and (c) Mode 2 (S/B = ¾).

The 1st POD mode obtained for *S/B* = ¼ is illustrated in Figure 6(a). Most of the energy of this mode is observed in the flow outside of the tandem configuration, little energy is observed in the passage. This energy distribution is similar to the single model case, which is why this mode is defined as a single mode in Table 1. The 1st POD mode determined for *S/B* = ¾ is shown in Figure 6(b). For this separation distance, an increase in energy is observed both on the outside as well as in the passage. This mode is responsible for in-phase vortex shedding behavior of the vortex streets behind both models, in Table 1 this mode is specified as the coupled mode. This mode also is characterized by alternating separation from either sidewall in the passage, something observed in the snapshots of figure 5 as well. Figure 6(c) shows the 2nd POD mode determined for *S/B* = ¾, this mode is responsible for large velocity fluctuations in the gap between the models. In Table 1 this mode is defined as the gap flow mode. For some S/B values, the mode is characterized by combined separation from both sidewalls simultaneously in the passage, something observed in the snapshots of figure 5 as well. .

The modes illustrated in Figure 6 and provided in Table 1 are similar with the flow patterns described by Yen and Liu (2010). They performed smoke visualizations on similar models in a laminar boundary layer ($2262 < Re < 12560$) for opening ratios of $S/B = 0$ to 12, and observed a number of distinct flow patterns:

1. the single mode ($S/B < 0.1$);
2. the gap-flow mode ($0.1 < S/B < 6$);
3. the coupled vortex shedding mode ($S/B > 6$).

The specific ranges defined by Yen and Liu for the three observed modes, suggests that these modes do not exist simultaneously in laminar boundary layer flow. The energy fractions specified in Table 1 shows that these modes can coexist and that the gap-flow mode, for the studied cases, is an energy-wise secondary flow mode with respect to the single and coupled mode. The gap-flow mode coexists with the coupled mode. The difference in oncoming turbulence levels between both studies could be responsible for the different observations between the current work and the study performed by Yen and Liu (2010). Although the spectral characteristics of the pressure measurements performed by Yen and Liu (2010) suggest less stringent ranges for the different flow modes in a laminar flow as well.

Table 1. Energy fractions of flow modes obtained with POD and comparison with Yen and Liu (2010).

Separation Distance	Energy fractions per flow mode			Flow mode Yen and Liu
	Single	Coupled	Gap-flow	(2010)
Isolated	20%	-	-	Single
S/B = 1/4	16%	-	-	Gap-flow
S/B = 1/2	-	16%	6%	Gap-flow
S/B = 3/4	-	16%	6%	Gap-flow
S/B = 1	-	15%	7%	Gap-flow

4 CONCLUSIONS

Particle Image Velocimetry (PIV) and pressure measurements were performed to obtain a better understanding of the flow phenomena and related pressure effects encountered in a tandem

configuration of high-rise models in an atmospheric boundary layer. The mean and standard deviation values of the velocity field and the model pressure coefficient distribution were determined. Increases in mean and standard deviation velocity were observed in the passage with decreasing normalized separation distance (*S/B*).The regions of high standard deviation velocity fluctuations can be related to wall pressures in the passage region. Although the mean flow shows no backflow in the passage, intermittent separation from the sides of the passage occurs. POD is implemented to determine the most energetic modes. Three modes can be observed, single, coupled and gap-flow. For the isolated building and S/B=1/4 case, the single mode is dominant. For the other separation distances, both gap-flow and coupled mode coexist, with the coupled mode being dominant energy-wise. This is in contract with literature on laminar boundary layer flows, where only isolated modes are observed, and only the gap-flow mode is present in the currently investigated S/B ranges. The differences should be caused by the turbulence in the oncoming boundary layer. The currently observed coupled and gap–flow mode can be linked to separation of one or both inner walls in the passage respectively. An investigation into a more direct link between observed flow modes, velocity fluctuations and peak façade pressures is intended in future research.

ABSTRACT: The local flow field of a surface-mounted finite-height square prism was studied experimentally in a low-speed wind tunnel using particle image velocimetry (PIV). The prism was mounted normal to a ground plane and was partially immersed in a flat-plate turbulent boundary layer. Four finite square prisms of aspect ratios AR = 9, 7, 5 and 3 were tested at a Reynolds number of Re = 4.2×10^4. PIV velocity field measurements were made in a vertical plane parallel to the mean flow direction on the flow centreline, within two diameters upstream and five diameters downstream of the prism, and also above the free end. In the near-wake region, the large recirculation zone contains a vortex immediately behind and below the free end; the size and strength of this vortex increases as the aspect ratio of the prism decreases. A second vortex is found behind the prism near the prism-wall junction; this vortex was not observed for the prisms of AR = 5 and 3, indicating a distinct wake structure for these prisms compared to those of AR = 9 and 7.

KEYWORDS: Bluff body, finite square prism, near wake, recirculation zone, vortex structures, particle image velocimetry

1. INTRODUCTION

The flow around surface-mounted circular cylinders of finite height is more complex than the familiar case of a two-dimensional or "infinite" circular cylinder [1]. Surface-mounted cylinder-like or prismatic structures are found in many engineering applications, such as the flow past high-rise buildings, oil storage tanks, chimneys and cooling towers. For these bluff bodies, the flow field is strongly influenced by the flow around the free end and the flow around the junction between the cylinder and the surface.

The flow around a finite square prism of side length, D, and height, H, mounted normal to a ground plane (Fig. 1) is influenced by the aspect ratio, AR (= H/D), the Reynolds number, Re (= DU_∞/ν, where U_∞ is the freestream velocity and ν is the kinematic viscosity), and the relative thickness of the boundary layer on the ground plane, δ/D (where δ is the boundary layer thickness at the location of the prism). The flow around the prism-wall junction (at the ground plane) and over the free end cause the local flow field to become strongly three-dimensional. Some of the most extensive insight into the wake vortex dynamics (vortex shedding, streamwise vortex structures) of the finite square prism comes from recent experimental studies by Wang et al. [2, 3], Wang and Zhou [4], and Bourgeois et al. [5]. These studies used a variety of experimental techniques, including flow visualization, thermal anemometry, laser Doppler velocimetry (LDV), and particle image velocimetry (PIV).

Because of the complexity of the flow field around the surface-mounted finite-height square prism, and the many influencing parameters, further study is needed to obtain a complete physical understanding of the wake behavior, especially very close to the prism, i.e., the local

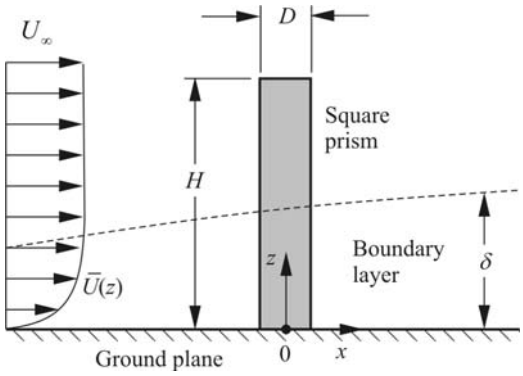

Figure 1. Schematic representation of the flow past a finite-height square prism mounted normal to a ground plane and partially immersed in a flat-plate boundary layer.

flow field. In the present study, the local flow fields of surface-mounted finite-height square prisms were investigated in a low-speed wind tunnel using the PIV technique. Of particular interest in the present study were the flow in the near-wake region and the effect of aspect ratio.

2. EXPERIMENTAL APPARATUS

The experiments were conducted in a low-speed closed-return wind tunnel with a test section of 1.96 m (length) × 0.91 m (height) × 1.13 m (width). The streamwise freestream turbulence intensity was less than 0.6% and the mean velocity non-uniformity outside the test section's wall boundary layers was less than 0.5%. An aluminum ground plane was installed on the floor of the wind tunnel test section and a fully developed turbulent boundary layer was produced on the ground plane at the location of the finite square prism.

Four different, smooth, aluminum square prism models, all of the same width, D = 31.5 mm, were tested. The free end of each prism was a flat surface with sharp perimeter edge. Each prism had a different height, giving prisms with AR = 9, 7, 5, and 3, similar to the earlier experiments of [1,6]. The prisms were anodized flat black to minimize unwanted reflections from the laser light sheet used for the PIV measurements. Each prism was partially immersed in the turbulent boundary layer on the ground plane. The experiments were conducted at a freestream velocity of U_∞ = 20 m/s, giving a Reynolds number, based on prism width, of Re = 4.2×10^4.

The wind tunnel data were acquired using a computer with a 1.8-GHz Intel Pentium 4 processor, a National Instruments PCIe-6259 16-bit data acquisition board, and LabVIEW software. The freestream conditions were obtained with a Pitot-static probe, Datametrics Barocell absolute and differential pressure transducers, and an Analog Devices AD590 integrated circuit temperature transducer. To characterize the boundary layer on the ground plane, a boundary layer Pitot tube and an X-wire boundary layer probe were used to measure its mean velocity profile. At the location of the prism (with the prism removed), the boundary layer thickness was δ = 54 mm providing a thickness-to-width ratio of δ/D = 1.7 and a thickness-to-height ratio ranging from δ/H = 0.2 (for AR = 9) to δ/H = 0.6 (for AR = 3).

Velocity field measurements in the vicinity of the finite square prism were made with a PIV system. The laser light (532 nm) was supplied by a 200-mJ/pulse dual Nd:YAG Gemini PIV 15 laser from New Wave Research, which had a maximum pulse frequency of 15 Hz. A TSI

light arm was used to deliver the laser beam from the laser to the light sheet optics. The light sheet optics included either a −50-mm or −25-mm cylindrical lenses and 500-mm, 750-mm, or 1000-mm spherical lenses, depending on the location of the field of view. Images were acquired with a CCD camera (MegaPlus ES4020, double frames, 2048 × 2048 pixels) and captured by a 64-bit EDT PCI DV C-Link frame grabber on a computer workstation. The timing of the laser, camera, and frame grabber was controlled by a Berkeley Nucleonics 505-8C digital delay generator synchronizer. The flow was seeded by atomized propylene glycol droplets produced by a theatrical fog machine.

PIV measurements were made in vertical (*x*-*z*) planes located on the centreline of the test section ($y = 0$). The light sheet optics were located above the wind tunnel test section and the laser light was directed through a small aperture in the test section roof and towards the ground plane. The field of view was 61 mm × 61 mm (1.9*D* × 1.9*D*) yielding an image resolution of about 30 μm/pixel. For the tallest prism (of AR = 9), more than 25 fields of view were used to build a composite picture of the flow field upstream and downstream of the prism. For each field of view, an ensemble of 1,000 sample images was acquired from which the mean velocity vector field was determined. Image pairs were processed with a half-padded FFT cross-correlation algorithm, a relative maxima peak detection algorithm, and a Gaussian sub-pixel interpolation algorithm. A Hart correlation-based (CBC) validation method [7] with 50% overlap was used for reducing the sub-pixel errors and eliminating spurious vectors from the PIV results. The cellular neural network (CNN) method [8] together with dynamic threshold outlier identification was used as a post-interrogation algorithm to detect spurious vectors in PIV measurements. Most fields of view were analyzed with initial interrogation areas of 32×32 pixels. Owing to large pixel displacements in some limited regions of the flow, initial interrogation sizes of 64×64 pixels were used in the remaining fields of view. In all cases a two-level analysis technique was used that halved the interrogation area size during the second pass. In addition, a 50% interrogation area overlap was used in all cases. The resulting velocity vector fields contained approximately 127 × 127 and 63 × 63 velocity vectors with a vector spacing (spatial resolution) of approximately 0.015*D* and 0.03*D*, respectively. This spatial resolution is significantly greater than the seven-hole probe experiments of Sumner et al. [1], the X-probe measurements of Adaramola et al. [6], and the PIV studies of Wang and Zhou [4] and Park and Lee [9] in the literature. The uncertainty in the mean velocity measurements was estimated to be about 2%.

3. RESULTS AND DISCUSSION

Figure 2 shows the local mean velocity vector field on the wake centerline ($y/D = 0$) for each of the four prisms (of AR = 9, 7, 5, and 3); the corresponding mean flow streamlines are shown in Figure 3. In Figure 2, the in-plane mean velocity components are made dimensionless with the freestream velocity ($\overline{U}/U_\infty$, $\overline{W}/U_\infty$). The mean fields are calculated from an ensemble of 1,000 instantaneous PIV velocity fields.

Upstream of the prism, for all four aspect ratios, part of the approach flow moves up and over the tip and separates from the leading edge of the free end. No flow reattachment occurs on the free end (Figs. 2 and 3). The other part of the approach flow, closer to the ground plane, moves downwards as it nears the prism and recirculates upstream of the prism-wall junction. It is in this region where the familiar horseshoe vortex is located (although it cannot be discerned in Figs. 2 and 3). In the near-wake region, a strong downwash flow (downward-directed velocity vectors in Fig. 2) is observed immediately downstream of the free end in the near wake of the

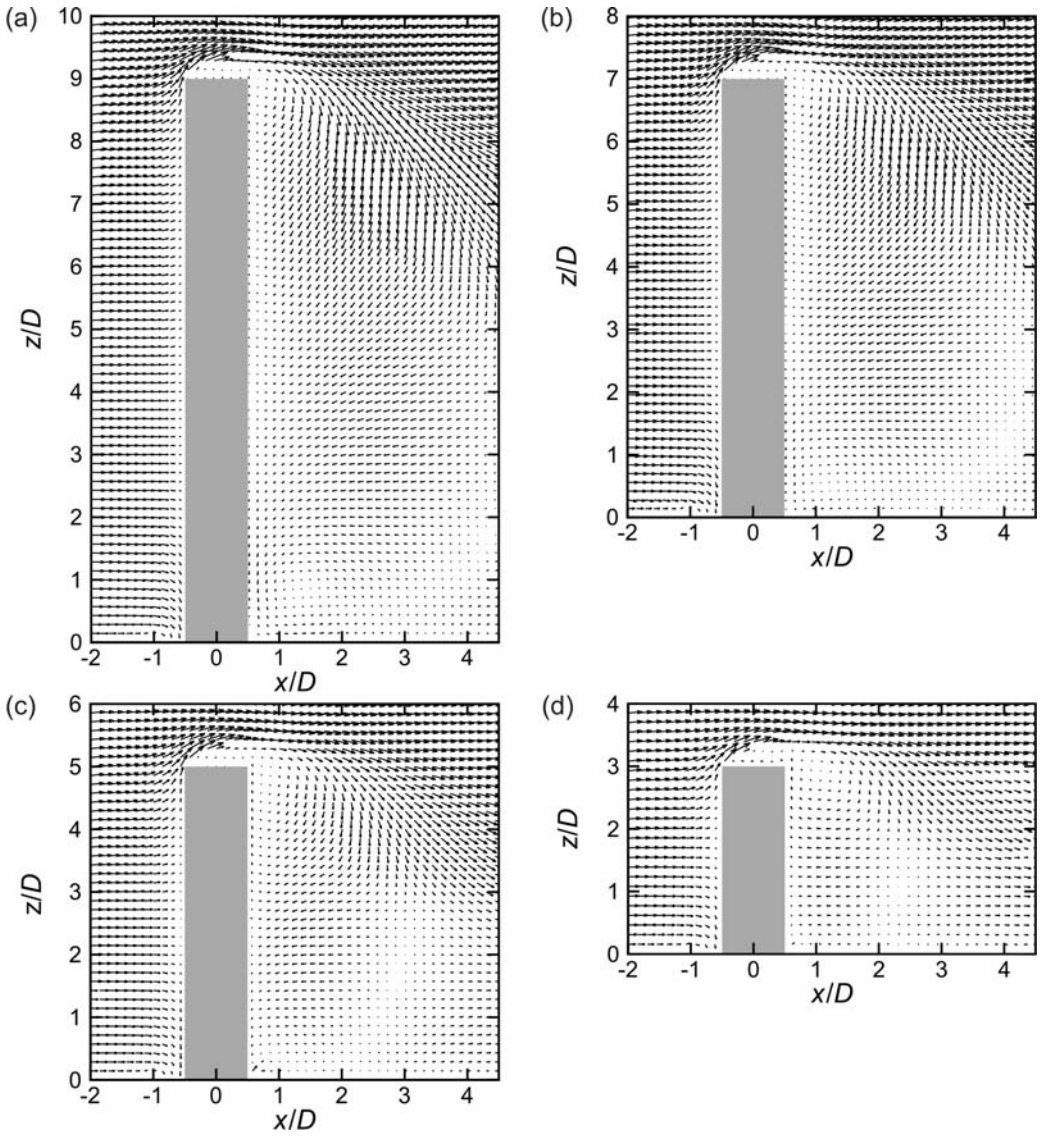

Figure 2. Mean velocity vector field ($\overline{U}/U_\infty$, $\overline{W}/U_\infty$ components) in a vertical plane on the wake centerline (y/D = 0, the symmetry plane): (a) AR = 9; (b) AR = 7; (c) AR = 5; (d) AR = 3.

prism (Fig. 2). The downwash originates downstream of the free-end recirculation zone, persists in the streamwise direction and descends into the central portion of the wake.

In the mean streamlines shown in Figure 3, part of the downwash flow is directed towards the ground plane and returns upstream to stagnate onto the rear surface of the prism; a large recirculation zone forms behind the prism. The rest of the downwash flow moves away from the prism into the far wake. As seen in Figure 3, a small vortex forms immediately downstream of the trailing edge of the free end. The size of the vortex is a function of the prism aspect ratio, such that the largest vortex occurs for the smallest aspect ratio (AR = 3, Fig. 3d). According to Figures 3a,b,c, for AR = 9, 7 and 5, respectively, some of the downwash flow is directed along the prism wall toward the ground plane, whereas for AR = 3 (Fig. 4d), flow moves upwards along the prism wall toward the free end, resulting in a larger vortex just below the free end.

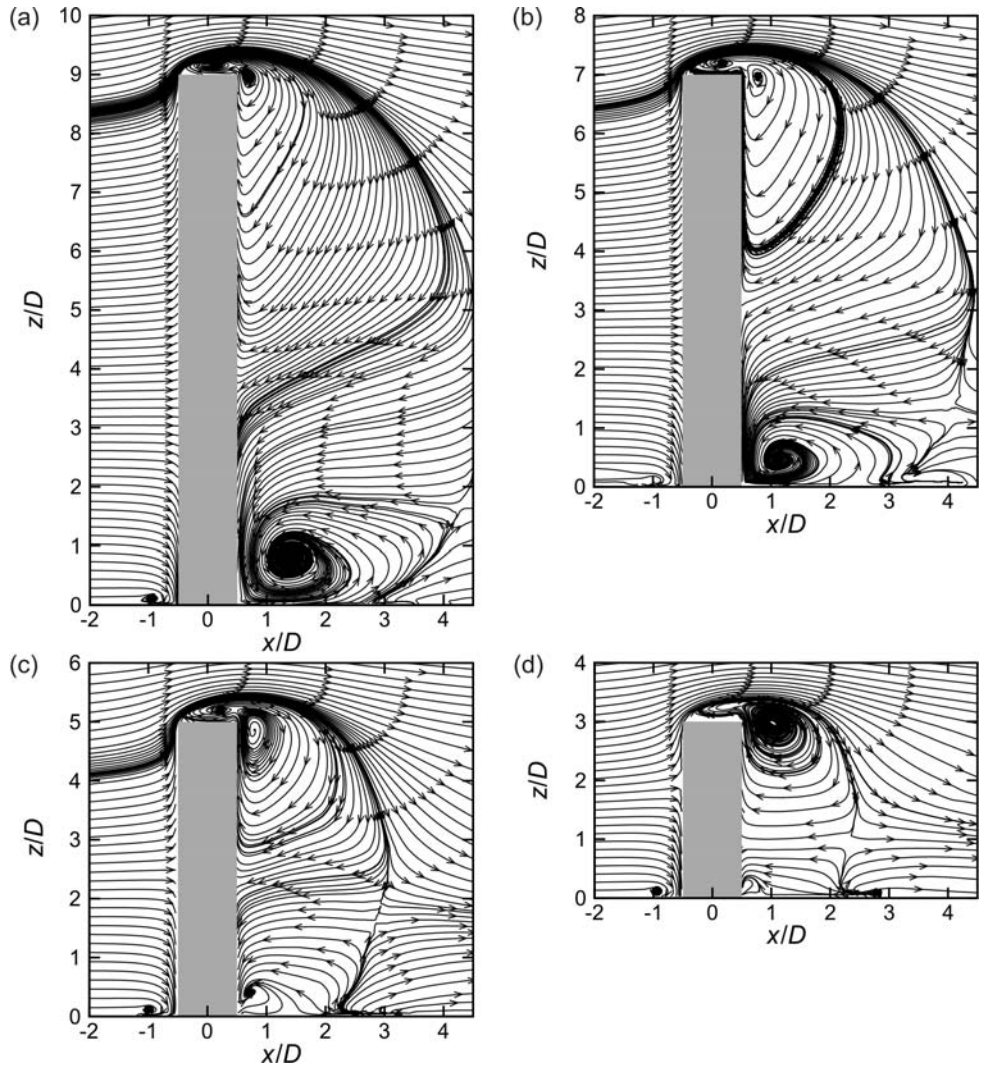

Figure 3. Mean streamlines in a vertical plane on the wake centerline (y/D = 0, the symmetry plane), corresponding to the mean velocity fields in Figure 2: (a) AR = 9; (b) AR = 7; (c) AR = 5; (d) AR = 3.

According to Figures 2 and 3, another vortex, with CCW sense of rotation, can be found immediately behind the prism, near the prism-wall junction, for AR = 9 and 7 (Fig. 3a,b); enlargements of these vortices are shown in Figure 4. This vortex is much weaker and nearly absent for the prisms of AR = 5 and 3 (Figs. 3c,d and 4c,d). The distinct near-wake structure for AR = 3, and to some extent for AR = 5, suggest the critical aspect ratio for these prisms is between AR = 5 and AR = 3.

Figure 5 shows how the maximum length of the recirculation zone is dependent on the square prism's aspect ratio. According to this figure, the maximum length of the recirculation zone increases from L_{max}/D = 2.3 for AR = 3 to L_{max}/D = 4.2 for AR = 9. In Figure 5, the present data are compared to the square prism data of Wang and Zhou [4] and Bourgeois et al. [5]. Good agreement can be seen between the present data and the other studies for prisms of AR = 3, 5, and 7.

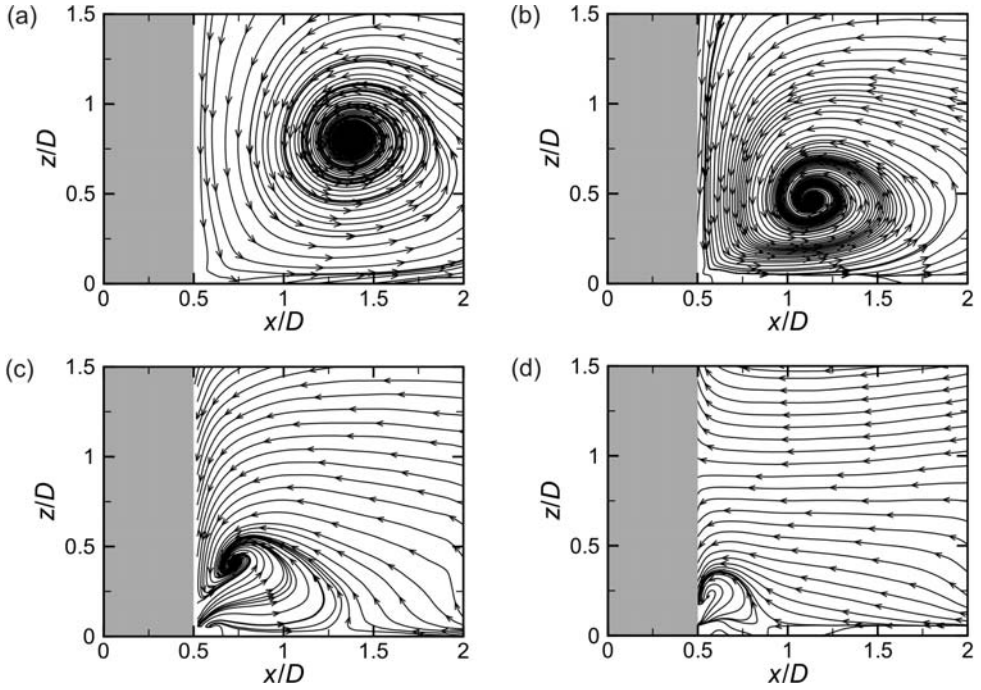

Figure 4. Mean streamlines immediately behind the prism at the junction with the ground plane: (a) AR = 9; (b) AR = 7; (c) AR = 5; (d) AR = 3.

A contour plot of the streamwise turbulence intensity (u'/U_∞), on the wake centreline, is shown in Figure 6. The highest values of streamwise turbulence intensity are encountered above the free end of the prisms of AR = 9, 7, and 5 (Figs. 6a,b,c), while the highest value of u'/U_∞ for AR = 3 (Fig. 6d) occurs farther downstream, showing a distinct turbulence structure for AR = 3. For all four prisms, the highest values of wall-normal turbulence intensity (w'/U_∞, not shown) are encountered within the recirculation zones of the prisms. The location of highest wall-normal turbulence intensity in the near-wake region tends to move downward and towards the prism as the aspect ratio of the prism decreases.

The Reynolds shear stress field on the wake centreline for AR = 3 (Fig. 7d) is distinct from those for AR = 9, 7, and 5 (Fig. 7a,b,c). For the three most slender prisms, the near-wake region is characterized by two regions of elevated Reynolds shear stress: a region of negative shear stress at the top of the wake and a region of positive shear stress closer to the ground plane. For AR = 3 (Fig. 7d), however, the region of positive shear stress below the free end is almost absent, showing a distinct wake structure for this prism. Furthermore, the positive Reynolds shear stress just below the prism free end decreases in size and level as the aspect ratio of the prism decreases; it disappears for AR = 3.

The mean cross-stream vorticity ($\overline{\omega_y} D/U_\infty$) fields for the four finite square prisms are shown in Figure 8. Upstream of the prism, the negative (CW) vorticity near the ground plane reveals the presence of the boundary layer and horseshoe vortex. For all four aspect ratios, negative vorticity is generated as the flow moves around the free end and downward into the near-wake of the prism. It is apparent that as the square prism aspect ratio decreases, the region of mean cross-stream vorticity behind the prism becomes larger in area and extends farther downstream. Close to the prism-wall junction, and immediately behind the prism, a small region of positive (CCW) vorticity is found for the prisms of AR = 9, 7 and 5 (Figs. 8a,b,c). This corresponds to the small recirculation shown earlier (Figs. 3a,b,c and 4a,b,c). Compared to AR =

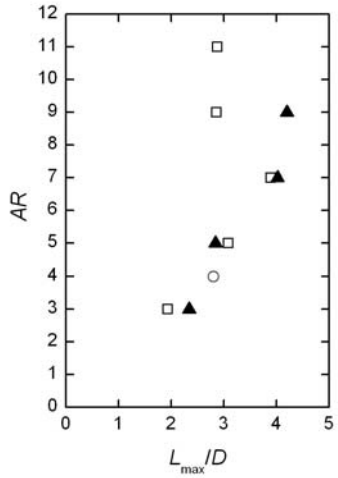

Figure 5. Maximum streamwise length of the mean recirculation zone for different aspect ratios. ▲, Present study, square prism, Re = 4.2×10^4; □, Wang and Zhou [4], square prism, Re = 9.3×10^3; ○, Bourgeois et al. [5], square prism, Re = 1.2×10^4.

9, 7, and 5, no region of positive vorticity is found in the region immediately behind the prism at its junction with the wall for the prism of AR = 3 (Fig. 8d).

4. CONCLUSIONS

In the present study, the local flow field and near wake of a surface-mounted finite square prism were investigated in a low-speed wind tunnel at Re = 4.2×10^4 using PIV. The prism was mounted normal to a ground plane and was partially immersed in a flat-plate turbulent boundary layer with δ/D = 1.7 at the location of the prism. Four prism aspect ratios were considered, AR = 9, 7, 5, and 3. PIV velocity measurements were made in a vertical plane on the flow centreline, upstream and downstream of the prism, with a special focus on the near-wake recirculation zone. The results of the present study have improved the limited state of information on the local flow field of a surface-mounted finite square prism and the influence of aspect ratio.

In the near-wake region, a large recirculation region forms behind the prism. Downwash flow enters the central portion of the wake where some flow from the free end reverses and moves toward the rear surface of the prism. A small vortex is located just downstream of the free end behind the prism and below the main downwash flow. This vortex is found for all four aspect ratios. Near the ground plane and close to the prism-wall junction, a second vortex forms; this vortex is weak or nearly absent for the prisms of AR = 5 and 3. The maximum length of the recirculation zone (L_{max}/D) increases with the prism aspect ratio from 2.3D for AR = 3 to 4.2D for AR = 9. Elevated levels of wall-normal turbulence intensity and Reynolds shear stress also occur above the free end of the square prism. Cross-stream vorticity production also occurs around the free end and into the downwash region behind the prism. This region of mean vorticity extends farther downstream as the aspect ratio decreases.

Unsteady features of bluff body wake with application to building wake length

L. Cheng, K. M. Lam*

Department of Civil Engineering, University of Hong Kong, Pokfulam, Hong Kong

ABSTRACT: This study is targeted at obtaining fluctuating characteristics of building wakes through measurement of unsteady velocity fields with time-resolved particle image velocimetry (PIV). Proper orthogonal decomposition is applied to the PIV data to identify low-dimensional substructures of the building wake. This leads to a more reliable estimation of the fluctuating ground-level length of the building wake from an instantaneous PIV snapshot. The statistics of unsteady wake lengths is important in the probability-based risk assessment of critical events of wind environment around buildings such as dispersion of hazardous pollutants, pedestrian danger and risks to aircraft landings on airport runways.

KEYWORDS: Building wake, particle-image velocimetry, proper orthogonal decomposition

1 INTRODUCTION

Wind environment around buildings has received increasing attention from researchers for a number of applications. Building wakes are known to affect dispersion of pollutants by wind. Environmental wind conditions on the pedestrian level are modified by the presence of buildings. A recent review can be found in Blocken and Carmeliet [1]. In high-rise urban areas, massive tall building developments are often accused of reducing the available wind flow to the downwind low-rise part of a city for ventilation and pollutant dispersion [2,3]. Tsang et al. [2] conducted parametric wind tunnel studies to investigate the wind environment around a group of buildings and concluded that the air movement behind the buildings is governed by the backflow created by vertical recirculation and flow passing through building separations. The relationship between these two kinds of flow determines the existence of low wind speed zones, which may impair air ventilation, and high wind speed zones, which may cause pedestrian discomfort. Yim et al. [3] studied the adverse impacts of this "wall effect" with computational fluid dynamics. The numerical results suggest that alignment of high-rise buildings leads to "wall effect" not only on air ventilation but also on pollutant dispersion rate.

Another undesirable effect of building wakes is the possible risks to aircraft landings on airport runways [4]. The objective of this study is triggered by a number of assessments of building-induced disturbance to wind flow field near runways of the Hong Kong Airport. There exist concerns about the spatial extent of building wakes causing sudden changes in wind speeds on the runways.

There have been numerous wind-tunnel and numerical investigations of wake characteristics and pollutant dispersion behaviors behind buildings of different sizes and geometries [1] but the experimental and numerical results are mostly limited to time-averaged mean wind speeds and statistical properties such as turbulence intensities. While these mean flow properties are generally useful in applications such as assessment of wind environmental conditions around tall buildings for pedestrian comforts or pollutant dispersion efficiency in downwind regions, unsteady and fluctuating flow quantities are equally important in critical situations such as dispersion of

hazardous matters and building-induced wind shear events on runways. These latter applications call for a probability approach for appropriate risk assessment and data on the fluctuating characteristics of building wakes are required. As a basic feature, it is desirable to know the maximum and minimum spatial extents of the building wake over time.

This paper reports an attempt to obtain some characteristics of fluctuating building wake through laboratory measurement. Unsteady velocities in the wake of a surface mounted bluff body are measured with time-resolved particle image velocimetry (PIV) and proper orthogonal decomposition is employed to interpolate PIV database and identify low-dimensional substructures of the building wake.

2 EXPERIMENTAL TECHNIQUES

In this study, turbulent flow behind a tall building model was measured with PIV. Fig.1 shows the schematic of the experimental arrangement. The first set of experiments was carried out in a water channel with width of 0.3 m. The target geometrical scale of the testing was 1:1000. The building model was a square-section tall building of height H = 75 mm and breadth B = 30 mm. For optical access, the building model was made of plexiglass. To simulate wind profiles over a suburban terrain, three triangular spires and 750 mm fetch of roughness elements were placed on the ground level plate upstream of the building model. Experiments were performed with the water depth 0.375 m above the ground level plate and flow velocity $U_H \approx 0.13$ m/s at the roof height of the building model. The Reynolds number was $\mathrm{Re} \approx U_H B/\nu = 4{,}350$.

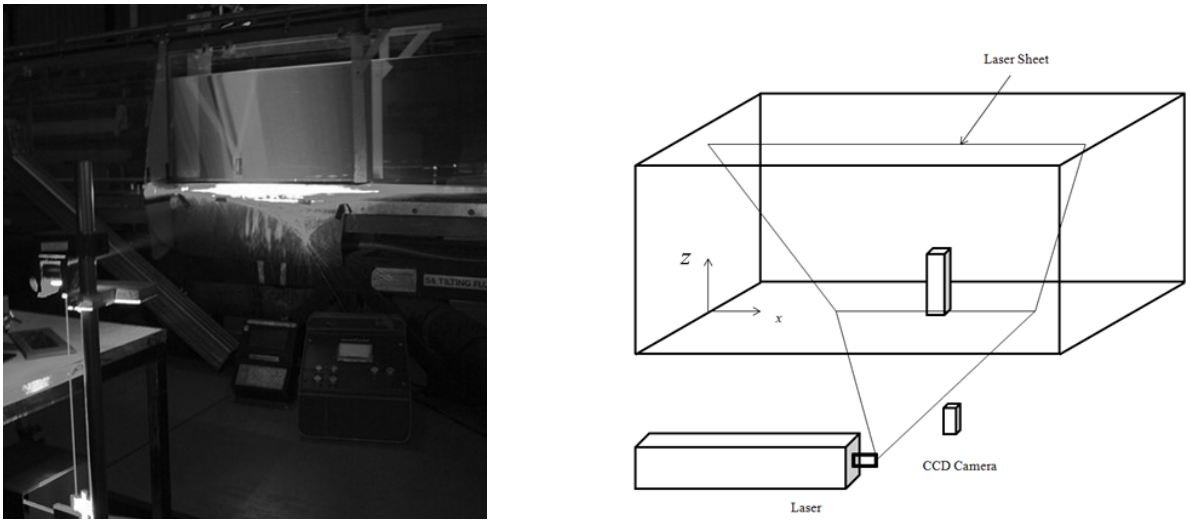

Figure 1. Experimental setup for PIV measurement.

A continuous-wave Argon-ion laser was used to generate a laser sheet to illuminate a two-dimensional plane of the flow. For flow on the central stream-wise vertical plane (x-z) of the building wake, the laser sheet was shone from below the transparent ground level plate. Neutrally buoyant polyamid particles of 35 μm nominal diameter were used to seed the water. Flow images were captured with a high speed camera (model PCO 1200hs) viewing through the transparent side window of the water channel. The camera had a resolution of 1280×1024 pixels and was set at a speed of 100 image/s to capture a time sequence of particle images of 1000-image length.

Particle images recorded on two consecutive images were analyzed for an instantaneous PIV snapshot using a PIV analysis software. The analysis was based on the spatial cross-correlation algorithm [5] but with adaptive and multi-pass interrogation windows. In the final iteration, PIV vectors were obtained on interrogation areas of size 32×32 pixels and with a 50% overlap. Thus, the two-dimensional velocity field at each time instant was consisted of 79×63 vectors of U and V.

3 POD ANALYSIS

Proper orthogonal decomposition (POD) is an efficient and elegant method of identifying lower order substructures by projecting the high-dimensional data onto a lower-dimensional space and capturing the dominant features (coherent structures) of the spatial-temporal fields with POD modes. POD is widely used in many disciplines such as image processing, signal analysis and data compression, with applications to turbulent flows starting from Lumley [6]. Kostas et al. [7] applied the snapshot POD analysis on both velocity data and vorticity data to investigate flow behind a backward-facing step at Reynolds numbers 580 and 4660. Adrian et al. [8] studied a fully developed channel flow at Reynolds number 5387 with POD analysis of PIV velocities and suggested that POD is effective at identifying the inhomogeneous spatial distribution of various eddy scales.

This study adopts the snapshot POD method [9] which solves the eigenvalue problem necessary for POD analysis in an efficient way. The implementation of POD analysis is as follows. From PIV measurement, a set of velocity components (u, v) sampled over N time steps for a period of T are obtained. First, the time-average velocity field is calculated and removed from each member of the ensemble, such as:

$$\overline{u}(x,y)=\frac{1}{N}\sum_{n=1}^{N}u(x,y,t_n)$$

The fluctuating velocity field is then given by:

$$u'(x,y,t_n)=u(x,y,t_n)-\overline{u}(x,y)$$

The two-point averaged spatial correlation function is then computed by:

$$R(x_i,x_j;y_i,y_j)=\frac{1}{N}\sum_{n=1}^{N}u'(x_i,y_i,t_n)u'(x_j,y_j,t_n)$$

The eigenvalue problem can be solved as:

$$R\Phi=\lambda\Phi$$

The N POD modes are obtained as the columns (φ) of the eigenfunctions Φ. The corresponding element of the eigenvalue vector λ defines the relative contribution of each mode to the fluctuating velocity field. Thus, the cumulative energy contribution from the first k modes is given by:

$$E_k=\sum_{i=1}^{k}\lambda_i\Big/\sum_{i=1}^{N}\lambda_i$$

After obtaining the POD modes, reconstruction of any of the original PIV snapshots can be performed using all or some of the modes as:

$$u_i(x,y,t) = a_i(t)\varphi_i$$

The coefficients $a_i(t)$ are obtained from the projection of the original data onto the POD modes:

$$\mathbf{A} = \left\langle \Phi^T, C \right\rangle$$

4 RESULTS AND DISCUSSION

The first target flow information is the fluctuating ground-level length of the building wake on the x-z plane. Figure 2 shows an example of instantaneous velocity field in the building wake from one PIV snapshot. Due to the low density of seeding particles in the wake, valid PIV velocity vectors cannot be obtained at some points. Ideally, the velocity vector map can show how wind flow over the building roof subsequently curves downwards towards the ground and the ground-level wake length can be determined by the point of reattachment. In the practical situation, the flow is highly turbulent and three-dimensional. It is difficult to trace the instantaneous streamlines and determine the wake length.

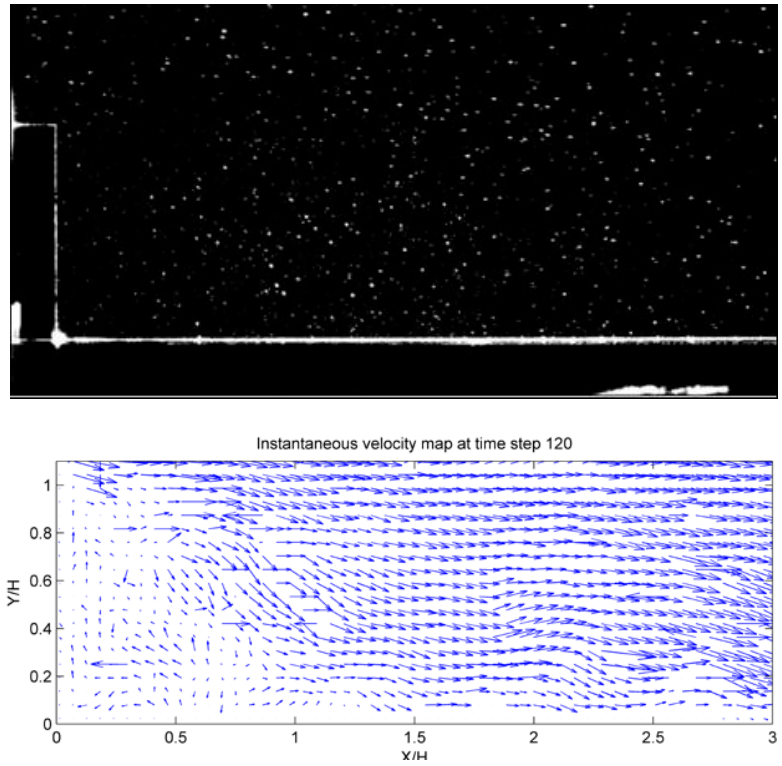

Figure 2. Example of PIV snapshot: single flow image; instantaneous velocity filed in the building wake.

The mean velocity vectors on the *x*-*z* plane averaged over all 1,000 PIV snapshots were shown in Fig. 3. The time-averaged mean flow paths and the recirculating flow behind the building are clearly revealed. However, it should be noted that this mean flow pattern will not occur at any instant along the time-axis. Figure 4 shows the axial distributions of the mean velocity component

U and the axial turbulence intensity near the ground level. The data are taken from the PIV interrogation windows closest to the ground. The mean axial velocities change from negative values inside the building wake to positive values downstream of the mean wake length. The mean building wake length is found for the change of sign at $L_w/H = 0.69$. At or very near to this location, the turbulence intensity reaches its peak value.

Figure 5 shows the velocity profiles of mean horizontal velocity components as a function of height above ground at locations upstream and downstream of the mean building wake length. Upstream of the mean building wake length, at $x/H < 0.69$, there always are some velocities having negative values. Downstream of the mean building wake length, velocities are all positive with magnitudes gradually increasing with increasing downstream distance. In other words, the mean building wake length is the location where the separation streamline from the building roof reattaches to the ground or the location where the ground-level velocities returns to the downstream direction from the reverse flow direction within the building wake.

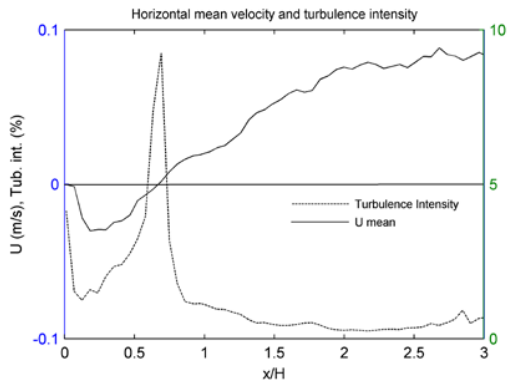

Figure 4. Mean horizontal velocity component and turbulence intensity near ground.

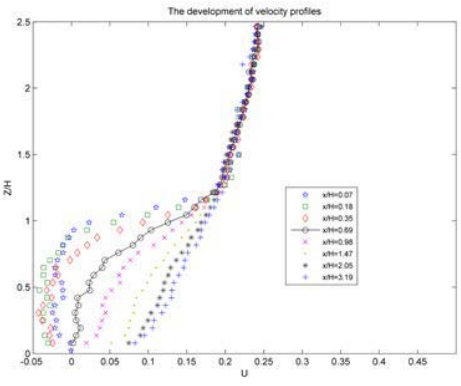

Figure 5. Profiles of mean horizontal velocities.

Attempt is made to apply the above feature to estimate the instantaneous building wake length from a PIV snapshot such as that in Fig. 2. From the instantaneous velocity vectors at any instant, the variation of horizontal velocity components along the lowest measurement points near the ground level is examined. The building wake length at that instant is determined as the length from the rear face of the building model to the location beyond which the instantaneous horizon-

tal velocities at the ground level become always positive. This is the location where the separation streamline from the building roof reattaches to the ground or the location where the ground-level velocity returns to the downstream direction from the reverse flow direction with in the building wake.

This method of wake length estimation is applied to the ensemble of 1,000 PIV snapshots. Figure 6 shows the probability density function (pdf) of the ensemble of unsteady building wake lengths. It is found that near a half of ensemble have the building wake lengths distributed over a wide range between $L_w = 0.2H$ and $1.2H$. The other half have very short wake lengths at $L_w < 0.2H$. This pdf distribution is not consistent with the feature of the mean flow pattern in Figs. 3-4. It appears that the instantaneous flow pattern consists of a number of flow structures of scales much smaller than the mean recirculating vortex. Wind flow separates on the roof leading to an unsteady shear layer behind the building model. Along the shear layer, a series of small-scale vortices are generated and this may contribute to the very small building wake lengths at some instants.

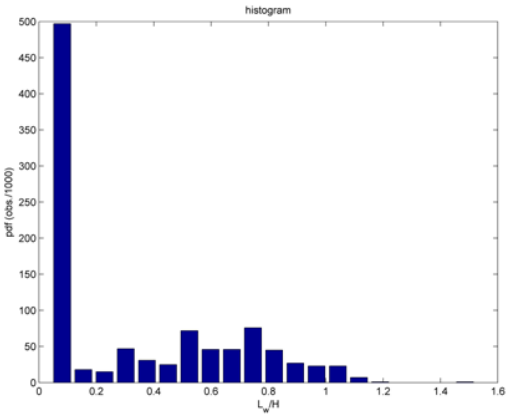

Figure 6. Histogram of building wake length of original data.

The result of Fig. 6 shows that it is not satisfactory by conducting probabilistic analysis directly with the raw velocity data. Thus, POD analysis is attempted as a potential approach in solving this problem. The two plots in Fig. 7 show the mean contours and the first five POD modes of the horizontal and vertical velocities. From the mean contour of horizontal velocity U, it can be discovered that the streamline from the top of the building reaches the ground level at the point around $x/H \approx 0.7$ and there exist some small scale turbulence before the reattachment point. In the first two U-POD modes, there exist a lot of small scale fluctuations throughout the building wake, while for modes 4 and 5 the scales of turbulent eddies become larger. In the V-POD modes, the turbulence scales are relatively larger than those in U-POD modes. Figure 8 shows that the cumulative energy of the first 50 POD modes. It is surprising to find only around 22% of the total energy is contained with these modes. The poor energy convergence may be attributed to the large variety of scales present throughout the flow. The increased level of flow complexity near the reattachment region may result in a less efficient decomposition.

Using the first 10 POD modes, the 1000 instantaneous velocity fields are reconstructed. In using only the lower modes, turbulent eddies of smaller scales are removed and only the more coherent flow eddies are retained. The unsteady building wake lengths are then estimated from these reconstructed velocity fields with the same method of ground-level horizontal velocities. Figure 9 shows the resulting pdf of the building wake lengths. The unrealistic peak at very smaller values is very much reduced and the distribution is now over a narrow range between $L_w =$

0.4H and 0.9H and with a peak at $L_w \approx 0.75H$. This peak value coincides with the mean flow patterns in Fig. 4. The original flow structure behind a building on the two-dimensional plane is complicated and upstream of the reattachment point, there exist many small-scale flow eddies behind the building. But with the reconstructed data, the small-scale structures are filtered and the reattachment point can be more easily determined. The probability distribution of L_w in Fig. 9 is valuable in the probability assessment of building wake effects such as ventilation efficiency and runway operation.

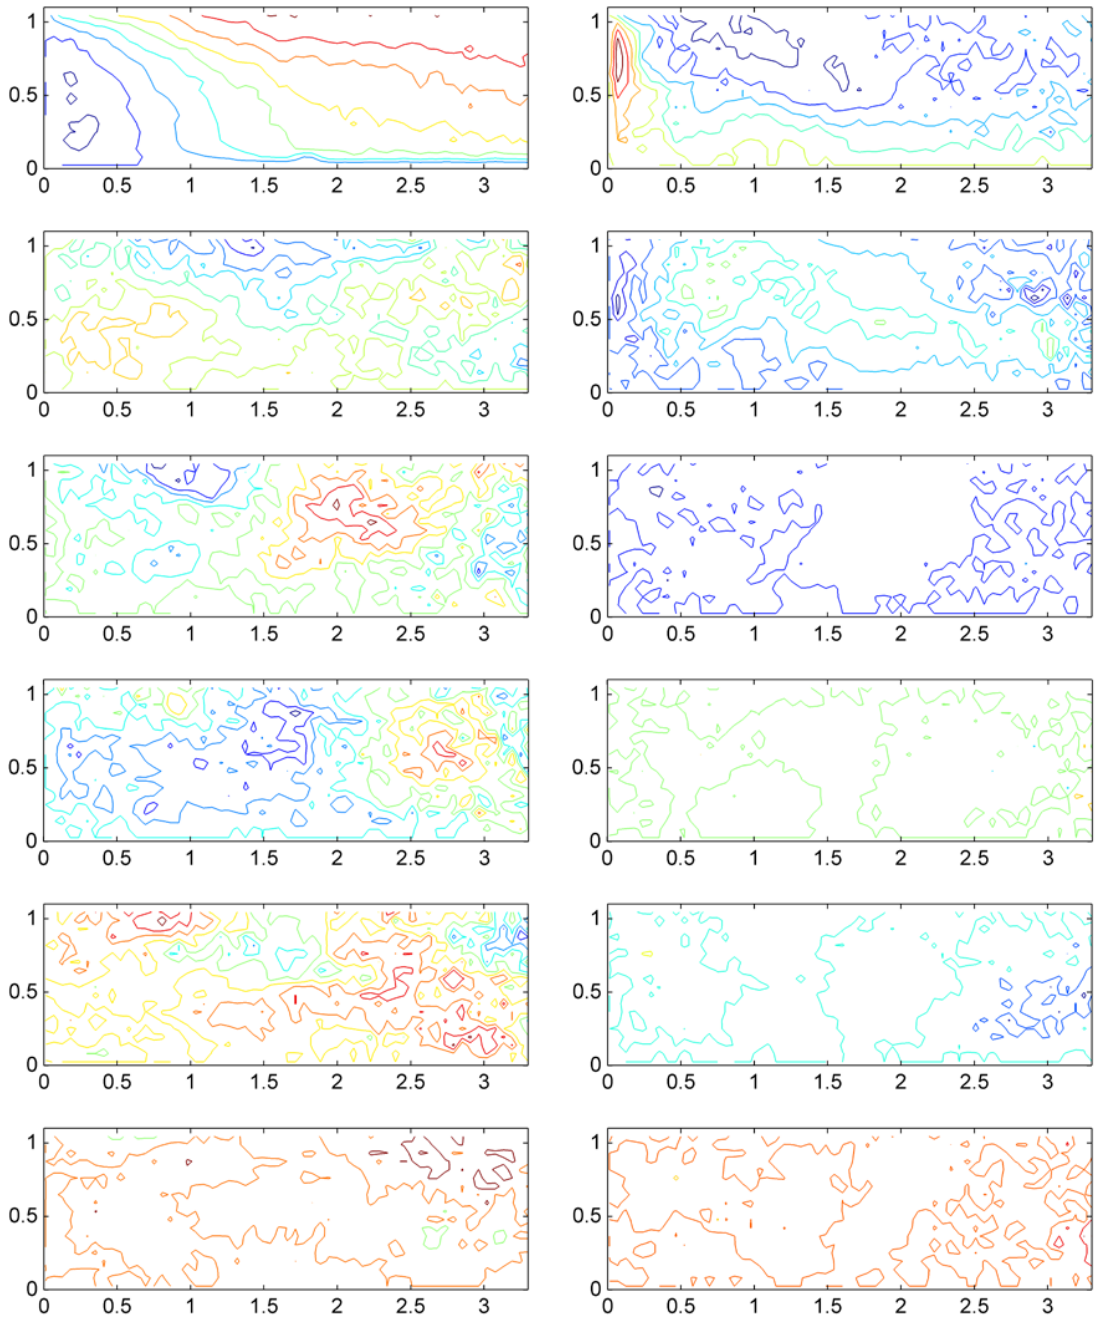

Figure 7. Mean flow and first five POD modes of horizontal (U) and vertical (V) velocities.

5 CONCLUDING REMARKS

Unsteady velocity fields on the central vertical plane of a building wake are measured with time-resolved PIV in an attempt to determine some statistics of the fluctuating building wake length on the ground level. It is found that presence of small scale turbulent eddies and three-dimensionality of the flow renders estimation of the wake length from an instantaneous PIV snapshot difficult. The use of POD analysis allows filtering of small-scale flow eddies in the reconstructed velocity fields, leading to a more reliable estimation of the building wake lengths. The statistics of fluctuating characteristics of the building wake are useful in the probability-based risk assessment of critical events such as dispersion of hazardous matters and building-induced wind shear events on runways.

The Reynolds number in the reported experiments is not sufficiently high to model full-scale wind flow past a real building. More refined experiments are being carried out on building models of a larger geometric scale in a boundary layer wind tunnel. Time-resolved PIV measurements will be made to measure the unsteady flow fields on both horizontal and vertical planes in the building wake.

ABSTRACT: The structure of the conical vortices on and behind the cube in uniform smooth flow and turbulent boundary layer flow when flow attacks normal to the diagonal line is investigated by synchronous measurements of 3D-SPIV and multi pressure sensor systems. The conical vortex at one side is always stronger than that at the other side. The conical vortices at the both sides sway in a body on the cube, and the strength of vortices changes all the time. The side at the stronger vortex changes occasionally in relatively long interval An arch-type vortex is formed behind the cube in any times of which shape is reentrant at the center and inclines to the side of the stronger conical vortex. When the conical vortex at one side is stronger, the vortex at the other side is drawn into the one side of the arch-type vortex.

KEYWORDS: Cube, 3D-SPIV, Conical vortex, Arch-type vortex, Switching phenomenon, Flow interaction

1 INTRODUCTION

When flow attacks to a flat roof from an oblique angle, a pair of conical vortices is formed on the roof. The vortices induce strong suction on the roof along the windward edges. Roof tiles are often scattered by the local strong peak negative pressure induced by the conical vortices [1],[2],[3],[4],[5],[6].

The vortex at one side of the roof is always stronger than that at the other side. The stronger vortex switches side by side occasionally in smooth flow. This phenomenon is known as the switching of flow pattern [6],[7]. On the other hands, a very strong conical vortex is formed on one side in turbulent flow when a strong gust attacks to the eave in a particular angle of attack of around 25 degree, and the pulse like extremely large negative pressure is induced [6].

In order to investigate how the switching is induced and what causes the switching, Nishimura et al. measured pressure on the flat roof in smooth flow with and without a splitter plate in the wake [8]. According to the experimental results, they have mentioned that the switching is induced by flow instability related with an interaction between the conical vortex and the separated shear layer from the side of the model in the wake. This remark is deduced from the simultaneous measurement of pressure fluctuations on the roof and the base floor.

This research has been planned to make clear the mechanism of the switching and the interaction between the conical vortices and the separated shear layer in the wake.

2 EXPERIMENTAL DESCRIPTION

In order to achieve the objectives of the research, the three dimensional stereoscopic PIV system (3D-SPIV) is used to measure three components of velocity vector on and behind a cube synchronized with pressure measurement on the cube. The experiments were carried out at the boundary layer wind tunnel of Building Research Institute in Japan with the test section of 3m x

2.5m. In order to avoid the effect of naturally developing boundary layer on the tunnel floor, a horizontal flat plate was set at 30cm above the tunnel floor shown in Figure 1. In the experiments, two kinds of approaching flow are used. One is a nearly smooth uniform flow (USF) and the other is turbulent boundary layer flow (TBL). Figure 2 shows profiles of mean wind speed and turbulence intensity in stream wise direction in the both flow at the position of the cube. According to the profile of USF shown as red circles, the flow is influenced by boundary layer developed on a flat plate up to 40mm from the plate and blue circles show TBL. The flow is uniform and the turbulence intensity is below 1% beyond 40mm. TBL was produced by roughness blocks and spires. The turbulence intensity is 13% to 20% up to 100mm in TBL.

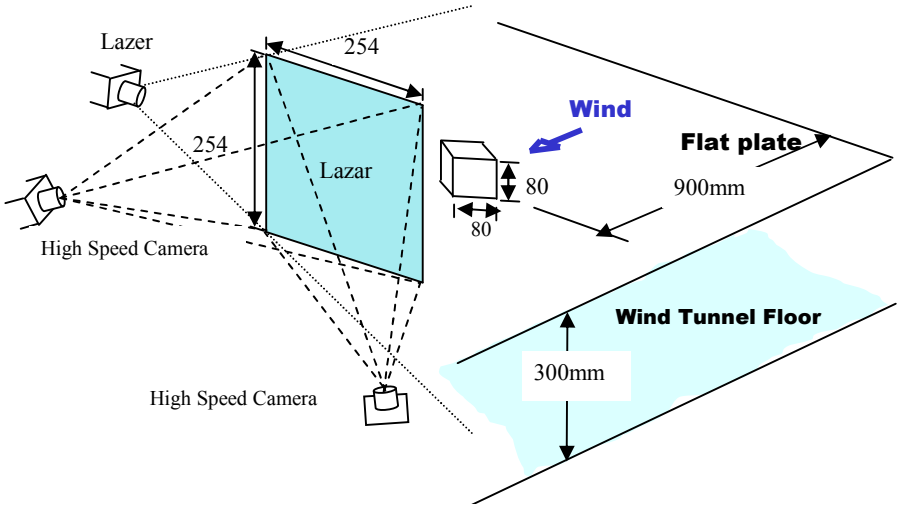

Figure 1 Experimental set up for 3D-SPIV in USF

A cube of which side is 80mm is used for the experiment in USF, and a cube of which side is 50mm is used for the experiment in TBL. The cube was set at 957mm downstream from the windward edge of the flat plate to the center of the cube normal to the diagonal line in USF. In TBL, the cube was set at 825mm. The reference wind speed, U, was set at 5m/sec at 100mm above the plate. The coordinate is defined as x in stream wise direction, y in cross flow direction and z in vertical direction. The characteristic length is the length of diagonal line of the cube, which is defined as D, so the Reynolds number based on D and U are 24960 and 15600 respectively in USF and TBL.

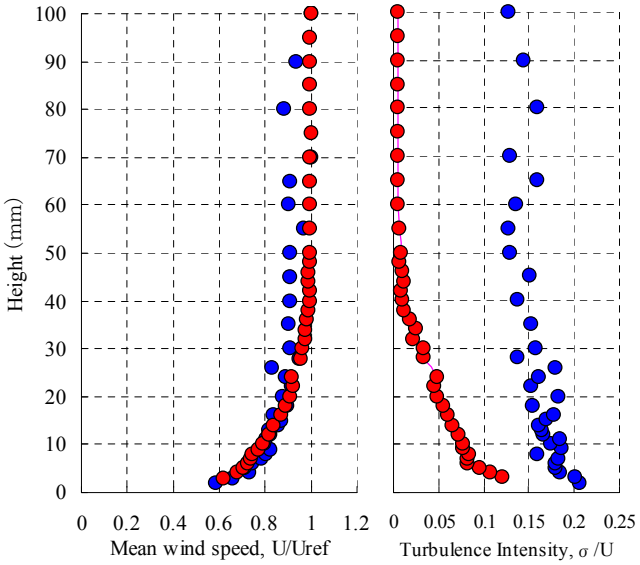

Figure 2 Profiles of mean velocity and turbulence intensity

Figure 1 shows the experimental set up for 3D-SPIV in USF which can measure three components of velocity vector on a plane based on two pairs of shots taken by two high speed cameras. The measurements in USF were carried out in 7 perpendicular planes (y-z plane) on the cube and in the wake behind the cube at x/D=-0.5, -0.25, 0, 0.25, 0.5, 1.0, 1.5. In the measurements, instantaneous velocity vectors at 77 x 63 points on each plane of which resolution is 4.26mm, were calculated from a pair of shots, which are taken by high-speed video cameras with intervals of 0.05msec. In each run 2727 pairs of the shot were taken at 250Hz rate. On the other hands, the measurements in TBL were carried out in 16 perpendicular planes from x/D=-0.25 to

3.0 with intervals of 0.25D. In the measurements, instantaneous velocity vectors at 63 x 63 points on each plane of which resolution is 4.11mm, were calculated from a pair of shots, which are taken by high-speed video cameras with intervals of 0.05msec. In each run 2727 pairs of the shot were taken at 500Hz rate. See the detail of the 3D-SPIV in Kawai et al. [9].

3 EXPERIMENTAL RESULTS AND DISCUSSIONS

3.1 *Flow structure on and behind the cube in USF*

Figure 3 shows the velocity vectors and the stream-wise component of the vorticity as the isogram in the five perpendicular planes (y-z plane). Red zone shows anti-clockwise vorticity and blue zone shows clockwise vorticity. The large vorticity zone produced by the conical vortex enlarges towards the downstream until x=1D. The zone is almost disappear at x=1.5D, which means the conical vortices are drawn into an arch type vortex in the wake as discussed later in detail. Figure 4 shows the velocity vectors and the stream-wise component of the vorticity at x=1D. It is shown in Figure 4 that strong downwash is induced by the conical vortices and the vortex at the left hand side is drawn towards the right hand side.

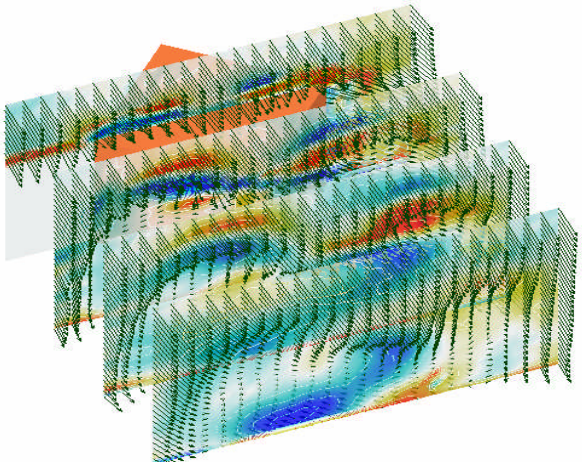

Figure 3 Velocity vectors and stream-wise vorticity on and behind the cube in USF

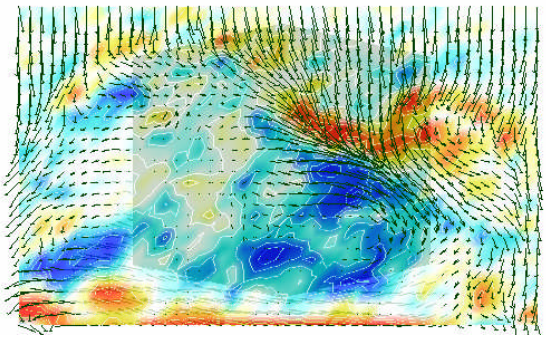

Figure 4 Velocity vectors and stream-wise vorticity at x=1.0D in USF

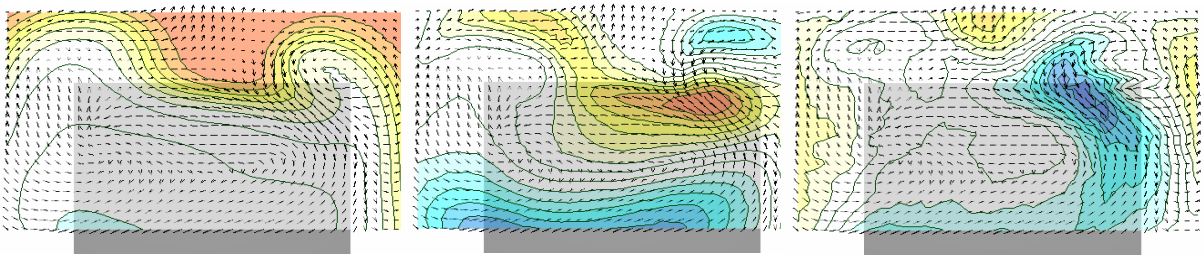
3.2 *POD analysis of velocity fluctuation behind the cube in USF*

In order to make clear the structure of the wake behind the cube and the draw of the conical vortex, POD analysis is carried out for the velocity fluctuations. Figure 5 shows the first modes for the three components at x=1D together with the velocity vector in the first mode. (a), the stream wise component of the velocity fluctuation, shows that an center of the separated shear layer is depressed and the layer moves and inclines to the right side. (b), the lateral component of the velocity fluctuation, shows that the draw of the left side conical vortex to the right side is shown as



(a) Stream-wise component (b) Lateral component (c) Vertical component

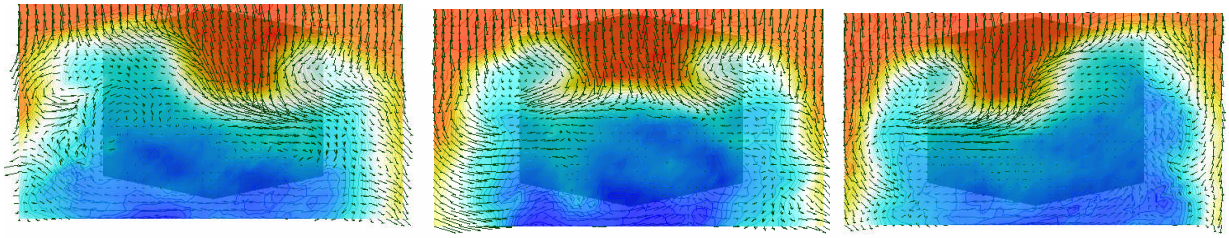
(a) x=0.5D (b) x=1.0D (c) 1.5D

Figure 6 First mode of POD of stream-wise vorticity fluctuation in USF.



(a) x=0.5D (b) x=1.0D (c) 1.5D

Figure 7 Sway of the conical vortex and switching phenomenon of the flow in USF.

wake at x=1.5D. On the other hands the conical vortex at the right hand side stays at the same position at x=0.5D, 1D and 1.5D though its vorticity becomes weaker as x increase.

3.3 *Sway of the conical vortex and switching phenomenon of the flow in USF*

As discussed in the former section, the flow is unsymmetrical and the conical vortex at one side is always stronger than that at the other side. However, the stronger vortex side changes occasionally in relatively long interval. This phenomenon is known as the switching of the flow pattern. The phenomenon is discussed in this section.

Figure 7 shows the velocity vectors and the stream-wise component of the velocity at x=1D when the switching phenomenon occurs. Red zone shows positive and blue zone shows negative. White zone shows when the velocity is 0, and it corresponds with the center of the shear layer. (a) shows that the vortex at the left hand side is stronger, (b) shows that the vortex at the right hand side is stronger and (c) is the instant of the switching from (a) to (b).

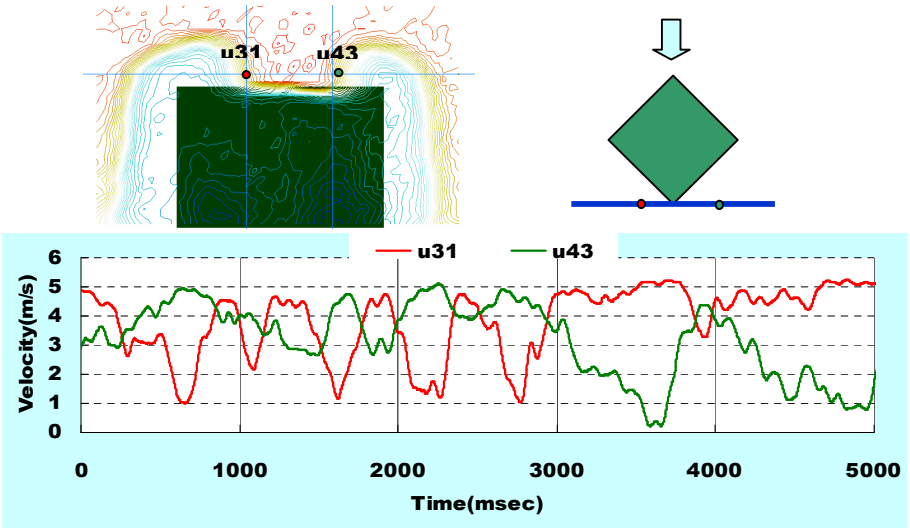


Figure 8 Velocity fluctuations at the edge of the shear layer.

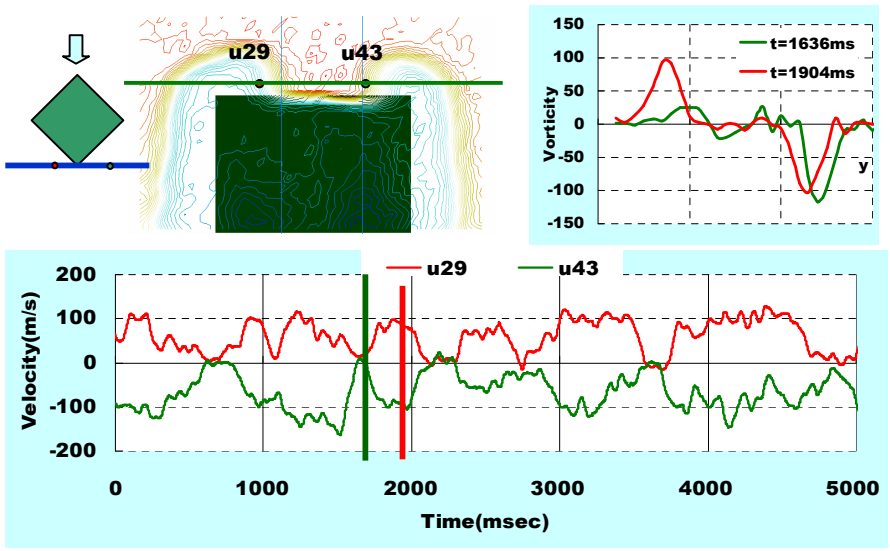


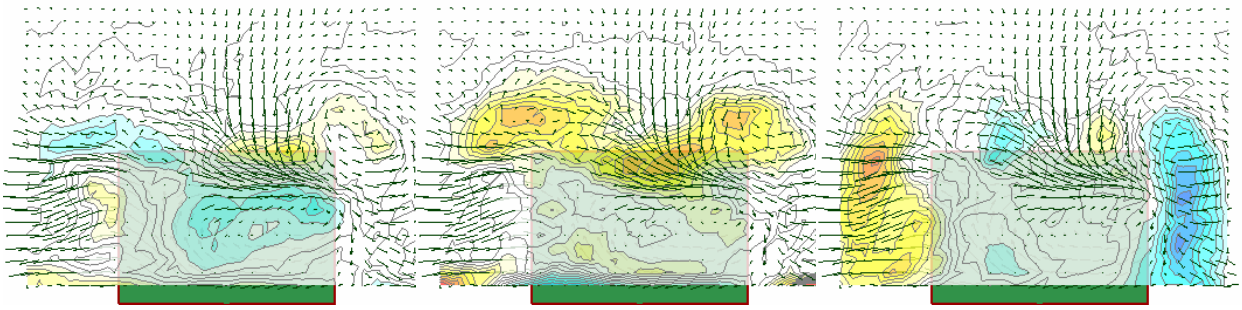
The conical vortex sways all the time even when the vortex at one side is stronger Figure 8 shows time history of stream wise velocity component just out side of the shear layer behind a cube in USF when the vortex at the right hand side is stronger than that at the left hand side. The green line shows the velocity fluctuation at the right hand side, u43 and the red line shows that at the left hand side, u31. The velocities both at u43 and u31 fluctuate nearly regularly in the period of 0.4sec to 0.6sec until 3 second, and then the velocity at u43 decreases after the switching of the flow pattern occurs. The velocities at the both sides fluctuate out of phase. This means that the conical vortices sway quasi-periodically in a body suggested by Kawai el. [4]. The moment of switching corresponds when the pair of the vortices moves to the left.

Figure 9 shows time history of stream wise component of vorticity at u29 and u43 in USF when the vortex at the right hand side is stronger than that at the left hand side. The vorticity fluctuates in the same period of the velocity fluctuation shown in Figure 8. Figure .9b shows the profiles of the vorticity along the green line at the instant of 1636msec and 1904msec. When the vorticity at u43 is nearly 0 at 1636msec, the velocity at u43 reaches the peak and the peak value of the vorticity at the right hand side reaches the maximum. This corresponds that the conical vortex reaches to the most right side. In this instant, the vortex at the left hand side becomes weak as shown by a green line in Figure 9b. When the vortex moves to the left, the vorticity at u43 increases and then takes the peak at 1904msec. In this instant, the strength of the vortices at both sides is almost same as shown by a red line in Figure 9b. The switching occurs when the vortex at the left hand side is stronger a little than that at the right hand side at the instant of 3000msec.

3.4 *Structure of flow in the wake and pressure on the cube in TBL*

The general feature of the flow on and behind the cube does not so change from USF to TBL except that the sway of the conical vortex is not so regular but random and the switching is affected by the approaching turbulence.

In order to investigate the interaction between the conical vortex and the separated shear layer from the side, the three components of the vorticity are calculated at x=0.75D and shown in Figure 10 with the velocity vector. (a) is the stream wise component, (b) the lateral component and (c) is the vertical component of the vorticity. The large positive stream wise vorticity zone (clock-wise vorticity) shown as blue region in Figure 10a spreads under the negative vorticity zone (anti-clock-wise vorticity) at the right hand side. The pattern of the isogram is similar to that



(a) Stream-wise component (b) Lateral component (c) Vertical component

Figure 10 Three components of vorticity in TBL

of Figure 6b in USF. The lateral component of the vorticity shown in Figure 10b shows again the draw of the vortex from the left to the right. The large positive and negative zones of the vertical component of the vorticity locate at the outside of the cube which is induced by the separated shear layer from the side. Moreover, the small zones of negative and the positive vertical vorticity are seen near the center of the cube which is induced by the reentrant arch-type vortex behind the cube.

Figure 11 shows the pressure distribution on the cube when the strength to the conical vortex at the right hand side becomes the maximum. Blue zone shows negative and red zone shows positive. When the conical vortex at the right hand side becomes much stronger that that at the left hand side, the negative pressure on the upper surface at the right hand side becomes larger and the large negative peak pressure is induced near the windward corner. The negative pressure on the right leeward side increases at the same time. Particularly, the large negative peak pressure acts on the leeward corner at the right hand side.

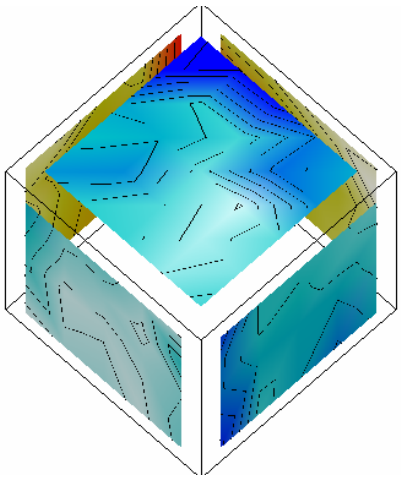


Figure 11 Pressure distribution the cube in TBL when the strength of the conical vortex at the right hand side reaches to peak.

3.5 *Structure of vortex behind the cube*

Figure 12 shows the three dimensional stream lines behind the cube in TBL. The stream lines are drawn from x=0.75D. According to Figure 12, the roll up of the separated shear layer from the side seems to connect to the roll up of the shear layer over the cube and to form an arch-type vortex. When the conical vortex at the right hand side is stronger than that at the left hand side, the conical vortex at left hand side is drawn into the wake to bring the large clockwise circulation in the wake. The arch-type vortex inclines greatly to the right side by the interaction between the conical vortex and the separated shear layer. When the strength of the pair of vortices is same, the very clear arch-type vortex can be seen in the move.

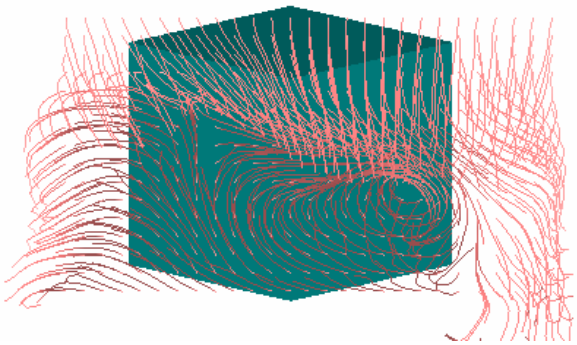

Figure 12 3D stream lines behind the cube in TBL Starting points are on the perpendicular plane (y-z plane) at x=0.75D.

According to the above results, the schematic picture of the vortex in the wake behind the cube is shown in Figure 13 when the conical vortex at the right hand side is stronger than that at the left side. The shape of the arch-type vortex is reentrant at the center by the down wash induced by the pair of the conical vortices and inclines to the right. When the conical vortex at the left hand side is drawn to the right, the sign of the vorticity of the conical vortex and the arch-type vortex is opposite each other and the conical vortex is drawn into the wake over the arch-type vortex. On the other hand, the vorticity of the conical vortex at the right hand side has the same sign of that of the arch-type vortex, so the conical vortex makes to increase the vorticity of the arch-type vortex.

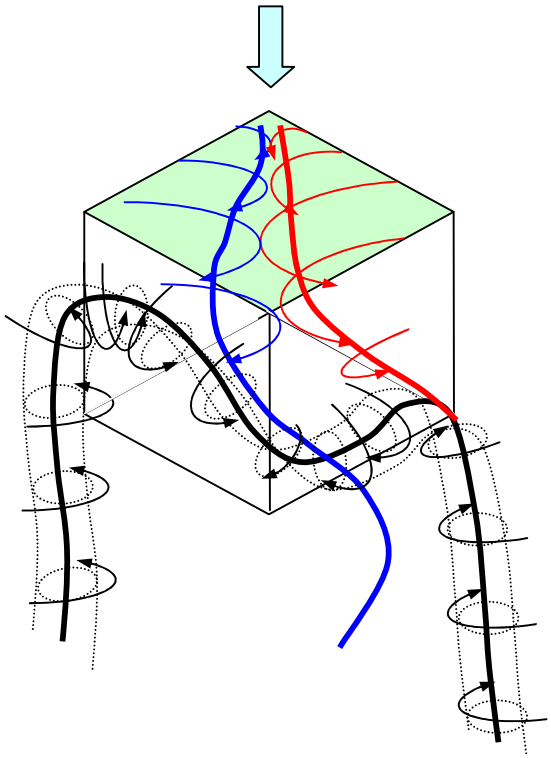

Figure 13 Schematic model of the interaction between the conical vortices and arch-type vortex behind the cube.

4 SUMMARY AND CONCLUSIONS

The structure of the conical vortices on and behind the cube in USF and TBL when flow attacks normal to the diagonal line is investigated by synchronous measurements of 3D-SPIV and multi pressure sensor systems. According to the measurement, the following results are found.

(1) The conical vortex at one side is always stronger than that at the other side. The side at the stronger vortex changes occasionally in relatively long interval. By this change the flow pattern switches to the reflected pattern.
(2) The conical vortices at the both sides sway quasi-periodically in a body on the cube in USF, and the strength of vortices changes all the time. When the strength of the vortex at one side increases, the strength at the other side decreases.
(3) The trigger of the switching is brought by the sway of the conical vortex. When the order of the strength of the conical vortices changes at both sides by the sway, the flow pattern is switched to the reflected pattern.
(4) An arch-type vortex is formed behind the cube in any times of which shape is reentrant at the center and inclines to the side of the stronger conical vortex. When the conical vortex at one side is stronger, the vortex at the other side is drawn into the one side of the arch-type vortex.

The structure of the flow in TBL is similar generally to that in USF.

ABSTRACT: Prediction of site specific wind speed plays a key role in the determination of wind-induced response of structures. The wind speed value is typically taken from the local code of practice, which is IS:875 - Part 3 [1] in India. Considering that this code hasn't been updated for the last 25 years, a revisit of the wind speed including the last three decades of data is warranted. In this paper, the design wind speeds for the metro cities of India have been assessed based on the local airport data.

KEYWORDS: Design wind speed, India.

1 INTRODUCTION

India is witnessing an unprecedented amount of construction in the tall building area to meet up with the ever increasing demand for housing in the Indian metros (Mumbai, Delhi, Kolkata, and Chennai – see Figure 1). Significant growth in tall building sector is connected to the growing economy, and this is expected to persist for long time.

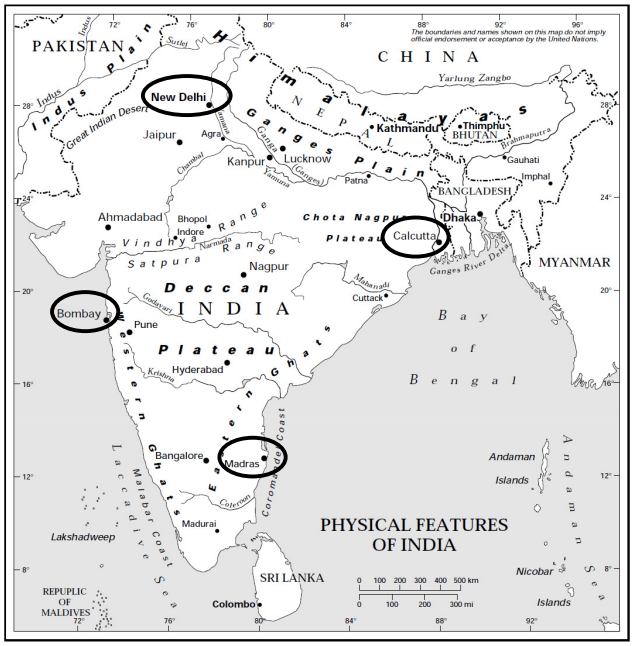

Figure 1. Map of India showing metros.

In connection with this growth, tall building construction requirements are changing frequently. Tall building committee is set up in Mumbai to review all the design and regulate the tall building construction in Mumbai. Also, many tall building designs are nowadays confirmed through wind tunnel tests determining wind loads and accelerations precisely. Challenges behind the wind design of tall buildings are emerging as well in the form of complex geometries, surroundings and structural forms.

One another important parameter for wind design is the wind climate itself. Indian wind loading standard [1] provides the basic wind speed (3-sec gust) for all the locations in India with the help of a wind map. This has been widely used for design by most of the practitioners. Note that 10% change in speed can alter the subjected load at least by 20% and also this has significant impact on acceleration prediction as well. In view of this there exists a dire need to assess the wind speed accurately across the subcontinent based on authentic data. Note that the wind map of India in the IS:875 – Part 3 [1] is based on the measured wind speed data at the airports up to early 1980's. In addition to this data, another 30 years of data spanning between 1980 and 2010 were included in this study.

2 WIND CLIMATE OF INDIA

India is situated roughly between 8^{o}N and 37^{o}N latitude, where there are four climatic zones namely alpine, sub-tropical, tropical and arid. In India, synoptic climate drivers cause pressure system winds. The synoptic climate drivers are (1) North-east monsoon (Winter monsoon) and (2) South-west monsoon (Summer monsoon). In case of north-east monsoon, the cold dry air over North Asia during October and March creates high-pressure areas blowing winds from north-east to south-west. Though winds lost their moisture while crossing central Asia, gets humidity from Bay of Bengal while crossing and resulting into showers in south India. In case of south-west monsoon, the hot air that rises over south Asia during April and May creates low-pressure areas into which the cooler, moisture-bearing winds from the south ocean flow. These climate drivers are pictorially shown in Figure 2.

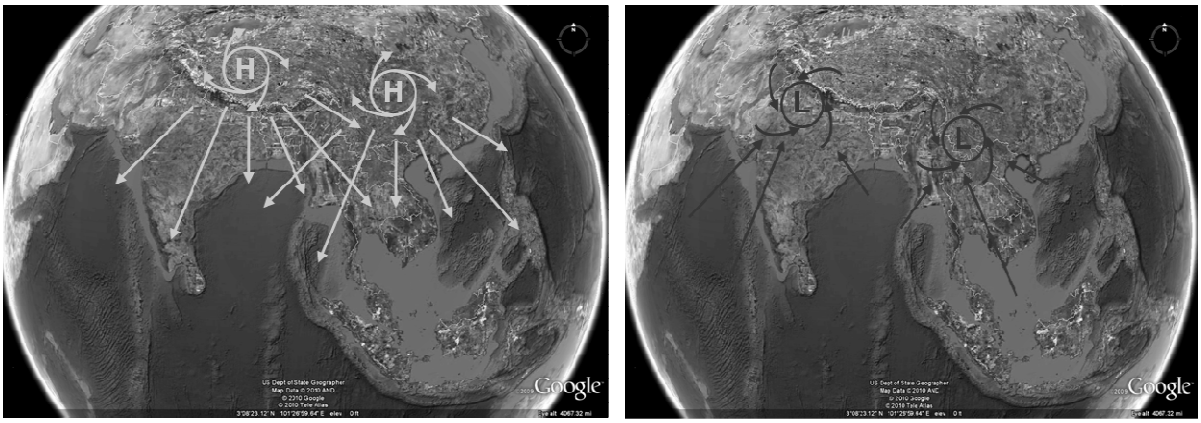

Figure 2. North-east monsoon, South-west monsoon.

In addition, thunderstorm winds are common in India. Thunderstorm winds are localized phenomenon caused by temperature gradient in cloud resulting in vertical convective motions. Tropical cyclones (rotating type wind) are also common in India especially in the east coastal regions.

Mumbai is located in the west coast (Lat 19° 04'N, Lon 72°52' E) and the wind climate is influenced by synoptic system monsoons and thunderstorms. In the past, cyclonic systems never made a landfall in Mumbai. Most of these cyclonic systems made landfall further north of Mumbai and Mumbai is only affected by the very outer bands of the cyclonic systems. The frequency of occurrence of cyclones over Arabian Sea is lower than that over the Bay of Bengal on the east coast of India due to the colder water currents in Arabian Sea.

Delhi is located in the interior of north India (Lat 28° 38'N, Lon 77°13' E). Delhi wind climate is influenced by monsoons and thunderstorms. Kolkata is located in the north east coast (Lat 22° 34'N, Lon 88°21' E). Kolkata wind climate is influenced by monsoons, thunderstorms and cyclones. Chennai is located in the south east coast (Lat 13° 04'N, Lon 80°15' E). Similar to Kolkata, Chennai wind climate is also influenced by monsoons, thunderstorms and cyclones.

Synoptic system monsoons and cyclonic systems cover a vast area and prolong for several hours/days and therefore, anemometer measurements from airports likely can capture the wind characteristics of these systems at least at lower levels. However, in the case of thunderstorms, considering its local nature and short duration, airport measurements alone may not be sufficient to capture its strength in case when this happens on another part of the same city away from airport. Therefore, other means of measurements such as wind profiler, radiosonde, doppler radars, GPS receivers, aircraft reconnaissance, and meso-scale regional numerical prediction should be explored. The design wind speed predictions based on airport data shall be checked against other measured data to confirm the inclusion of the severity of the thunderstorm activity in the region.

3 DESIGN WIND SPEED FOR MUMBAI

Traditional methods for assessing the wind climate for wind engineering purposes are based on analysis of long term surface records from a nearby meteorological station, typically measured at a height of 10 m above ground. For this assessment, hourly surface wind data from the following stations were used: (1) Chhatrapati Shivaji International Airport (CSI, Station Index: 43003, before known as SantaCruz Airport) for a period of 1969 – 1999 provided by India Meteorological Department (IMD) at Pune, (2) Chhatrapati Shivaji International Airport (CSI) data for a period of 2000 – 2007 provided by NCDC (National Climatic Data Center of USA), and (3) Colaba Observatory (Station Index: 43057) data for a period of 1969 – 2007 provided by IMD at Pune. Provided hourly surface wind data were carefully reviewed and subsequently filtered to avoid the contamination of reliable data with the potentially erroneous readings.

Measured wind speeds are adjusted by direction to compensate for the effects of upwind terrain and surface characteristics using ESDU [2] methods. This correction for site-specific terrain effects generates winds corresponding to standard open terrain condition. Extreme value analyses are then performed for the determination of wind speeds with respect to return period. Site-specific Weibull climate models are also developed to assess the relationship between wind speed and return period, as well as to establish the directional distribution of strong winds.

Monthly peak mean hourly wind speeds were analyzed using the standard Gumbel method by fitting Fisher-Tippet Type I distributions to the data. Various fitting methods were used which included fitting velocity squared (V^2) instead of velocity (V), and using a least-squares fitting versus the method of moments. A comparison of the various fitting methods was used to evaluate the best fit to the data. The V least-squares fitting method as shown in Figure 3 provides the closest fit to the data.

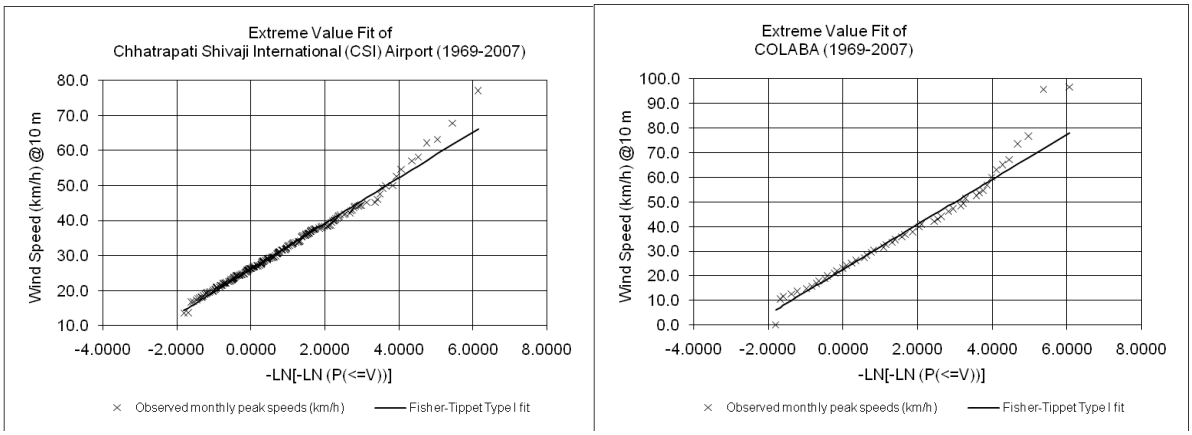

Figure 3. Extreme value fit of wind speed – Mumbai.

Based on this analysis, it is found that the estimated 50-year return period mean-hourly wind speed is 18.9 m/s and 22.5 m/s corresponding to CSI and Colaba data respectively. Recognizing the fact that the current structural design practice of India IS:875 - Part3 (1987) [1] is widely adopted as a reference document, the relationship between gust and mean-hourly speeds must be defined. Based on the ASCE 7-05 Standard [3] conversion factor of 1.52, the equivalent 3-seconds gust speeds are 28.7 m/s and 34.2 m/s corresponding to the CSI and Colaba data respectively. Further, the factor of 1.52 is confirmed by checking the gust/mean ratio obtained from the measurements as shown in Figure 4. These predicted speeds are similar to the recent predictions made by Lakshmanan et al. [4] for Mumbai based on the uncorrected gust data. However, note that these speeds are significantly lower than the IS code [1] recommended speed of 44 m/s for Mumbai. The hand book published by Standards Australia on the design wind speeds for the Asia-Pacific region [5] suggests a 3-sec gust wind speed of 39 m/s for Mumbai, which is about 11% lower than the suggested speed in the IS code. Recently, Aurelius and Cammelli [6] predicted considerably lower speed for Mumbai than those stipulated in the IS code. As per the current study, the best estimate 50-year return period Basic Wind Speed (3-seconds gust) for Mumbai is 39 m/s. This best estimate speed is higher than the predicted speed based on airport data and this is to account for uncertainties in the data. Similar wind speed values have also been obtained by analyzing the measured gust data.

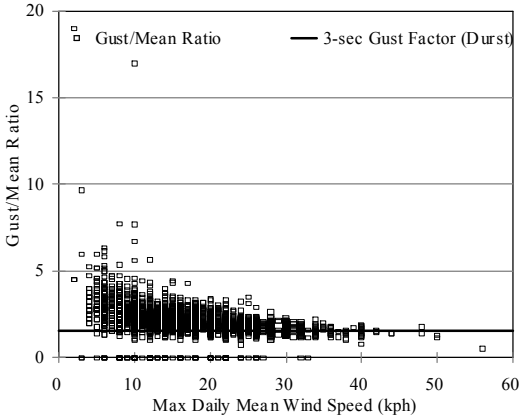

Figure 4. Gust to Mean Ratio – Mumbai.

4 DESIGN WIND SPEED FOR DELHI

For the assessment of wind speed for Delhi, hourly surface wind measurement data from the following stations were used: (1) Indira Gandhi International Airport data (IGI, Station Index: 42181, before known as PALAM Airport) for a period of 1969 – 1996 provided by IMD at Pune, (2) Indira Gandhi International Airport (IGI) data for a period of 1996 – 2009 provided by NCDC USA, and (3) Safdurjung Airport (Station Index: 42182) data for a period of 1969 – 2006 provided by IMD at Pune. Similar analysis as previously discussed was carried out, and the V least-squares fitting method as shown in Figure 5 provides the closest fit to the data.

Based on this analysis, it is found that the estimated 50-year return period mean-hourly wind speed is 27.1 m/s and 29.1 m/s corresponding to IGI and Safdurjung data respectively. The equivalent 3-seconds gust speeds are 41.3 m/s and 44.3 m/s corresponding to the IGI and Safdurjung data respectively. These predicted speeds are closer to the recent predictions made by Lakshmanan et al. [4] for Delhi based on the uncorrected gust data. RWDI also performed extreme value analysis on the uncorrected peak daily gust data for 38 years. The IGI gust data yields a 50-year gust value of 46 m/s at 10 m height, while the Safdurjung data yields a 50-year gust value of 44 m/s. These gust speeds are in the same range as the earlier predictions based on mean-hourly data. Also, note that these speeds are closer to the IS code [1] recommended speed of 47 m/s for Delhi. The hand book published by Standards Australia on the design wind speeds for the Asia-Pacific region [5] suggests a 3-sec gust wind speed of 44 m/s for Delhi, which is about 6% lower than the suggested speed in the IS code. As per RWDI's analysis, the best estimate 50-year return period Basic Wind Speed (3-seconds gust) for Delhi is 44 m/s.

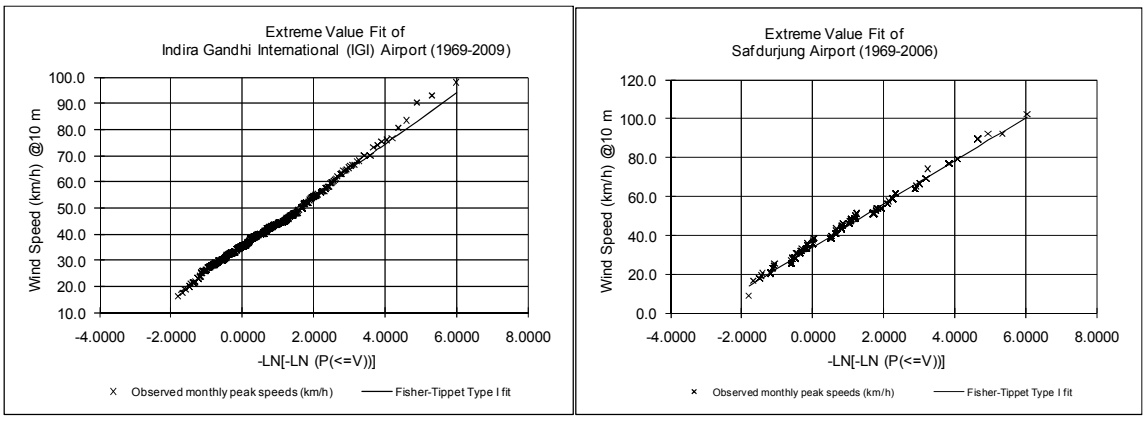

Figure 5. Extreme value fit of wind speed – Delhi.

5 DESIGN WIND SPEED FOR KOLKATA

For the purpose of this assessment, 3-hourly/1-hourly surface wind measurement data from the following stations were used: (1) Netaji Subhash Chandra Bose International Airport data (Station Index: 42809, before known as DUM DUM Airport) for a period of 1969 – 1987 provided by IMD at Pune and (2) Netaji Subhash Chandra Bose International Airport data for a period of 1987 – 2010 provided by NCDC USA. Similar analysis as previously discussed was carried out, and the V least-squares fitting method as shown in Figure 6 provides the closest fit to the data.

Based on this analysis, it is found that the estimated 50-year return period mean-hourly wind speed is 30.5 m/s. The equivalent 3-seconds gust speed is 46.4 m/s. This predicted speed is matching the recent predictions made by Lakshmanan et al. [4] for the Kolkata Dum Dum station based on the uncorrected gust data. Note that these speeds are about 5% lower than the IS code [1] recommended speed of 50 m/s for Kolkata. The hand book published by Standards Australia on the design wind speeds for the Asia-Pacific region [5] suggests a 3-sec gust wind speed of 44 m/s for Kolkata, which is 12% lower than the suggested speed in the IS code. As per RWDI's analysis, the best estimate 50-year return period Basic Wind Speed (3-seconds gust) for Kolkata is 47 m/s.

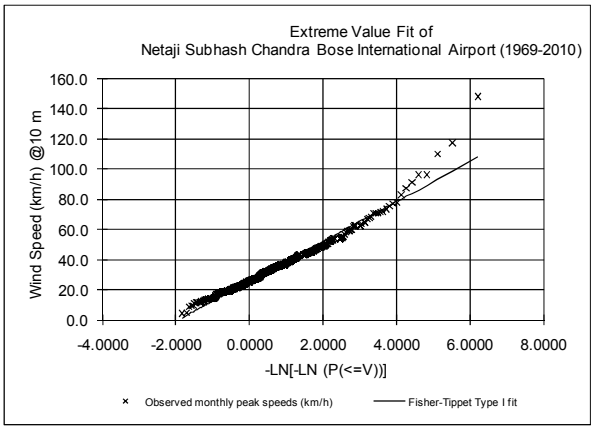

Figure 6. Extreme value fit of wind speed – Kolkata.

6 DESIGN WIND SPEED FOR CHENNAI

For the purpose of this assessment, 3-hourly/1-hourly surface wind measurement data from Minambakkam International Airport (MIA) for a period of 1973 – 2010 provided by NCDC USA were used. Similar analysis as previously discussed was carried out, and the V least-squares fitting method as shown in Figure 7 provides the closest fit to the data.

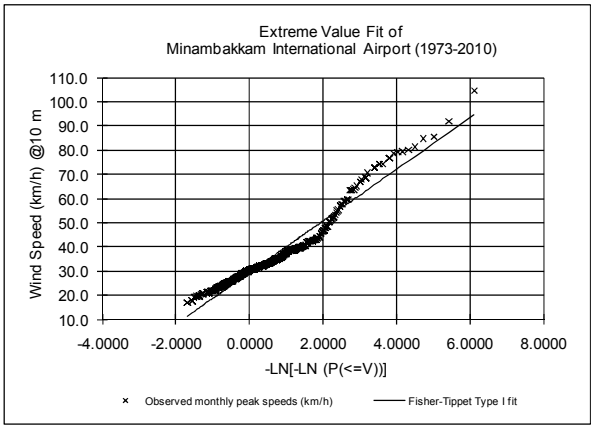

Figure 7. Extreme value fit of wind speed – Chennai.

Based on this analysis, it is found that the estimated 50-year return period mean-hourly wind speed is 27.1 m/s. The equivalent 3-seconds gust speed is 41.2 m/s. This predicted speed is in between the recent predictions made by Lakshmanan et al. [4] for two stations (MIA and Harbour) in Chennai based on the uncorrected gust data. However, note that these speeds are significantly lower than the IS code [1] recommended speed of 50 m/s for Chennai. The hand book published by Standards Australia on the design wind speeds for the Asia-Pacific region [5] suggests a 3-sec gust wind speed of 44 m/s for Chennai, which is 12% lower than the suggested speed in the IS code. As per the current study, the best estimate 50-year return period Basic Wind Speed (3-seconds gust) for Chennai is 44 m/s.

7 DISCUSSION

The summary of the findings are shown in Table 1. In general, the wind speeds in the IS code map seem higher than reality. Mumbai and Chennai basic wind speed values in the code appear conservative. Based on all the evidence that we have provided in this paper, the basic wind speed for Mumbai and Chennai can be at least 10% lower than the current value in the code. In

Table 1. 50-yr Return Period Basic Wind Speed Data

Location	Based on	Basic Wind Speed (m/s)
Mumbai	IS: 875	44.0
	HB 212	39.0
	Lakshmanan et al. (CSI Airport)	35.0
	Lakshmanan et al. (Colaba)	28.0
	RWDI (CSI Airport)	28.7
	RWDI (Colaba)	34.2
	RWDI - Best Estimate	39.0
Delhi	IS: 875	47.0
	HB 212	44.0
	Lakshmanan et al. (Safdurjung)	39.0
	Lakshmanan et al. (IGI Airport)	45.0
	RWDI (Safdurjung)	44.3
	RWDI (IGI Airport)	41.3
	RWDI - Best Estimate	44.0
Kolkata	IS: 875	50.0
	HB 212	44.0
	Lakshmanan et al. (Calcutta)	41.0
	Lakshmanan et al. (Dum Dum)	46.0
	RWDI (Nataji Subhash Chandra Bose)	46.4
	RWDI - Best Estimate	47.0
Chennai	IS: 875	50.0
	HB 212	44.0
	Lakshmanan et al. (Minambakkam)	39.0
	Lakshmanan et al. (Harbour)	45.0
	RWDI (Minambakkam)	41.2
	RWDI - Best Estimate	44.0

RWDI's opinion, further studies utilizing upper air data and meso-scale modelling [7] would be helpful in reinforcing the current findings and recommend appropriate speed for strength design of structures. In addition, a special dispensation from local building authorities of the corresponding cities to use the lower speed is warranted. Until then for strength design, we recommend IS code specified speed for all the cities.

The data reported in Table 1 corresponding to Lakshmanan et al. [4] is based on uncorrected gust data. In their work, it was assumed the peak wind data as the speed sustained over 1- minute duration and subsequently converted to 3-seconds format by multiplying all the peak data by a factor of 1.16. So, their prediction based on corrected data is the value reported in Table 1 factored by 1.16. On the other hand, based on discussions with IMD, it is our understanding that the data has been measured at the end of every hour for a two minute period and subsequently, two minute average has been reported on every hour and also a maximum gust speed is recorded for a day. Although the gust data doesn't specify an averaging time, the trend of the ratio of the peak gust to the maximum mean hourly speed is towards approximately 1.5 which indicates it is likely close to a 3-seconds gust. So it is of our opinion that the gust speeds reported by IMD need not undergo any correction as done by Lakshmanan et al. [4].

Recently, government of India initiated STORM programme [8] for better understanding of the structure and characteristics of the severe local thunderstorms in the eastern and north-eastern India covering West Bengal, Jharkhand, Orissa, Assam and parts of Bihar. These areas were affected by severe thunderstorms during the pre-monsoon months (in particular April & May). These thunderstorms are locally named as "Kalbaishakhi" meaning calamities in the month of Baishakh. These storms are also called "Nor'wester" meaning travelling from north-west to south-east. These severe thunderstorms bring thunder, squall lines, lightening and hail cause extensive losses in agricultural, damage to structure and also loss of life. The STORM programme includes both observations and numerical predictions. These data can be explored in the future. The squalls associated with Nor'wester are mostly from a northwesterly direction. The highest winds in these squalls are reported to be 140-150 kph [8]. Note that Kolkata is prone to Nor'wester storm where the code suggested speed is 50 m/s (180 kph). Note that the highest reported speed must be associated with a higher return period than 50-year return period used in the code. Further, Sutapa Chaudhuri and Anirban Middey [9] reported the peak gust speed during thunderstorm activity in Kolkata based on radiosonde and rawinsonde data. They reported peak gust speeds ranging between 40 to 120 kph. This is based on 140 thunderstorm activity over Kolkata during pre-monsoon season (April-May) for the years 1997-2009.

In contrary to the current results of this study, Prem Krishna [10] and Subhash and Tamura [11] reported the occurrence of high wind speed cyclonic storms in the eastern coast of India than the recommended basic wind speed for the region specified in IS:875 – Part 3 [1]. Though the risk associated with the occurrence of these extreme storms is not completely understood, they are of the opinion that the applicability of the IS: 875 – Part 3 wind speed map especially at the east coast needs to be investigated further.

With regard to Cyclonic storms on the east coast (between Thoothukudi and Kolkata) and west coast (between Trivandrum and Daman Diu), the best track data of tropical cyclone disturbances over the north Indian ocean published at the web site of IMD has been investigated. The published data is for the duration from 1990 till 2010. The landfall of cyclonic disturbances has been categorized based on the coast and the speed. The maximum sustained surface speed has been converted to 3-sec gust speed and the frequency of occurrence of different intensity storms has been determined and plotted in Figure 8.

Note that very few low intensity storms made landfall on the west coast in comparison to the east coast. The maximum 3-sec gust wind speed resulted out of these storms are much lower than the maximum IS:875 speed of 44 m/s for the west coast below Daman and Diu. Many significant cyclonic activities were originated in Arabian Sea but majority of those storms were swept away

by the prevailing easterly winds expected in latitudes below 30^o. As a result, many of these storms originated in Arabian Sea made landfall in Yemen, Oman and east of Africa.

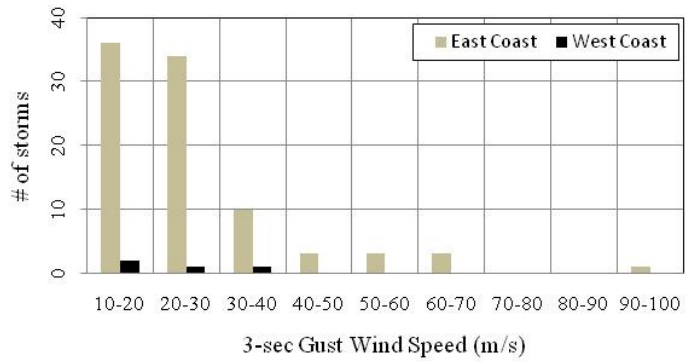

Figure 8. Frequency of cyclonic disturbances on Indian coast between 1990 and 2010.

On the other hand, significant number of cyclonic activities originated in Bay of Bengal, travelled with the prevailing easterly wind and made landfall on the east coast of India. Figure 8 depicts that occasional severe storms made landfall on the east coast of India. The speed corresponding to some of these storms are indeed higher than the IS code speed of 50 m/s for these regions. However, the return period associated with these storms are unknown. Further investigations in this regard using simulations are essential.

8 CONCLUDING REMARKS

The design wind speed for four metro cities of India (Mumbai, New Delhi, Kolkata and Chennai) has been investigated based on data measured at the airports. In summary, the design wind speeds for metro cities of India have been found to be about 5-10% lower than the wind speed provided in Indian standard. This can have significant impact on the prediction of wind-induced loads/motions of structures.

In general, the quality of the data prior to couple of decades is poor. This restricts the duration of years of good data to 10-20 years. Further, there is little dialogue between the community who uses the data and the community who measures them. For instance, three hourly wind direction measurements are still ongoing which is basically not useful for knowing the wind directionality with certainty. Considering the numerous uncertainty in measured data, further study of wind climate is recommended using upper air data and meso-scale modelling. This study will be extremely beneficial for all the future developments in metros and nearby regions. Further, this will provide adequate confidence to lower the speed than what is in the code currently and also help to change the wind speed map in the code.

Statistical spectrum model of wind velocity at Beijing Meteorological Tower

Yang Qingshan,Tian Yuji, Li Bo and Chen Bo

School of Civil Engineering, Beijing Jiaotong University, Beijing 100044, China

Abstract: The wind velocity spectra at Beijing Meteorological Tower are calculated using Hilbert-Huang transform and Fourier transform, respectively. A innovative model of wind velocity spectrum, which is accordant with the characteristics in both the inertial subrange and the large eddies range, is presented in this paper. The method of least squares is adopted to obtain the parameters in the model. Then the differences between the FFT spectrum and the HHT spectrum are compared. It is indicated that the values of the HHT spectrum in the energy containing range are slightly larger than those of the FFT spectrum while the values of the HHT spectrum in both inertial subrange and dissipation subrange are very close to that of Fourier spectrum. It is concluded that the HHT spectrum describes elaborately and accurately the spectrum values in the low frequencies and the fitted wind velocity model provides a reference for reconstructing the near-ground wind field of Beijing city in wind tunnel test and for numerical simulation.

Keywords: turbulent spectrum, wind velocity spectrum, inertial subrange, HHT, FFT

1 Turbulent spectrum theory

The theory of the turbulent spectrum originated from Richardson's view of the energy cascade [1], that is to say, the turbulence is composed of eddies of different sizes. When the energy enters into the atmosphere, the kinetic energy of the molecules increases and then the large eddies flow, break up and transfer their energy to somewhat smaller eddies. These smaller eddies undergo a similar break-up process, and transfer their energy to the smallest eddies. This is called energy cascade, in which energy is transferred to successively smaller and smaller eddies until the kinetic energy is dissipated by the molecular viscosity.

In turbulent flow at sufficiently high Reynolds number, the energy of the small-scale motions is determined by the kinematic viscosity and the energy transfer rate. This is called Kolmogorov's first hypothesis. In the region of small eddies, the energy of the relatively larger eddies is uniquely determined by the energy transfer rate, independent of the kinematic viscosity. This is called Kolmogorov's second hypothesis [2]. According to the two hypotheses, the atmospheric molecules absorb energy and flow in the form of the large eddies; the energy containing range is composed of these large-scale eddies. The turbulent motions of the small-scale eddies are statistically isotropic and form a universal equilibrium range, in which the energy transfer range is named the inertial subrange while the region of the smallest-scale eddies is designated as the dissipation subrange. From the second hypothesis it follows that the turbulent spectrum in the inertial subrange is deduced from the dimensional analysis and is expressed as

$$E(k) = C\varepsilon^{2/3}k^{-5/3} \tag{1}$$

where k is the wavenumber, ε is the energy transfer rate, and C is a universal constant. In Equation (1), the turbulent spectrum is nominated as the Kolmogorov $-5/3$ law.

Since 1940s', many researchers have devoted their attention to studying the turbulent spectrum and many spectrum models have been established. It is assumed that the turbulent energy is transferred from large to small eddies in terms of an "eddy viscosity" [3]. This logical assumption indicates that the transfer term in the turbulent spectrum dynamic equation is represented by the same form of the viscous dissipation term. Kolmogorov's $-5/3$ law in the inertial subrange is confirmed after some other assumptions are introduced while the spectrum decay quite rapidly with the -7th power of the wave number in the region of the smallest eddies. The same conclusions were drawn by some other predecessors [4, 5].

The decay of the spectrum of isotropic turbulence was investigated when the external forces causing the turbulent motion were removed [6]. The approximate solution of the spectrum dynamic equation gives that the spectrum is pro-

portional to the wavenumber in the region of the larger eddies while the spectrum drops off much faster for the largest eddies. Furthermore, some experimental results show that the spectrum values of the largest eddies are not the maximum and that the spectrum of the largest eddies decays with the -4th power of the wave number [7].

Traditionally, the energy spectrum of the homogeneous and isotropic turbulent flow is the Fourier transform of its auto-correlation function, i.e.,

$$E_j(k) = \frac{1}{\pi}\int_{-\infty}^{+\infty} Q_j(\xi)\exp(-ik\xi)d\xi \tag{2}$$

where k is the wavenumber, $E_j(k)$ is designated as the one-side spectrum of jth ($j = u, v, w$) turbulent component, where u, v, w are the symbols of longitudinal, horizontal and vertical components, respectively, and $Q_j(\xi)$ is the spatial correlation function of jth component. Considering the even function $Q_j(\xi)$ in homogeneous turbulence, Equation (2) can take the form of the correlation coefficient $q_j(\xi)$ and it follows that

$$E_j(k) = \frac{2\sigma_j^2}{\pi}\int_0^{+\infty} q_j(\xi)\exp(-ik\xi)d\xi \tag{3}$$

where σ_j^2 is the variance of the jth turbulent component, and $q_j(\xi)$ is the spatial correlation coefficient, $q_j(\xi) = Q_j(\xi)/\sigma_j^2$. When the wavenumber k tends to zero at the two sides of Equation (3), it is obtained that

$$E_j(0) = 2\sigma_j^2 L_j/\pi \tag{4}$$

where L_j is the integral length scale of jth component ($L_j = \int_0^{+\infty} q_j(\xi)d\xi$). It is indicated that the spectrum value of zero wavenumber is dependant on the integral length scale and the standard deviation of the fluctuating wind. Under the condition of roughness terrain, the integral length scale increases with the increase of height while the standard deviation decreases with the increase of height; hence, the turbulent spectrum varies with the increase of height. When the wavenumber k is equal to zero, the derivative of $E_j(k)$ is zero, i.e.,

$$dE_j(k)/dk\big|_{k=0} = 0 \tag{5}$$

The aforementioned research results of turbulent spectrum are illustrated in Figure 1, in which the energy spectrum curve varies with the wavenumber.

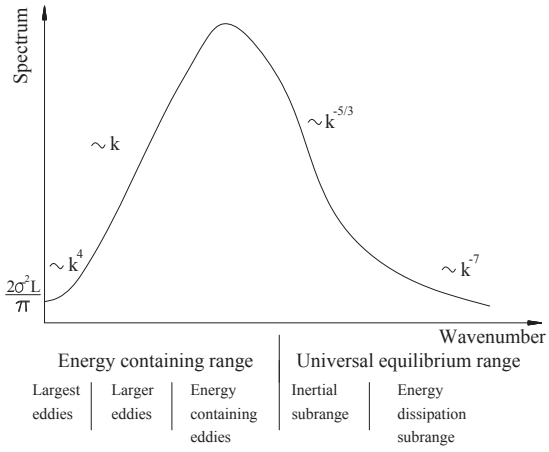

Figure 1 Illustration of turbulent spectrum and wavenumber

2 Wind velocity spectrum model

From Taylor's hypothesis or the frozen-turbulence approximation, the wavenumber can be expressed as the frequency, $k = 2\pi n/U$, where n is the frequency and U is the mean wind velocity, and the wavenumber spectrum of turbulence is represented by the frequency spectrum, $E_j(k) = US_j(n)/2\pi$, where $S_j(n)$ is the one-side power spectrum of jth turbulent component in the frequency domain. Considering Equations (4) and (5), the power spectrum $S_j(n)$ must satisfy the following two conditions, i.e.,

$$S_j(0) = 4\sigma_j^2 L_j/U \tag{6}$$

$$dS_j(n)/dn\big|_{n=0} = 0 \tag{7}$$

Based on the Kolmogorov's second hypothesis, the power spectrum in inertial subrange was presented by Batchelor in 1953 [8], which is given by

$$\frac{nS_j(n)}{u_*^2} = \alpha_j f^{-2/3} \tag{8}$$

where u_* is the friction velocity, α_j is a constant, and f is the Monin similarity coordinate, $f = nz/U$ and $f > 0.2$. Simiu and Scanlan [9] deduced the constant in Equation (8) of longitudinal velocity uctuation of wind turbulence and $\alpha_u = 0.26$ while Tieleman [10] gave the constants of the three components and $\alpha_u = 0.27$, $\alpha_v = 0.36$ and $\alpha_w = 0.36$.

In 1946, Von Karman [11] presented an empirical power spectrum model of the longitudinal turbulent flow observed in grid generated turbulence in a wind tunnel as

$$\frac{nS_u(n)}{u_*^2}=\frac{4f\beta_u L_u/z}{\left(1+70.8f^2L_u^2/z^2\right)^{5/6}} \tag{9}$$

where β_u is the turbulence intensity coefficient, $\beta_u=\sigma_u^2/u_*^2$, and z is the height. It is obvious that Karman spectrum $S_u(n)$ in Equation (9) satisfies the two conditions shown in Equations (6) and (7); meanwhile, it satisfies other three requirements, as presented by Simiu [9], for wind velocity spectrum; the third requirement is that the Karman spectrum $S_u(n)$ in Equation (9) is consistent with Equation (8) in the inertial subrange if $L_u\approx 0.3\beta_u^{3/2}z$; the fourth requirement is that $S_u(n)$ is a monotonically descending function; the fifth requirement is that the integral of $S_u(n)$ is the variance. In fact, the Karman spectrum is an interpolated expression of the spectrum in the inertial subrange and the spectrum value at zero frequency.

Karman spectrum was fitted statistically from the data of the homogenous and isotropic turbulence, therefore it is unsuitable for the wind spectrum of the roughness terrain in the near-ground range [9]. It is evident that Karman spectrum agrees well with Equation (8) in free stream conditions while it deviates slightly from the spectrum curve at the energy containing range and the dissipation subrange. In the energy containing range, Karman spectrum curve is an approximately horizontal line; it is implied that the large eddies with different frequencies contain the similar or identical amounts of kinetic energy. This overestimates the spectrum values at the energy containing range. Therefore, the wind-resistant design of lower frequency structures, such as an oil platform or a cable-stayed bridge, assures more safety when Karman spectrum is used.

The foundation of studying the wind velocity spectrum in wind engineering is established on the basis of Equations (8) and (9). As stated by Solari [12], the spectral formulas in engineering practice are actually deduced from three procedures. The first procedure is the direct use of Equation (9) in practice, in which parameters L_u and β_u are determined by the actual turbulence observed at the rough sites[13-15]. The second procedure consists of the polynomial spectral equations valid in the energy containing range and linked smoothly to Equation (8) to represent the spectrum at the inertial subrange. The third procedure is to define a single expression, such as Karman spectrum, to describe the spectrum at zero frequency and in the inertial subrange. A universal spectrum formula for homogenous and isotropic turbulence was presented by Fichtl [18], which has the form

$$\frac{nS_j(n)}{u_*^2}=\frac{A_j f}{\left(1+B_j f^{\gamma_j}\right)^{5/(3\gamma_j)}} \tag{10}$$

where A_j, B_j and γ_j are the three parameters to be determined. It is clear that the requirement of Equation (6) is satisfied if $A_j=4\beta_j L_j/z$ and the other four requirements are satisfied. Based on different observations, some expressions of spectrum like the form of Equation (10) have been presented [16, 19-25] since 1960s', in which parameter γ_j is usually specified as 1, 2 or $5/3$.

To avoid the determination of the friction velocity u_* and the coefficient β_u during the statistical process for the actual wind flow, Karman spectrum in Equation (9) is rewritten as

$$\frac{nS_u(n)}{\sigma_u^2}=\frac{4f_u}{\left(1+70.8f_u^2\right)^{5/6}} \tag{11}$$

where f_u is a dimensionless coordinate, and $f_u=nL_u/U$. After the three parameters U, L_u and σ_u^2 are specified by their empirical formulas on any height, Karman spectrum on this height can be expressed definitely. Equation (11) is directly used by Japanese Wind Code (AIJ-RLB-2004) and Australian Code (AS/NZS 1170.2-2002). An empirical spectrum model presented by Solari [19] is adopted by American Wind Code (ANSI/ASCE 7-10), i.e.,

$$\frac{nS_u(n)}{\sigma_u^2}=\frac{6.868f_u}{\left(1+10.302f_u\right)^{5/3}} \tag{12}$$

The spectrum expression in European Wind Code (BS EN 1991-1-4:2005) is similar to Equation (12) and it is

$$\frac{nS_u(n)}{\sigma_u^2}=\frac{6.8f_u}{\left(1+10.2f_u\right)^{5/3}} \tag{13}$$

Both Chinese Wind Code (GB50009-2006) and Canadian Code (NBCC-2005) directly use Davenport spectrum [26], that is,

$$\frac{nS_u(n)}{\sigma_u^2}=\frac{2x^2/3}{\left(1+x^2\right)^{4/3}} \tag{14}$$

where $x=1200n/U_{10}$ and U_{10} is denoted as the 10-minute mean wind speed over a flat, open terrain at a height of 10m. Davenport spectrum was fitted on the basis of different data observed in different countries, at different terrains and different heights. It cannot reflect the variation of the spectrum at different heights. The value of Davenport spectrum at zero frequency is zero, and less than the theoretical value shown in Equation (6). Compared with the three spectra models presented respectively by Karman [11], Simiu [17] and Solari [19], the values of Davenport spec-

trum are much smaller in the low frequency range and larger in the high frequency range.

3 HHT and Hilbert energy spectrum

In the history of wind engineering, Fourier transform is the efficient tool for transforming the time histories of wind velocity and pressure into the spectra in the frequency domain. In fact, a time history is represented by the summation of many sine and cosine complex functions via Fourier transform. These trigonometric functions are symmetrical and stationary, therefore a crucial restriction of the Fourier transform is that the measured signals must be strictly periodic or stationary. In the process of Fourier spectrum analysis, the transient characteristics of a time history are lost since Fourier transform is the integral with respect to time; on the other hand, Fourier transform needs many high-frequency harmonic waves to fit non-stationary data. These spurious harmonics might make mathematical sense, but do not really make physical sense at all and can disorder the energy spectrum distribution. Consequently, the values of energy spectrum at the low-frequency range are usually underestimated in engineering practice [27]. The other signal processing methods based on Fourier transform, such as short-term Fourier transform, Wigner-Ville distribution, suffer all the limitations of the Fourier analysis.

As the measured time histories of wind flow manifest strong nonlinear and nonstationary features, it is necessary to select the relatively stationary records of wind velocity as the samples of Fourier transform. The advent of wavelet transform in 1980s' provided an attractive method to analyze nonstationary process. Some researchers in wind engineering tried to use wavelet transform to analyze the measured signals of wind velocity [28-30]. Wavelet transform, whose basis function is also priori as it is for Fourier transform, decomposes a time history into a series of wavelet components, which have the nonlinear and nonstationary characteristics. However, wavelet transform is a regional presentation of the data in time-frequency plane and is useful for characterizing gradual frequency changes, but does not provide the instantaneous frequencies.

In 1998, Hilbert-Huang transform (HHT) [31] was presented to serve as an innovative signal processing method to analyze adaptively nonlinear and nonstationary data. HHT is based on the empirical mode decomposition (EMD) method, which generates a collection of intrinsic mode functions (IMFs). Expressed as IMFs, the data have well-behaved Hilbert transform, from which the instantaneous frequencies can be estimated at a proper time. Thus, any event on the time as well as the frequency axis can be localized. The IMFs can serve as the basis of an expansion of the data which can be linear or nonlinear, stationary or nonstationary, and they are complete, nearly orthogonal and adaptive.

In the traditional statistical analysis of turbulence, the power spectrum density resulted from Fourier transform of correlation function describes the fluctuating wind energy distribution in the frequency domain. Similarly, this concept can be extended to the definition of the fluctuating wind energy spectrum via HHT, i.e., the Hilbert energy spectrum, which describes detailedly the fluctuating wind energy distribution in the time-frequency plane. Assuming $u(t)$ is the fluctuating wind velocity of longitudinal component, the analytical signal of $u(t)$ is as follows

$$\begin{aligned} u_a(t) &= u(t) + i\cdot\tilde{u}(t) = \sum_k \left[c_k(t) + i\cdot\tilde{c}_k(t)\right] \\ &= \sum_k A_k(t,n) e^{i\cdot\theta_k(t)} \end{aligned} \tag{15}$$

where $c_k(t)$ is the kth IMF of $u(t)$; $\tilde{c}_k(t)$ is denoted as the Hilbert transform of $c_k(t)$; $A_k(t,n)$ is the amplitude of kth analytical component in time-frequency plane and $A_k(t,n) = \sqrt{c_k^2(t) + \tilde{c}_k^2(t)}$; $\theta_k(t)$ is the instantaneous phase; n is the instantaneous frequency, and $n = d\theta_k(t)/(2\pi dt)$.

It is recognized that the energy contained in analytical signal $u_a(t)$ is two times as much as that of the original signal $u(t)$, i.e., $\sum_k A_k^2(t,n) = 2u^2(\mathrm{t})$. The duration T of the fluctuating wind history is divided into N_1 intervals and the time step is Δt while the frequency range $f_{\max}/2$, where $f_{\max}$ is the sampling frequency, is divided into N_2 intervals and the frequency step is Δn. Then the Hilbert energy spectrum of $u(t)$ can be defined as the energy density distribution in a time-frequency space divided into equal size bins of $\Delta t \times \Delta n$ with the value in each bin designated as $\sum A_k^2(t,n)/(2N_1N_2)$ at the proper time and the corresponding instantaneous frequency, that is,

$$S_u(t,n) = \frac{\sum_k A_k^2(t,n)}{2N_1N_2\Delta t\Delta n} \tag{16}$$

It is clear that the double integrals of Hilbert energy spectrum $S_u(t,n)$ with respect to time and frequency result in the variance of the fluctuating wind history. If integrating the Hilbert energy spectrum $S_u(t,n)$ with respect to time only, the Hilbert marginal spectrum with respect to frequency is defined simply as

$$S_u(n) = \int_0^T \frac{\sum_k A_k^2(t,n)}{2N_1N_2\Delta t\Delta n} dt \tag{17}$$

The definition of the Hilbert marginal spectrum in Equation (17) would facilitate comparison with the Fourier power spectrum. The marginal spectrum reflects the wind energy

distribution at each instantaneous frequency whereas the Fourier power spectrum represents the wind energy distributed in the global frequency.

4 Wind spectrum at Beijing Meteorological Tower

The Beijing Meteorological Tower (Figure 2), which is situated inbetween the Northern 3rd Ring Road and the Northern 4th Ring Road of Beijing city, was set up in 1978 by the Institute of Atmospheric Physics (IAP), Chinese Academy of Sciences (CAS). Before 1990, there was no any high structure near the tower, thus the tower was the best station to observe meteorology and measure the suburb boundary layer of Beijing city. Since 1990s', the scale of Beijing city has largely expanded with the tremendous urbanization. MuDan Yuan and GuanCheng Yuan residential buildings with height less than 60m were built in 1990s' in the north and south of the tower. GuanCheng Yuan residential buildings, located closely to the tower, are the primary rough elements influencing the near-ground wind flow. The tower is now surrounded by residential buildings of 30m to 60m in height and is located in a prosperous city zone completely. Hence, the meteorological tower becomes the best observation station to study the urban boundary layer (UBL) of Beijing city.

In 2000, three supersonic anemometers named UAT_1, whose sampling frequency is 10Hz, were installed at the 47m, 120m and 280m above ground level, respectively to record the turbulence flow. Since then, more and more measured records of turbulence flow have been accumulated. The wind velocity spectrum is investigated in this paper using the measured turbulent records by the tower from 2005 to 2007, plus partial records of 2002. All of the records were provided by IAP, CAS.

(a) 1980s' (b) 2010s'

Figure 2 Beijing Meteorological Tower

According to the previous research, the northwest wind dominates in the spring, autumn and winter. Thus all the 10-minute, northwest wind records of the three seasons in 2002, 2005, 2006 and 2007 were classified by the mean speeds at 47m. The number of samples in each speed block is listed in Table 1.

It is known from Equations (6), (8)~(14) that the turbulent spectrum values are dependant on the integral length scale and the mean speed. Therefore, both the integral length and the mean speed varying with the height must be determined before the wind spectrum is fitted.

The integral length scales of the wind samples in each block are calculated. It is indicated that the mean integral length scales increase with the increase of the wind speeds while the slope of the integral length scale curve becomes smaller and smaller. The varied integral length scales exhibit a stable value when the wind speed is larger than 8m/s at 47m. Then the integral length scales of the 378 samples of the last four blocks in Table 1 are reanalyzed. It is shown that the probability distribution of the integral length scales of the 378 samples scatters in a very large range, in which the probabilities of occurrence of the largest or the larger integral length scales are very small. After the singular samples in the last four blocks shown in Table 1 are discarded, the integral length scales and the mean speeds are calculated and listed in Table 2. The fitted profiles of the integral length scales using the available samples are as follows:

$$L_u = \begin{cases} 90\left(Z/30\right)^{0.55}, & 30\text{m} < Z \le 450\text{m} \\ 90, & Z \le 30\text{m} \end{cases} \tag{18}$$

$$L_v = \begin{cases} 45\left(Z/30\right)^{0.70}, & 30\text{m} < Z \le 450\text{m} \\ 45, & Z \le 30\text{m} \end{cases} \tag{19}$$

$$L_w = \begin{cases} 15\left(Z/30\right)^{0.85}, & 30\text{m} < Z \le 450\text{m} \\ 15, & Z \le 30\text{m} \end{cases} \tag{20}$$

After Hilbert-Huang transform is conducted, the analytical signals of the available samples are obtained. Then the Hilbert energy spectra defined in Equation (16) and the marginal spectra defined in Equation (17) are calculated. Figures 3~5 give the dimensionless marginal spectra and their mean spectra (the thick solid line) of the longitudinal components for the wind speed blocks.

It can be seen from the spectra curves in double logarithm coordinate system that the nine mean spectra are nearly straight lines if the dimensionless frequency nL_u/U is larger than 0.2. Therefore it is reasonable to regard the point of $nL_u/U = 0.2$, where the corresponding frequency n is about 0.016Hz, as the lower bound of the inertial subrange. After the nine mean spectra curves in the inertial subrange ($n = 0.016 \sim 0.5\text{Hz}$) are fitted with linear model, the slope of the fitted line varies from -0.507 to -0.664 with 95% confidence and the mean slope is -0.588, which is less than the theoretical value -2/3 (shown in Equation (8)) of the homogenous and isotropic turbulence because the wind flow at

Beijing Meteorological Tower is influenced by the rough surface. Considering this phenomenon, it is assumed approximately that the dimensionless spectrum $nS_u(n)/\sigma_u^2$ of the longitudinal component is proportional to the dimensionless frequency $f_u^{-3/5}$ ($f_u = nL_u/U$) in the inertial subrange and the counterparts of the horizontal and vertical components take the same forms.

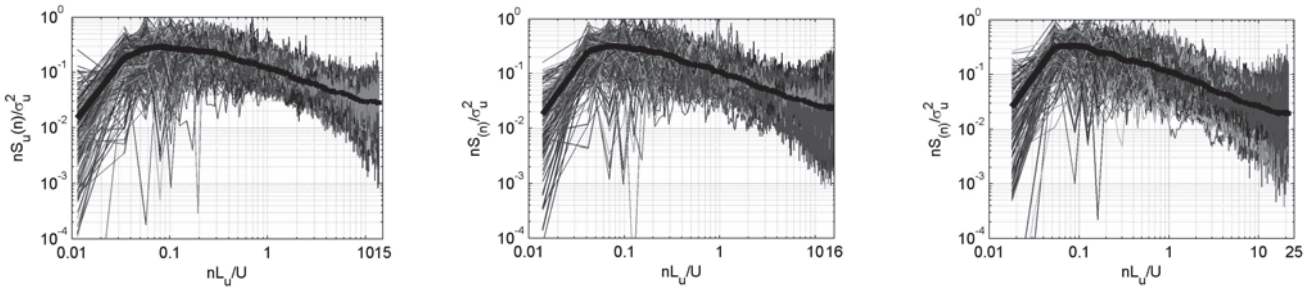
	Mean speed (m/s)	10.5	10.6	10.5	14.5	14.6	14.7	18.1	17.8	17.8

According to the universal formula of the empirical wind velocity spectrum in Equation (10), the following expression is presented to fit the fluctuating wind velocity spectrum at Beijing Meteorological Tower, that is,

$$\frac{nS_j(n)}{\sigma_j^2} = \frac{a_j f_j}{\left(1 + b_j f_j^{\gamma_j}\right)^{8/(5\gamma_j)}} \tag{21}$$

where σ_j^2 is the variance of the jth component and a_j, b_j and γ_j are three parameters to be estimated. Equation (21) is an interpolation function of the spectrum in the inertial subrange and the theoretical spectrum value at zero frequency if a_j=4, and it mainly describes the shape of spectrum in the inertial subrange, in which $S_j(n)$ is proportional to $f_j^{-8/5}$, and does not represent well the shape of the spectrum in energy containing range and the dissipation subrange.



(a) At the height of 47m (b) At the height of 120m (c) At the height of 280m

Figure 3 Longitudinal spetra and mean spectra for wind speed at 8-9m/s

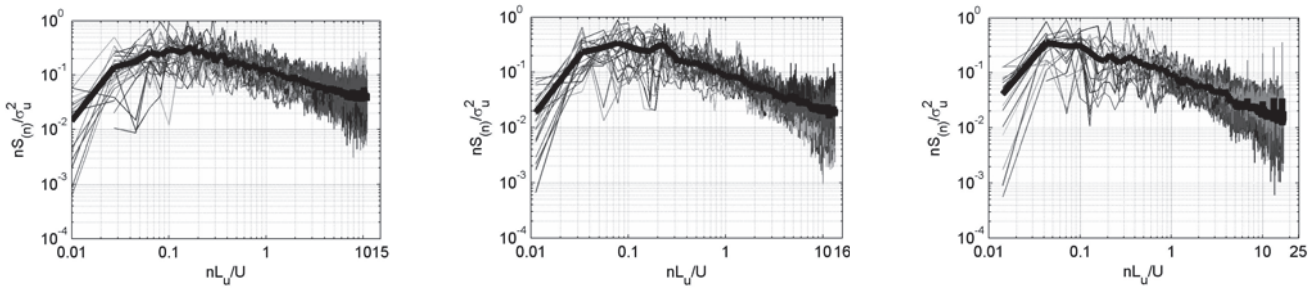
Figure 4 Longitudinal spetra and mean spectra for wind speed at 9-10m/s



(a) At the height of 47m (b) At the height of 120m (c) At the height of 280m

Figure 5 Longitudinal spetra and mean spectra for wind speed at 10-12m/s

To fit better in the energy containing range, another expression of the fluctuating wind velocity spectrum is presented in this paper, i.e.,

$$\frac{nS_j(n)}{\sigma_j^2}=\frac{4f_j\left(1+a_jf_j\right)}{\left(1+b_jf_j^{\gamma_j}\right)^{13/(5\gamma_j)}} \tag{22}$$

It is evident that the requirement of Equation (6), $S_j(0)=4\sigma_j^2L_j/U$, is satisfied at zero frequency while the derivative at zero frequency is a constant, $dS_j(n)/dn=4\sigma_j^2L_j^2a_j/U^2$, which means that the $S_j(n)$ is a linear function with the slope of $4\sigma_j^2L_j^2a_j/U^2$, agreeing with the conclusion of Heisenberg [6] in the region of the larger eddies. In the inertial subrange, the dimensionless spectrum $nS_j(n)/\sigma_j^2$ is approximately proportional to $f_j^{-3/5}$ if f_j is larger than 0.2. This agrees with the mean spectra shapes, shown in Figures 3~5, in the inertial subrange. In a word, Equation (22) is consistent with the characteristics of spectrum shape in large eddies range and the inertial subrange.

With the increase of the mean wind speed, the number of the available samples decreases. If the total samples of the speed bocks in Table 2 are collected to fit the spectrum, the contributions of the high speed samples can not be reflected because the number of high speed samples is much less than the number of the low speed samples. To overcome this drawback, the nine mean spectra curves shown in Figures 3~5 are collected and considered as the fitted target. The fitted results using Equations (21) and (22) are plotted in Figures 6~8. By using the fast Fourier transform (FFT), the same process is conducted and the fitted spectra are indicated in Figures 9~11.

Compared with the calculated spectra using HHT, the deviatability of the FFT spectra in the high frequency range is much larger in the universal equilibrium range. Figures 12~14 show the comparison of the fitted spectra using HHT and FFT. It is apparent that the fitted spectrum value using HHT is larger than the counterpart using FFT in the energy containing range, and the peak frequency of the HHT spectrum is less than that of the FFT spectrum. This phenomenon can be explained by FFT itself: Because many high frequency harmonic waves in FFT are introduced to fit the peak of a time history, the high frequency spectrum becomes larger and correspondingly the low frequency spectrum becomes smaller. It is known that the HHT spectrum behaves better than the FFT spectrum in the energy containing range.

In the inertial subrange, the measured turbulent spectra at Beijing Meteorological Tower vary approximately with the -8/5 power of the frequency and agree closely with the Kolmogorov $-5/3$ law of the homogenous and isotropic turbulence. Hence, the fitted spectra can be compared with Karman spectrum (Figure 12). The FFT spectrum is very close to Karman spectrum both in the universal equilibrium range and in the large or largest eddies range while the Karman spectrum is slightly larger in the region of energy

containing eddies than the FFT spectrum. The HHT spectrum is larger than Karman spectrum in the energy containing range while it is approximately identical to Karman spectrum in the universal equilibrium range. Since Karman spectrum is based on FFT, its value in the energy containing range may be less than the accurate value.

5 Conclusions

The research history of the turbulent spectrum and the practical spectra models in the wind engineering is summarized briefly in this paper. Then an innovative wind spectrum model is presented to reflect additionally the characteristic of wind spectrum in the region of the large eddies. The wind velocity spectra of the measured turbulence at Beijing Meteorological Tower are calculated using HHT and FFT, respectively, and are fitted using the method of least squares to estimate the parameters in the empirical models. The fitted results show that the presented model can fit the measured spectra well as the universal spectrum model does while the spectrum values of the presented model in the region of the large eddies are more accurate and the theoretical value at zero frequency is satisfied.

During the process of calculating the wind velocity spectra of the measured turbulence using FFT, many high-frequency harmonic waves are introduced to fit the peaks of a nonstationary history. This confuses the energy distribution in the frequency domain and leads to the low values of the low-frequency spectrum. The wind velocity spectra resulted from HHT can reflect the wind spectra at the proper time and the corresponding instantaneous frequency, and can obtain the accurate spectra values in the region of the large eddies. Hence, the fitted spectrum using HHT is slightly larger than the FFT spectrum while the spectrum in the universal equilibrium range is very close to the FFT spectrum.

ABSTRACT: Based on nearly one year normal wind data and the wind data of typhoon Hagupit and Nesat observed by the meteorological towers located at South China Sea and the coast, the underlying surfaces of the meteorological towers were classified to two exposures, the characteristics of the power-law exponents of the wind profiles, turbulence intensities over different underlying surfaces were analyzed. It were found that when the roughness length of underlying surface was larger than 6cm, the power-law exponent at typhoon condition was 1.5-2 times compared with the power-law exponents of exposure D and C (0.3 and 0.22) given in Chinese code. The near surface wind speed decayed more significantly, the power-law exponent and the turbulence intensities were larger in typhoon condition than in normal wind condition, especially over the rough underlying surface. Rough underlying surface has significant amplification effect on the wind parameters in typhoon condition. The amplification factors were calculated and the mathematical relationship between the amplification factors and the underlying surface roughness lengths were established. Based on these mathematical relationships, the wind parameters at the place attacked by typhoon eye wall can be estimated by the roughness length of the underlying surface and the wind parameters in normal wind condition which were more easily to measure.

KEYWORDS: landing typhoon, power-law exponent of wind profile, turbulence intensity, roughness length, amplification factor.

1 INTRODUCTION

Typhoon has control impact on the urban planning and construction, design of major engineering structure. The impact of strong wind on building and structure can be divided into static load induced by mean wind and dynamic load induced by turbulent wind. The vertical distribution of the surface wind (wind profile for short) is often used to reflect the impact of the mean wind speed and is mainly described by the power-law in the code of wind resistance engineering. The power-law exponent can present the changing rate of the wind speed with height. The power exponents of the wind profiles corresponding to four kinds of exposures which are type A, B, C and D with different roughness in the code [1] are 0.12, 0.16, 0.22 and 0.3. The turbulence intensity is an index to assess the fluctuation of the wind field which is often used in the study of turbulent wind. Some observation facts showed that the characteristics of the wind profile and turbulent wind in typhoon process has significant difference with that in normal wind system. At present, most of the investigations of typhoon wind profiles were based on the wind data at typhoon periphery at which the wind speeds are not so strong. Tamura et al. [2] analyzed the power-law exponent of the wind profiles based on the typhoon periphery wind data observed at Seashore and two inland residential areas by Doppler sodar. The study showed that the power-law exponents are small at Seashore and apt to grow larger as the wind blows over a longer fetch with inland

roughness. Based on the data obtain from 52m observation tower, Shanmugasundaram et al. [3] found the power-law exponent of tropical cyclone was larger than that in normal wind condition and the power-law exponent would decrease with the wind speed. Song et al. [4] analyzed the gradient wind data observed at a complex terrain and found the wind profile over complex terrain didn't satisfied with the power-law even in neutral atmospheric condition. Chen [5] found that the gust factor has positive relationship with the roughness length of underlying surface and established an equation to describe the relationship according to the gust factors over different underlying surface. It seems that the typhoon wind parameters would increase to a certain extent by the influence of the special vortex structure and the rough underlying surface. In order to further investigate this amplification effect of power-law exponent of typhoon wind profile over rough underlying surface, the observation wind data of typhoon Hagupit and Nesat and the wind data obtained at the same towers in normal wind condition are compared and analyzed. It is hoped that some results which is meaningful in the engineering apply can be achieved.

2 BASIC DATA SOURCE AND PROCESSING

In order to analyze the variation characteristics of the typhoon wind profiles over different underlying surfaces, the observation data of two typhoon cases which can represent the whole typhoon processes and the observation site had obvious different the underlying surfaces were chosen and analyzed. The data in this paper included the measurement at three gradient observation towers near the passage of strong typhoon Hagupit made landfall in Guangdong, China in 2008 and one gradient observation tower near the passage of typhoon Nesat made landfall in Hainan, China in 2011.

2.1 *Description of landing typhoon Hagupit and the instrument setting*

Strong typhoon Hagupit landed to the coastal region of Chencun Town, Dianbai County, Maoming, Guangdong Province at 06:45 am (Beijing time, the same below) on 24th Sep. 2008 (Fig. 1). The maximum 3sec average gust wind speed recorded at the coastal meteorological station at the center of typhoon landfall was 58m/s while the maximum 10min mean wind speed was 48m/s.

There are three meteorological mast towers located near the passage of strong typhoon Hagupit which were Zhizai Island tower, Qinba tower, Wuyang tower and the shortest distances between these three towers and the center of typhoon Hagupit were 8.5km, 12km, 18.3km, respectively (Fig.1). The shortest distance between Zhizai Island and the coast was 4.5km. The 100m high gradient tower was located at the top of the island 10m above sea level.The anemometers were equipped at the heights of 10, 20, 40, 60, 80, 100m and wind vanes were set at the heights of 10, 60, 100m. But the wind vane at the heights of 10m and 100m were destroyed during the typhoon Hagupit center passed and the wind direction data were missing. Both of the 80m high Qinba tower and 70m high Wuyang tower were located at the coast with altitude of 19m and 7m high. The anemometers equipped at Qinba tower were at the heights of 10, 30, 50, 70, 80m while the anemometers equipped at Wuyang tower were at the heights of 10, 30, 50, 70m. The wind vanes were installed at 10m and 75m at Qinba tower and the wind vanes are installed at 10m and 70m at Wuyang tower. During the passage of typhoon Hagupit, the maximum 10min mean wind speed at 100m high of Zhizai Island tower, at 70m high of Qinba tower and Wuyang tower were 48.5m/s, 33.9m/s and 31.3m/s when the gust (3sec) wind speed were 59.8m/s, 43.6m/s and 44m/s respectively.

2.2 *Description of landing typhoon Nesat and the instrument setting*

Strong typhoon Nesat landed to the coastal area of Wengtian County, Wencchang, Hainan Province at 14:30 on 14th Oct. 2011 (Fig. 1) with the minimum air pressure of 960 hPa and the central wind force of 14 grads which had reach 42m/s. Xiuying tower located at the northeast of typhoon track. The shortest distances between these three towers and the center of typhoon Hagupit was 8km.

Xiuying tower was located at the coast with the coastline runs northeast-southwest. There were sparse houses at the southeast of the tower. The underlying surface of the tower is near surface sward. The anemometers and wind vanes were equipped at the heights of 10, 20, 40, 60, 80, 100m.The observed maximum 10min mean wind speed and gust wind speed were 34.2m/s and 41.3m/s at the height of 100m at Xiuying tower which appeared before the typhoon center passed. The NRG-Symphonie type #40 anemometer and type #200p wind vane were used at four observation towers.

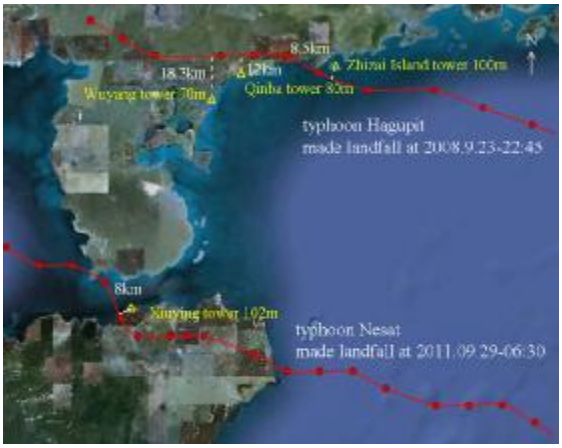

Figure 1. Path of typhoon Hagupit, Nesat and the location of the observation tower relative to the typhoon center

2.3 *Typhoon strong wind representative assessment*

Due to the eddy structure of typhoon system, the wind field structure and wind turbulence characteristics are obviously different in different locations relative to typhoon such as typhoon center, typhoon strong wind region and the periphery [6]. Since wind resistance engineering is mainly concerned with the characteristics of strong wind, the selected basic data must represent the whole observation process which included typhoon eye, typhoon strong wind and the periphery wind. According to the eddy structure of typhoon and the Beaufort scale of strong typhoon wind, two criteria should be fulfilled at the same time to prove whether the typhoon center has passed over the observation site [7]: (1) The wind direction with wind speed exceeding 8th grade Beaufort scale (10 min mean wind speed of 8th grade is 17.2 m/s) successively alters over 120°. (2) The variation of wind speed with time shows an “M” shape during the passage of typhoon and if a low wind speed less than 11 m/s (5th grade) occurs between two peak values, it can be judged as the typhoon eye area [8].

According to two criteria mention above, it can be claimed that the wind data obtained from these four meteorological towers were able to represent the specific wind characteristics of strong typhoon Hagupit and Nesat.

3 CLASSIFICATION OF THE UNDERLYING SURFACE

3.1 *Wind type classification base on the characteristics of the underlying surface*

Considering that the roughness of the underlying surface has direct impact on the characteristics of near surface wind, it is necessary to classify the observed wind according to the characteristics of the underlying surfaces so as to quantitatively investigate the differences between the winds over different underlying surfaces. The wind types were classified by the method recommended in the WMO technical document [9].According to the characteristics of the surrounding surfaces of four observation towers, the wind can be divided into two types:

The wind obtained by Zhizai island tower can be seen as inshore sea surface wind: wind came from 67.5°–247.5° (clockwise, similarly hereinafter) underlying surface can be seen as onshore wind at inshore sea surface. The wind from other orientation was defined as offshore wind at inshore sea surface (Fig. 2a). Qinba, Wuyang and Xiuying tower can be seen as coastal tower: wind respetively came from 90°–247.5°, 45°–202.5° and 225°–67.5° underlying surface were onshore wind at the coast and the wind from other orientation was defined as offshore wind at the coast (Fig. 2b-3d).

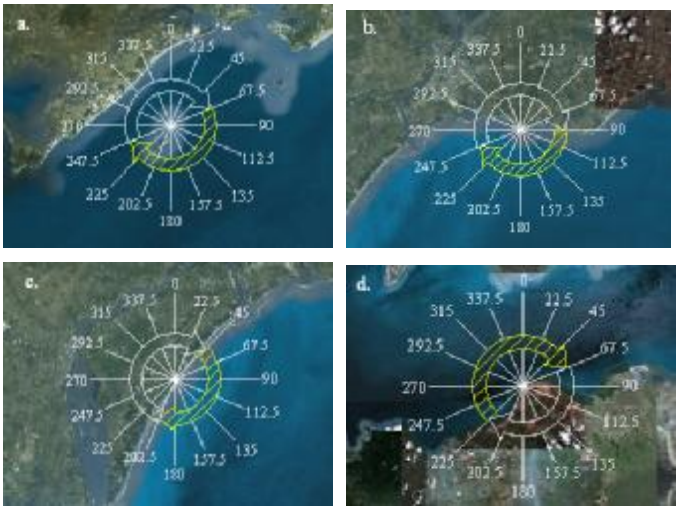

Figure 2. Wind type classification over different underlying surface.
(a: Zhizai Island tower; b: Qinba tower; c: Wuyang tower; d: Xiuying tower; shaded arrow: onshore wind orientation; hollow arrow: offshore wind orientation)

3.2 *Calculation of the underlying surface roughness length*

Aerodynamic roughness length is defined as the height at which the wind speed decreases to zero and this is an important parameter to indicate the roughness of the surface. For the purpose of examining that whether the classification of the near surface wind was reasonable. The roughness lengths of different underlying surfaces were calculated based on nearly one year of normal wind data (no influence by typhoon) in neutral atmospheric condition at each gradient tower and the logarithmic wind profile fitting method.

According to the wind profile equation given by Monin and Obukhov [10]:

$$\mathrm{U}(z) = u_* \left[\ln\left(z / z_0\right) - y\ (z / L) \right] / k \tag{1}$$

where κ=Karman constant, u*=friction velocity, z0=roughness length, ψ=Monin-Obukhov function, L=Monin-Obukhov length. Most strong wind happens in the neutral stability atmosphere and in the neutral stability condition, L=∞ and ψ=0. Eq.(1) can be simplified as below:

$$U(z) = u_* \ln(z / z_0) / k \quad (2)$$

where u* and z_0 are considered as the fitting parameters. By the method of the least square fitting, the height at which the wind speed becomes zero can be seen as roughness length z_0. The calculation result of the roughness lengths is given in Table 1.

Table 1 also gave the detailed description of the underlying surface at the orientation of land and sea. Compared with the roughness length and the description of the underlying surfaces, the roughness length calculated by logarithmic-law fitting can even describe the slight variations of different underlying surfaces.

Table 1. Roughness length of different underlying surface in normal wind condition

Observation tower	Wind type	Orientation (clockwise)	Description of the underlying surface	Roughness length (cm)
Zhizai Island tower	Offshore wind at inshore sea surface	247.5°-67.5°	Sea surface nearby and there is 4.5km wide sea area between the tower and the land northwest.	0.0682
	Onshore wind at inshore sea surface	67.5°-247.5°	Open sea area, an island of 3.5 km2 lies on 180–210° to the tower and about 1 km from the tower	0.0204
Qinba tower	Offshore wind at the coast	247.5°-90°	Dense forest at the coast with residential area nearby	12.6567
	Onshore wind at the coast	90°-247.5°	Open sea area and the underlying surface of 211°–247.5° to the tower is bay	0.2732
Wuyang tower	Offshore wind at the coast	202.5°-45°	coast with cultivated land and sparse forest and residential area	6.0773
	Onshore wind at the coast	45°-202.5°	Complete open sea surface	0.0123
Xiuying tower	Offshore wind at the coast	67.5°-225°	There are sparse houses at the southeast of the tower. The underlying surface of the tower is near surface sward.	8.6109
	Onshore wind at the coast	225°-67.5°	Sea surface, there is 21km wide sea area between the tower and the land at the north.	0.6248

4 CHARACTERISTICS OF THE TURBULENCE PARAMETERS OVER DIFFERENT UNDERLYING SURFACES

4.1 *Selection of the wind data samples*

In consideration of the wind resistance engineering mainly focused on the strong wind characteristics, here we only chose the wind data with the wind speed exceeding 8th grade Beaufort scale to analyze. Due to the typhoon wind speed varied significantly with height so in this paper, it was specified that the selection of the 8th grade strong wind at Zhizai Island tower, Qinba tower, Wuyang tower and Xiuying tower were respectively based on the wind speed at the height of 60m, 70m, 70m and 60m.

When the strong typhoon occurred, the atmosphere was in neutral stability condition. In order to make a comparison with the typhoon wind, the normal wind data were also selected in neutral atmosphere.

4.2 *The parameter used to describe the characteristics of the wind profile*

Due to the lack of a universal mathematical model which can describe the complex wind profiles accurately. The power-law fitting (eq.3) is widely recommended to estimate the wind speed at different height in engineering design. The wind profile obtained by the least square fitting which is closest to the real wind is called best power-law fitting (best fitting for short hereafter). But under the consideration of the safety for engineering wind resistance, except for the best fitting, the envelope curve power-law fitting (envelope fitting for short hereafter, the fitting wind speeds obtained by the envelope fitting are larger or equal to the observed wind speed at all the observation heights) are also applied in order to assess and choose the most suitable power-law exponent.

$$u = u_1 \left(z / z_1 \right)^{a} \tag{3}$$

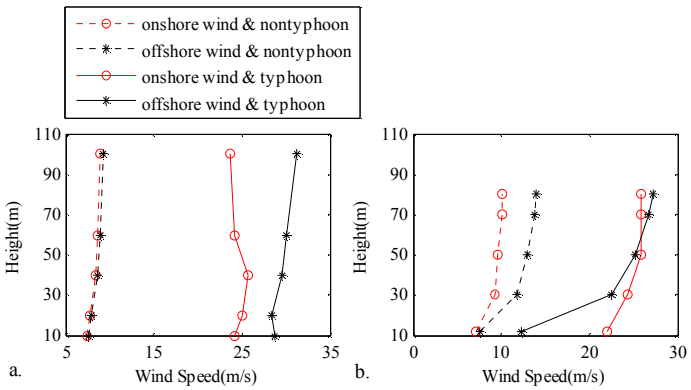
Where the u = the wind speed at the height of z, u_1 = the wind speed at the height of z_1, α = power-law exponent which can indicate the variation of the wind speed with height.

4.3 *The characteristics of the wind profiles over different underlying surface*

Figure 3 showed the mean wind profiles observed at four meteorological tower in typhoon and normal condition. All of the normal wind profiles basically accorded with the power-law. But the wind profiles observed at Zhizai Island tower which was the nearest observation site to the center of typhoon Hagupit appeared significant variation. The onshore wind profile showed an "S" shape and negative wind shear appeared at the height of 40m to 60m. And the wind profiles observed at other three towers were basically satisfied with the power-law.

In view of the normal wind profiles, the differences between the offshore wind profile and onshore wind profile were very small at Zhizai Island tower, Wuyang tower and Xiuying tower while that difference was very large for the case of Qinba tower. The offshore wind lower than 30m decayed more significantly than onshore wind at Qinba tower which maybe induced by the large roughness length difference between two exposures which was 12.38cm. And the roughness length differences between two exposures were 0.05cm, 6.07cm and 7.99cm at Zhizai Island tower, Wuyang tower and Xiuying tower respectively.

Whether for normal wind or typhoon wind, the near surface wind speed came from rough underlying surface decayed more significantly than that from smooth underlying surface, especially for typhoon wind. Comparison of the wind profiles from the same underlying surface showed that the typhoon wind decayed more significantly than that in normal wind condition, especially for offshore wind. The differences value between the wind speeds at the lowest two level at Qinba tower, Wuyang tower and Xiuying tower in typhoon wind condition were 2.4times, 5.3 times and 4.8 times compared with that in normal wind condition.



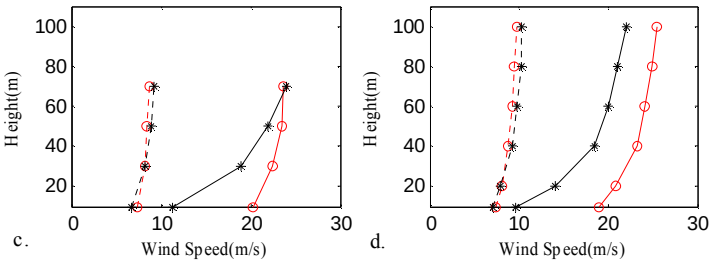


Figure 3. Wind profiles over different underlying surface.
(a: Zhizai Island tower; b: Qinba tower; c: Wuyang tower; d: Xiuying tower)

4.4 *The amplification effect of different underlying surfaces on power-law exponents of typhoon wind profiles*

Table 2 listed the power exponents of the best fitting and envelope fitting. The roughness lengths of offshore wind exposure at Qinba tower, Wuyang tower and Xiuying tower were 12.6567cm, 6.0773cm and 8.6109cm which were close to the class D or C exposures given in Chinese code. And the power exponents of the best fitting observed at the eyewall were 0.453, 0.404 and 0.382 while the power exponents of the envelope fitting were 0.661, 0.474 and 0.538 which were 1.5-2 times compared with the power exponent of class D, C exposures (0.3, 0.22) recommended by the code. The power exponents of the best fitting in normal wind condition were 0.342, 0.170 and 0.174 while that of the envelope fitting were 0.478, 0.180 and 0.188. The power-law exponent at Qinba tower was slightly larger than the value given in code while it were opposite for Wuyang and Xiuying tower. The wind profile exponent of the onshore strong wind which came from smooth sea surface (as the class A exposure in Chinese code) was less than the recommended value (0.12).

Table 2. Power-law exponents of typhoon wind profiles and normal wind profiles

Observation tower	Wind type	Roughness length (cm)	Normal wind		Typhoon wind		Amplification factor	
			α1	α2	α3	α4	α3/α1	α4/α2
Zhizai Island tower	Offshore wind	0.0682	0.086	0.088	0.028	0.036	0.327	0.414
	Onshore wind	0.0204	0.076	0.079	0.004	0.050	0.057	0.637
Qinba tower	Offshore wind	12.6567	0.342	0.478	0.453	0.661	1.326	1.382
	Onshore wind	0.2732	0.198	0.274	0.092	0.109	0.466	0.399
Wuyang tower	Offshore wind	6.0773	0.170	0.180	0.404	0.474	2.379	2.643
	Onshore wind	0.0123	0.083	0.089	0.084	0.092	1.011	1.033
Xiuying tower	Offshore wind	8.6109	0.174	0.188	0.382	0.538	2.201	2.864
	Onshore wind	0.6248	0.121	0.132	0.132	0.147	1.092	1.116

To calculate the ratio between the power-law exponents of typhoon wind profile and normal wind profile which is called amplification factors and figure 4 showed the variation of the amplification factors with roughness length. When the roughness length was small, the typhoon power-law exponents were generally less then that of normal wind. When the roughness lengths were larger than 0.6cm, the amplification factor became larger than 1. The amplification factor for best fitting and envelope fitting were 1.3-2.4 and 1.4-2.9 when the roughness length increased to nearly 10cm. It can be suggested that the rough underlying surface have significant amplification effect on the power-law exponent of strong typhoon wind profile.

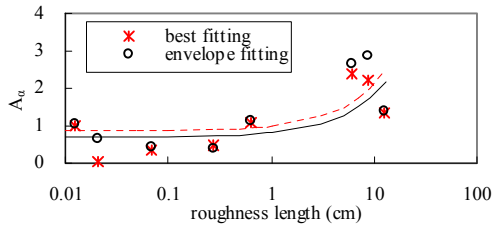

Figure 4. Relationship between the amplification factors of power-law exponent and the roughness length.

In order to quantitatively assess the amplification effect, the linear fittings were done according to equation 4.

$$A_a = A \cdot z_0 + B \tag{4}$$

where z0 = roughness length, Aα = amplification factor of power-law exponent, A and B were fitting parameters. The result shows that for best fitting: $A_a = 0.115 z_0 + 0.702$ and for envelope fitting: $A_a = 0.128 z_0 + 0.858$.

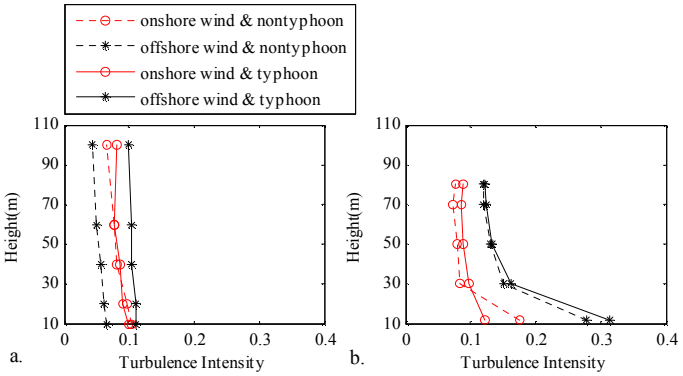
4.5 *Characteristics of turbulence intensity profile*

Turbulence intensity can reflect the wind fluctuant characteristics and the definition showed in equation 5.

$$I_i = s_i / U \tag{5}$$

where σ_i = standard deviation of turbulent wind u(t), v(t) and w(t) with 0.1s time period for i=1,2,3. U = 10min mean wind speed.

Figure 5 showed the turbulence intensity profiles. The turbulence intensity decreased with height and the turbulence intensity observed at inshore sea tower and the onshore wind observed at coastal tower were obviously less than that of the offshore wind at coastal tower. The typhoon turbulence intensity were generally larger than that in normal wind condition, especially under the influence of the rough exposure. The turbulence intensities at the lowest level at Zhizai Island tower, Qinba tower, Wuyang tower and Xiuying tower were 0.111、0.313、0.338 and 0.307 in typhoon condition which were 1.691, 1.123, 1.419 and 1.823 times compared with the turbulence intensities in normal wind.



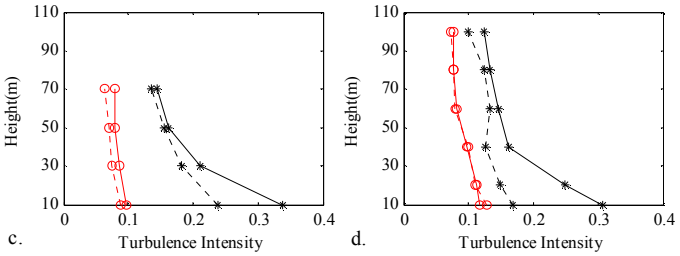


Figure 5. Turbulence intensity profiles over different underlying surface.
(a: Zhizai Island tower; b: Qinba tower; c: Wuyang tower; d: Xiuying tower)

4.6 *The amplification effect of different underlying surfaces on turbulence intensity*

Ratio between the turbulence intensity of typhoon wind and normal wind were calculated and the results showed the amplification factor were mostly larger than 1 except for some onshore wind samples and this suggested that the typhoon turbulence intensities were basically larger than that of normal wind.

Figure 6 showed the relationship between the amplification factor and the roughness length. The amplification factors increased with the roughness length of the underlying surface. The amplification factor can reach 1.832 when the roughness length increased to about 10cm. Linear fitting was applied according to equation 6 in order to quantitatively analyzing the amplification effect of the underlying surface on typhoon turbulence intensity.

$$A_{ti}=C\cdot z_0+D \tag{6}$$

where z_0 = roughness length, A_{ti} = amplification factor of turbulence intensity, C and D were fitting parameters. The result showed $A_{ti}=0.029z_0+1.112$.

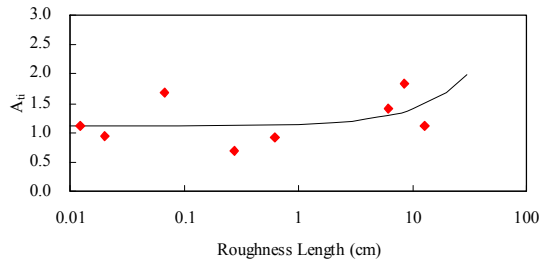

Figure 6. Variation of amplification factors of turbulence intensity and the roughness length.

These equations can applied to estimate the wind parameters at strong typhoon eye wall in the area influenced by typhoon frequently which means only the precise roughness length and the normal wind parameters were needed but not the wind data at typhoon eye wall. In fact, the opportunity to measure the strong typhoon passed over a given gradient tower face to face is rare.

5 SUMMARY AND DISCUSSION

Based on the normal wind data and the wind data of typhoon Hagupit and Nesat observed by the meteorological towers located at South China Sea and the coast, the power-law exponent and turbulence intensity over different exposure were analyzed. The results were found as follows.

(1) The wind profile in the near surface decayed more significantly than that in normal wind condition, especially for the wind came form rough underlying surface. When the roughness lengths

were larger than 6cm, the power-law exponent of typhoon wind profiles were 1.5-2 times compared with the power exponent of class D, C exposures (0.3, 0.22) recommended by the code.
(2) The amplification factor of best fitting and envelope fitting were 1.3-2.4 and 1.4-2.9 and the amplification factor of turbulence intensity can reach 1.832 when the roughness length increased to nearly 10cm. It can be seen that the rough underlying surface have significant amplification effect on the wind parameters of strong typhoon wind.
(3)The amplification factors of power-law exponent and turbulence intensity had positive relationship with roughness length. And these relationships can be precise described by linear equations. In the design of wind resistance engineering, the wind parameters at strong typhoon eye wall in the area influenced by typhoon frequently can be estimated based on the roughness length of the underlying surface and the wind parameters observed in normal wind condition.

The measured facts and change regulations achieved based on the data analysis of typical wind typhoon Hagupit and Nesat three observation towers were representative to some extent. But due to the complex structure of typhoon, the special area, size of typhoon eye, the thickness of typhoon eye wall and so on varied significantly in different typhoon case and the wind parameters were also influenced by the terrain, horizontal pressure difference, the distance between typhoon center and measuring site and so on. more observation cases are needed to examine the relationship between other influence factors and the wind parameter and find out more universal and regulations and conclusion.

ABSTRACT: This paper focuses on an investigation of hilly effects on vertical distributions of both mean wind speed and turbulence components within the surface layer. Profiles of wind speed and turbulence intensity under conditions with both upwind hills and downwind hills are presented and discussed. Phenomena of forced convection due to hill obstructions are observed and discussed through comparison with the log law models which correspond to the case with open flat terrain. Relationships between the vertical wind speed and longitudinal wind speed are highlighted. A stability parameter is introduced to help depict wind speed profiles using the log-linear model. Specific estimating operators for a number of key parameters involved in the log-linear model are proposed.

KEYWORDS: hill, wind profile, forced convection, wind speed, turbulence intensity, Sodar.

1 INTRODUCTION

Hilly terrain may bring in different wind characteristics from those under open flat terrain conditions. For example, speed-up effect near mountain crest has been recognized long time ago, and has been stipulated in wind load code of several countries and regions [1-4]. It has been reported that geometry and coverage (or roughness) of hills, as well as spatial distances away from hill crests have significant effects on the distributions of both mean wind speed and fluctuation components [5,6]. According to reference [7], studies on wind characteristics under hilly conditions began from the 1930s with simply phenomenological observations. Theoretical analysis of non-viscous flows over hills came out in the 1950s, and developed into a more matured research topic since the 1970s [8]. As the fast development of CFD techniques and wind tunnel tests in recent years, more specific studies on air motions under complicated hilly terrains have been conducted by numerical and wind tunnel investigations[9-11]. More detailed reviews on this topic are summarized by References [7, 12].

Hong Kong is sited on the southeast coastal line of mainland China, and is featured by complicated hilly/mountainous terrains. It is one of the most typhoon-prone areas in the world. The potential danger for aircrafts and dense distributions of high-rise buildings against strong winds makes it of great importance to clarify the hilly effects on near surface boundary layer wind characteristics. Up to now, Hong Kong Observatory (HKO) has established about 50 surface weather stations which are equipped with traditional meteorological instruments and 6 stations with remote sensing devices to serve for weather forecast for both daily life and civil aviation of Hong Kong International Airport (HKIA). Most of these stations are located among hills or mountains terrains and have been put into use for decades or years. This paper focuses on an investigation of wind profiles based on the wind data recorded from a Sodar profiler system during windstorms at a weather station around HKIA.

2 WEATHER STATION AND DATA QUALTITY CONTROL

2.1 *Local terrain of the weather station*

Sui Ho Wan (SHW) meteorological station is located at the foot of hills on the northeast coast of Lantau Island, and is in front of the runway of HKIA. Except for the north-west azimuth range where there is a stretch of open water, this station is basically surrounded by hills or mountains whose body heights extend from ~100m (east) to several hundred meters, as shown in Figure 1.

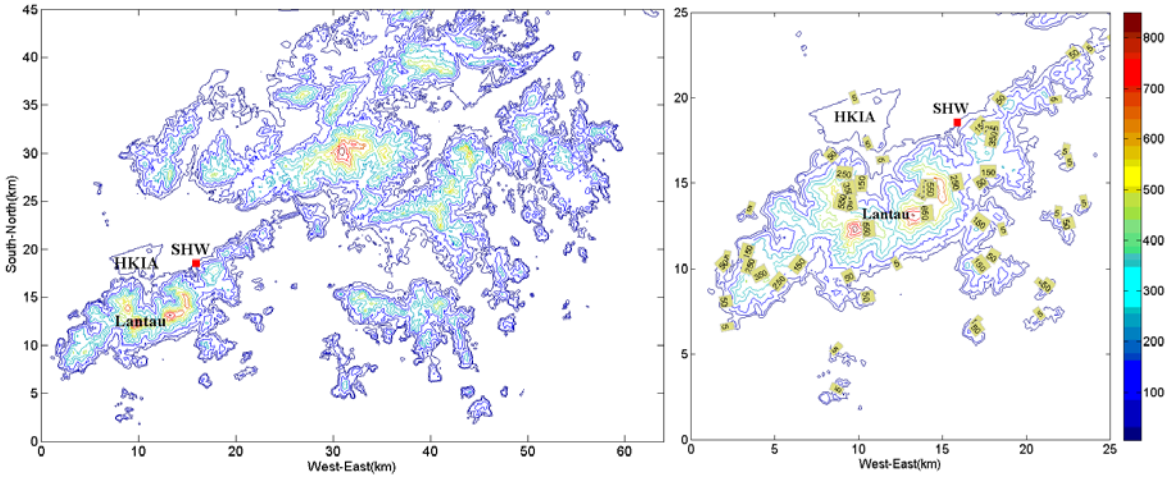

Figure 1. Location of the SHW meteorological station and surrounding terrain conditions.

2.2 *Data quality control*

SHW has been equipped with a Sodar profiler system by HKO for years. The profiler system can provide 5min-to-5min updated non-overlapping average wind profile records. The detecting range extends from 5m to 100m above the local ground (4.7m above the mean sea level) with a height resolution of 5m. But due to nearby obstructions, records below 25m (i.e., levels at 5, 10, 15, and 20m) are found to be contaminated severely by surrounding clutter interferences, and are discarded in this study. Consequently, there are totally 16 height levels where the recorded data are considered herein. For each of these levels, the recorded wind information includes the mean horizontal wind speeds and directions in a pair of orthogonal directions, a couple of standard deviation values of the corresponding horizontal wind speeds within the average duration, the vertical wind speed and corresponding standard deviation value, as well as the index numbers of signal-to-noise-ratio (SNR) in these 3 directions for data quality control. In this study, records with SNR index number no smaller than 8 are regarded as credible, and a profile with at least 13 credible records (totally 16) is regarded as acceptable. All the following analysis is based on the acceptable profiles during strong windstorms including tropical cyclones and severe monsoons from 2008 to 2010 (http://www.weather.gov.hk/cis/warndb_e.htm).

It is noteworthy that the Sodar profiler system may lose efficiency in case of heavy rains. Data collected under these conditions may be unaccepted through the quality control process. However, since strong winds are usually accompanied with heavy rains, a considerable amount of dataset recorded during high wind speeds is probably excluded. Another point to be noted is that the Sodar system can only detect components of wind velocity vector along the vertical direction (w), and a couple of horizontal directions (x, y) which are orthogonally distributed with each other and have been fixed during the installation of the Sodar system. The longitudinal mean wind speed U and the effective standard deviation σ_U, as well as the effective turbulence intensity (the effective value is adopted to distinguish it from the traditional form) are calculated:

$$U=\sqrt{U_x^2+U_y^2};\ \sigma_U=\sqrt{\sigma_x^2+\sigma_y^2};TI_i=\sigma_i/U,i=U,W. \quad (1)$$

3 RESULTS OF THE MEASUREMENTS

3.1 *Reference wind speed and direction*

Under thermally neutral stratification conditions, wind characteristics are generally dominated by wind strength and upwind terrain setups. Thus, it is necessary to categorize the records into different groups according to the reference wind speed and direction. We use the mean boundary layer (MBL) values which are defined as the arithmetic average wind speed V and the vector average direction θ of all height level records within 25-100m. Wind direction is defined as positive along clockwise from north, which is in consistence with the meteorological convention.

In consideration of both the local upwind terrains and the amount of selected datasets, the upwind azimuth of the weather station is uniformly divided into 6 sections sequentially from the north (or 0°) along clockwise, which are denoted as θi (i=1, 2, 3, 4, 5, 6). This study only considers θ2 (60-120°) and θ6 (300-360°) sections which correspond to the upwind hilly terrain and downwind hilly terrain, respectively. The reference wind speeds are divided into groups starting from 0 with an incremental step of 3m/s, which are denoted as Vi (i=1, 2, 3…).

3.2 *Results with upwind hills*

Wind flows from the θ2 azimuth section blow through the hilly obstruction before arriving to the SHW station. Figure 2 shows the profiles of the normalized longitudinal wind speed (U_{Norm}), the effective turbulence intensity (TI) and the vertical wind speed (W). It is found that both the longitudinal and vertical mean wind speed profiles demonstrate evidently different features from those under open flat terrain conditions. The ensemble mean longitudinal speed deviates gradually from the log-law predictions with height. The ensemble mean vertical wind speed increases in absolute value with height consistently, while the negative values of the vertical wind speed denote downward direction. On the other hand, the profiles of the horizontal TI show an exponentially decreasing trend with height.

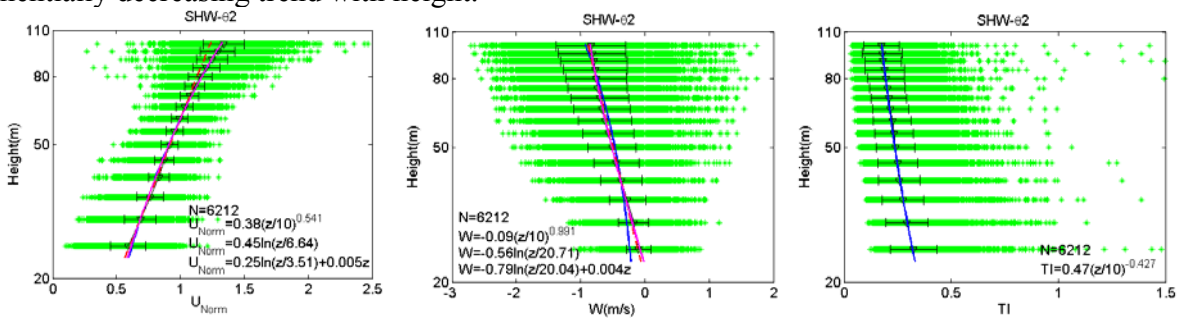

Figure 2. Profiles of normalized longitudinal speed (left), vertical speed (middle) and effective horizontal turbulence intensity (right), fitted by the power law (green line), log law (red dash line), and log-linear law (magenta line), with upwind hills (datasets with V>5m/s).

The log-law is generally used to model the vertical distributions of mean wind speed in the surface layer. Here and throughout this paper, a form of the log-law with no zero-displacement term is adopted due to the reasons: (1) by comparison, an introduction of a zero-displacement parameter is not very helpful to improve final fitting results; (2) according to ESDU-82026[13], zero-displacement for rugged hilly terrain (roughness length scale is 3-5m) is about $d=12z_0$, or 36-60m. This value is too large compared to the detecting range of 25-100m in this study.

Figure 3 shows the results in consideration of the wind strength effect. Profiles of the longitudinal mean wind speed follow both the power law and log-law quite well below certain heights. Beyond these heights, wind speed begins to speed up and sways to the right side of the log-law predictions. But, the power-law is still able to provide acceptable estimations. It is observed that the height where the log-law begins to depart from the ensemble measurement profiles decreases with wind strength. This is quite similar to the case of vertical speed profiles. The profiles of σ_U and σ_W have the same tendency with each other. The values basically increase with the reference speed. But, as wind speed strengthens, the profiles ascend monotonously along height first, then level off, and finally decrease vertically. The effective TI basically decreases with the increase of both the reference wind speed and height. But, in case of weak winds, thermal effect may dominate air motion, and TI shows much more fluctuations with distinctly large values.

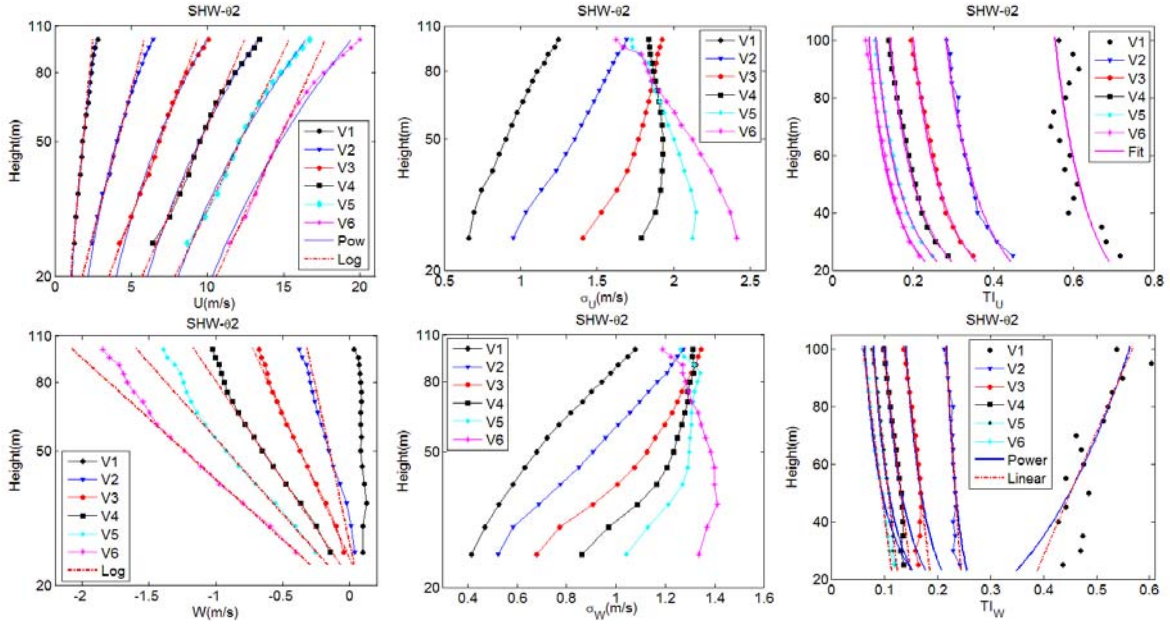

Figure 3. Profiles of ensemble mean wind speed (left) fitted by the log law and/or the power law, effective standard deviation of wind speed (middle), and effective turbulence intensity (right) fitted by the power law and/or the linear law in the θ6 azimuth section with upwind hills (Except for the case of TI_W fitted by 5^{th}-16^{th} height levels, all other fitting lines are based on the lowest 8 levels within the range of 25-60m); the y-axis with range of 20-110m is in a log format, while the one with a range of 20-100 is in the linear format, hereafters.

It is evident that there are correlations between the longitudinal wind speed and vertical wind speed components. Air flows overcoming the upwind hill obstructions go downwards as they move ahead. This forced downward convection process accompanies with energy transmission from the upper upwind flows to the beneath atmosphere. The larger the downward speed is, the stronger the longitudinal wind speed becomes. But more energy is expected to join air flows at the upper part of the beneath atmosphere during this superincumbent process, which leads to the deviation of the observed profiles from the log-law predictions. Similarly, more turbulent downward flows also correspond to more fluctuating longitudinal wind speeds.

Hence, the longitudinal mean wind speed values are dependent upon both local terrain setups and upwind flows. Analogue to the Monin-Obukhov (M-O) similarity theory[14], this study assumes that turbulence characteristic quantities within the forced convection surface layer can be described by using a stability parameter ξ. $\xi=0$,$\xi>0$, and $\xi<0$ correspond to conditions of the unforced convection, downward forced convection and upward forced convection, respectively.

Using the log-linear model, wind speed profile under thermally neutral conditions with the forced convection can be expressed as:

$$U(z) = (u_{*0} / k)\ln(z / z_0) + \xi z. \quad (2)$$

where k≈0.4 is the von Karman constant, u_{*0} is the surface friction velocity, z_0 is the roughness length scale and z is the height.

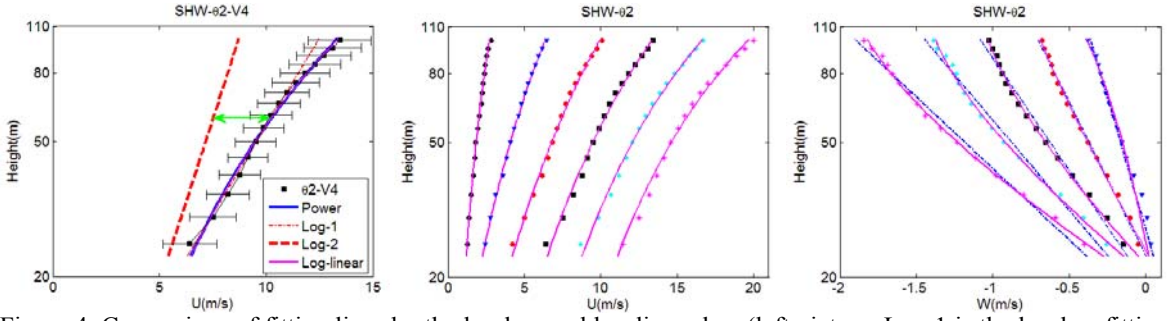

Figure 4. Comparison of fitting lines by the log law and log-linear law (left picture: Log-1 is the log-law fitting line using the lowest 10 levels data. Log-linear is the log-linear law fitting line. Log-2 is drawn from the log-linear line by setting ξ=0. Green line with arrows is the difference between the measurements and Log-2 line), profiles of longitudinal speed (middle) fitted by the log-linear model (in magenta), and profiles of vertical speed (right) fitted by both the log law (in blue) and log-linear model (in magenta) for the θ2 section.

The left picture in Figure 4 presents a comparison between the log-law model (Log-1) and the log-linear model (Log-linear) for the case of θ2 & V4. Another log-power line, denoted as Log-2, is also plotted, which is deduced from Equation 2 by setting ξ=0. As discussed above, Log-2 is governed by the local terrain roughness. It forms the asymptotic line that the mean wind profile should approach to downward the height. The deviation between the profile and the asymptotic line, indicated by the green arrowed line, stands for the wind component related to the downward flows. It is evident that a direct fitting of the longitudinal mean wind speed using the log-law (Log-1) would overestimate both the dynamic roughness length scale and the friction velocity.

Table 1. Fitting parameters for profiles of longitudinal wind speed for θ2 section with respect to different reference speeds (N: specimen number; R^2: fitting goodness).

				Power Law			Log Law		Log-linear Law			
Vi	*N*	U_{MBL}	σ_{MBL}	U_{10}	α	R^2	$2.5u_*$	z_0	$2.5u_*$	z_0	ξ	R^2
*V*2	2752	4.61	1.41	1.39	.665	.997	2.54	9.85	1.48	7.35	.025	.998
*V*3	2573	7.50	1.78	2.72	.564	.993	3.61	7.50	2.16	4.66	.033	.994

The other two pictures in Figure 4 show the ensemble mean profiles fitted by the log-linear model for both longitudinal (the middle picture) and vertical (the right picture) wind speeds. Table 1 and Table 2 list the key parameters involved in the fitting models. It can be seen that both the power law and log-linear law are able to provide favorite estimations for the longitudinal mean wind speed. But, the performance of the log-linear model is a little better. The power exponent decreases with the reference wind speed; while the stability parameter increases with it. For the vertical speed profiles, since both the log law and log-linear law agree with the measurements (nearly all R^2>0.995) well, the log-law with the simpler form is adopted. The results

for the V1 group are excluded herein, as which show remarkable deviations from those for other groups. This may be attributed to thermal effects under weak wind conditions.

3.3 *Results with downwind hills*

Results for the section θ6 with downwind hills are shown in Figure 5. Compared to the case of section θ2 with upwind hill obstructions, the longitudinal speed profiles for this section deviate from the log-law predictions to the left-hand-side. The vertical ensemble mean wind speed is positive and increases logarithmically along height. The effective turbulence intensity does not decrease monotonously with altitude. But, its variation follows three consecutive parts: the decreasing part, the leveling off part, and the increasing part. This is attributed to the less increase of U and a relatively faster increase of σ_U along height, which will be shown in Figure 6.

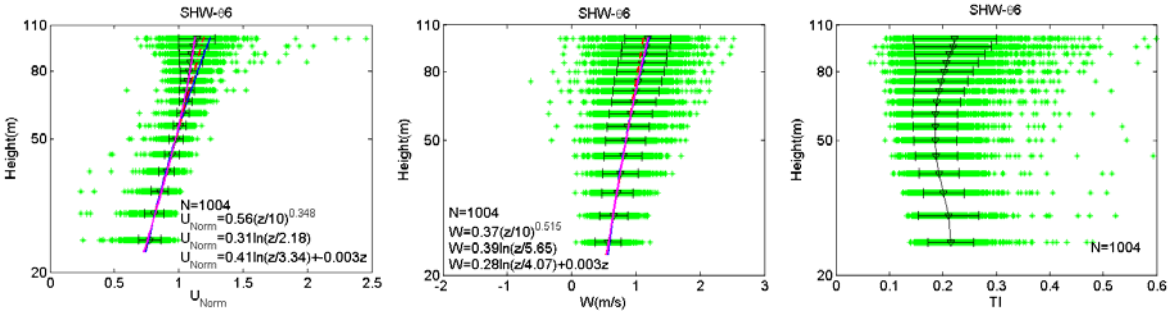

Figure 5. Profiles of normalized longitudinal speed (left), vertical speed (middle) and horizontal effective turbulence intensity (right), fitted by the power law (green line), log law (red dash line), and log-linear law (magenta line), for the θ6 azimuth section with downwind hills (datasets with V>5m/s).

Figure 6 shows the profiles of mean and standard deviation of wind speed as well as the effective turbulence intensity, with respect to different reference speeds. As the reference speed increases, the longitudinal speed deviates from the log-law predictions more evidently and the height where the log-law begins to fail to predict the measurements decreases consistently. Standard deviations, σ_U and σ_W, of wind speed increase with both the reference speed and height. σ_W is distributed in a linear form along height, compared to a more complicated nonlinear form of σ_U.

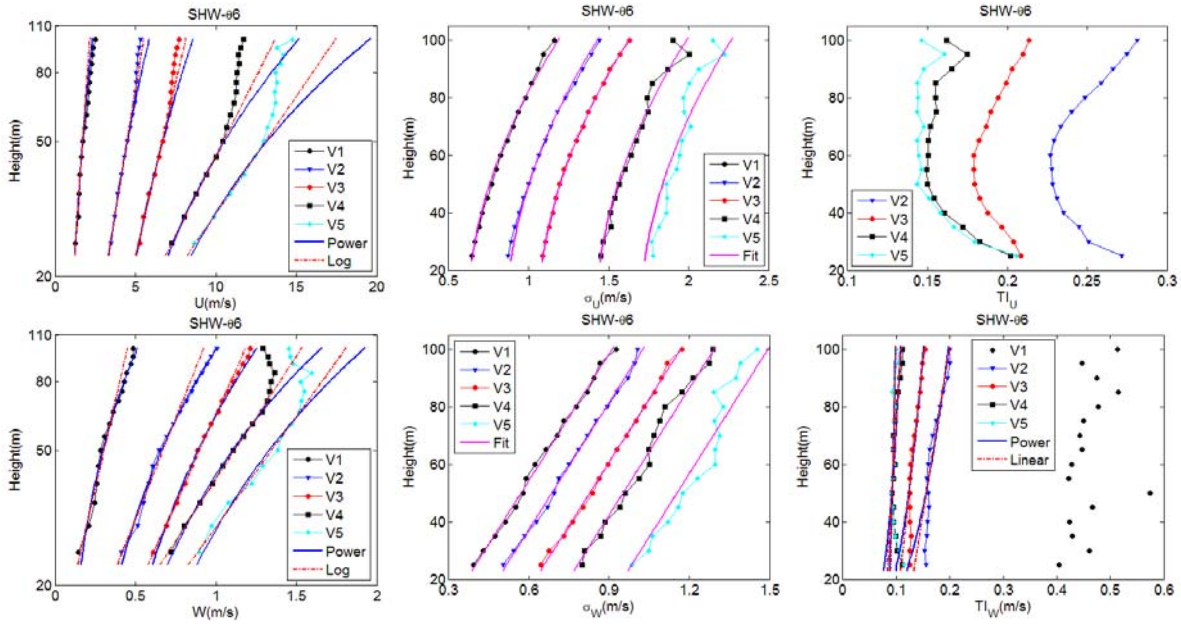

Figure 6. Profiles of mean (left) and standard deviation (middle) of wind speed, and effective turbulence intensity (right) in both longitudinal and vertical directions, for θ6 azimuth section with down-hills (fitting lines for U profiles are based on the lowest 6 levels data, W profiles are based on the lowest 10 levels data, TI_w profiles are determined by the top 12 levels data, others are based on the total 16 levels data).

Following the analysis method for the θ2 section, the log-linear law is adopted to model both the longitudinal and vertical wind speed profiles. Selected results are shown in Figure 7 and Tables 3-4. All of the fitting results agree well with the measurements, with the minimum R^2 of 0.968 for the vertical speed profile for the case of V5 where there are only 10 specimens. Opposite to the results of the θ2 section, direct usage of the log-law herein would underestimate both the roughness scales and the surface friction velocities. Meanwhile, the calculated z_0 increases with the reference speed, compared to the decreasing trend for the θ2 section. This may lie in that stronger wind, while disturbed by the downwind hills, will generate more turbulent air flows. This may also account for the continuous increase of σ_u and σ_w along altitude with respect to different reference wind speeds, compared to the situations of increasing first, then leveling off and finally decreasing along height with respect to different reference speeds for the θ2 section.

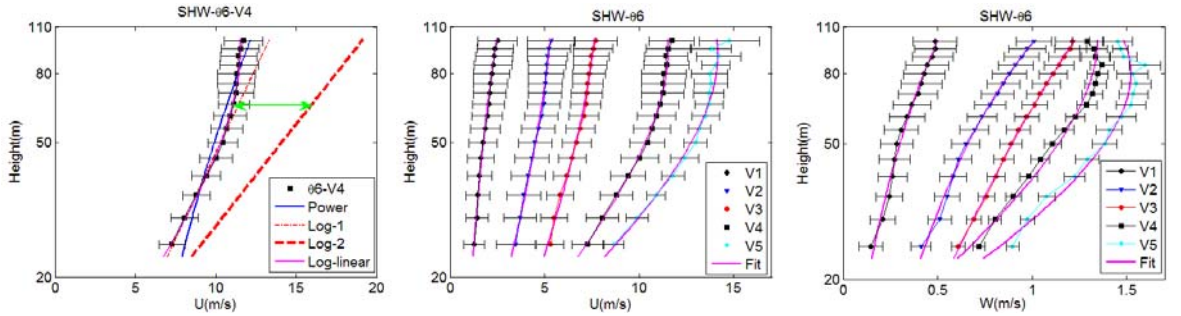

Figure 7. Comparison of fitting lines by the log law and log-linear law (left picture: Log-1 is the log-law fitting line using the lowest 10 levels data. 3.4 *Empirical models of key parameters*

From the above analysis, all the parameters involved in the fitting models are of wind speed dependence. This part will model these key parameters as a function of the reference wind speed, based on the fitting results as listed in Tables 1-4. The following criteria are adopted herein: (1) predictions should make sense under limiting conditions (e.g., $z_0>0$ for $U\rightarrow\infty$, 0); (2) predictions are able to reflect the varying trend of modeled parameters; (3) models should be robust.

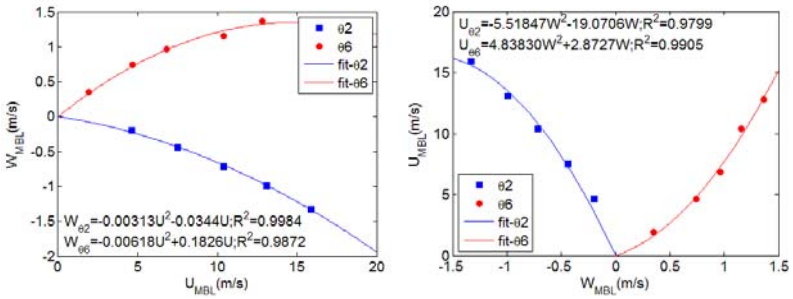

Figure 8. Correlations between the ensemble-mean boundary layer (MBL) values of longitudinal speed and vertical speed in both θ2 andθ6 sections using quadratic models.

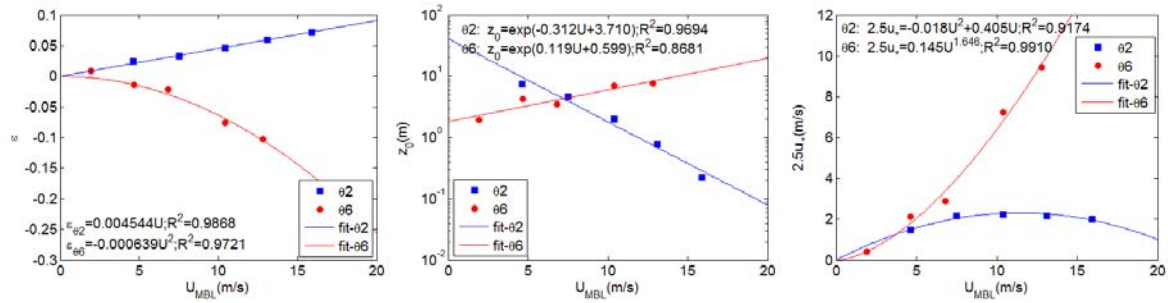

Figure 9. Correlations between the mean boundary layer (MBL) value of longitudinal speed and the stability parameter (ξ), effective dynamic roughness length scale (z_0), and the friction velocity (u_*).

Figure 8 shows the correlations between the mean boundary layer values (MBL) of the ensemble-mean longitudinal speed profile and the ensemble-mean vertical speed profile for both θ2

and θ6 sections, using quadratic models. In the left picture, U_{MBL} is the independent variable, while in the right picture, the independent variable is W_{MBL}. It can be seen that the modeled W_{MBL} for the θ6 section with respect to U_{MBL} in the left picture and the modeled U_{MBL} for the θ2 section with respect to W_{MBL} in the right picture are capped with peak values. But, there is no evidence for the existence of these upper limits. Therefore, the following two un-capped fitting equations are adopted, through which, U_{MBL} and W_{MBL} can be estimated from each other.

$$W_{MBL} = -3.13\times10^{-3}U_{MBL}^2 - 3.44\times10^{-2}U_{MBL}, \quad for\ \theta2; \tag{3}$$

$$U_{MBL} = 4.84W_{MBL}^2 + 2.87W_{MBL}, \quad for\ \theta6. \tag{4}$$

Figure 9 shows the results for the three parameters involved in the log-linear law (see Equation 2). The empirical fitting equations are given by:

$$\xi = 4.54\times10^{-3}U_{MBL}, \quad for\ \theta2; \tag{5}$$

$$\xi = -6.39\times10^{-4}U_{MBL}^2, \quad for\ \theta6. \tag{6}$$

$$z_0 = \exp(-0.312U_{MBL} + 3.71), \quad for\ \theta2; \tag{7}$$

$$z_0 = \exp(0.119U_{MBL} + 0.599), \quad for\ \theta6. \tag{8}$$

$$2.5u_* = -0.018U_{MBL}^2 + 0.405U_{MBL}, \quad for\ \theta2; \tag{9}$$

$$2.5u_* = 0.145U_{MBL}^{1.646}, \quad for\ \theta6. \tag{10}$$

Using Equations 2-10, the longitudinal mean wind profiles within the considered height range (25-100m) can be predicted, in case of giving the value of either U_{MBL} or W_{MBL}.

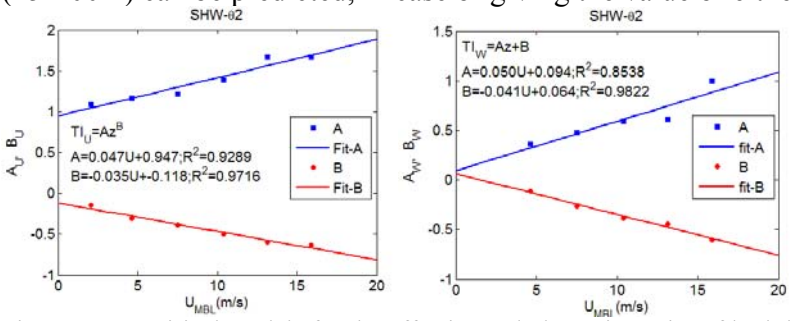

Figure 10. Empirical models for the effective turbulence intensity of both horizontal speed (left) and vertical speed (right) for the θ2 azimuth section.

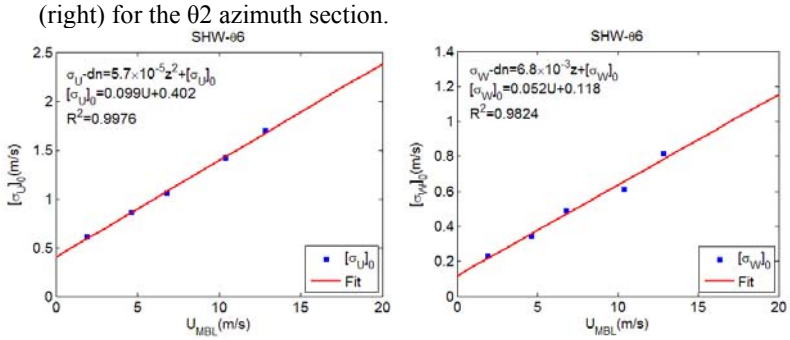

Figure 11. Empirical models for the effective standard deviation of both horizontal speed (left) and vertical speed (right) for the θ6 azimuth section.

The standard deviation of wind speed and the turbulence intensity (TI) can be inferred from each other through Equation 1. From Figure 3 and Figure 6, for the θ2 section, it is more feasible to model the effective TI first, and then formulate σ. But, for the θ6 section, the procedure is op-

posite, i.e., determining σ first and then computing the effective TI is more appropriate. The associated results are shown in Figure 10 (for θ2) and Figure 11 (for θ6):

$$TI_U = (0.047U_{MBL} + 0.947)z^{(-0.035U_{MBL} - 0.118)},\ for\ \theta 2; \tag{11}$$

$$TI_W = (1.97\times10^{-3}/U_{MBL} - 8.24\times10^{-4})z + 0.568U_{MBL}^{-0.533}\quad (U_{MBL} < 40),\ for\ \ \theta 2; \tag{12}$$

$$\sigma_U = 5.7\times10^{-5}z^2 + (0.099U_{MBL} + 0.402),\ \ for\ \theta 6; \tag{13}$$

$$\sigma_W = 6.8\times10^{-3}z + (0.052U_{MBL} + 0.118),\ \ for\ \theta 6. \tag{14}$$

Using Equation 1 and Equations 11-14, the effective standard deviation and the effective turbulence intensity of both horizontal speed and vertical speed can be determined.

From the previous analysis it can be seen that the effective standard deviation of horizontal wind speed and the vertical speed for both θ2 (Figure 3) and θ6 (Figure 6) sections are positively correlated with each other. Under open flat neutral conditions, the relationship between σ_W and σ_U can be depicted by the following equation as recommended in ESDU[15]:

$$\sigma_W / \sigma_U = 1 - 0.45\cos^4[\pi z/(2h)],\ h = u_*/(6f). \tag{15}$$

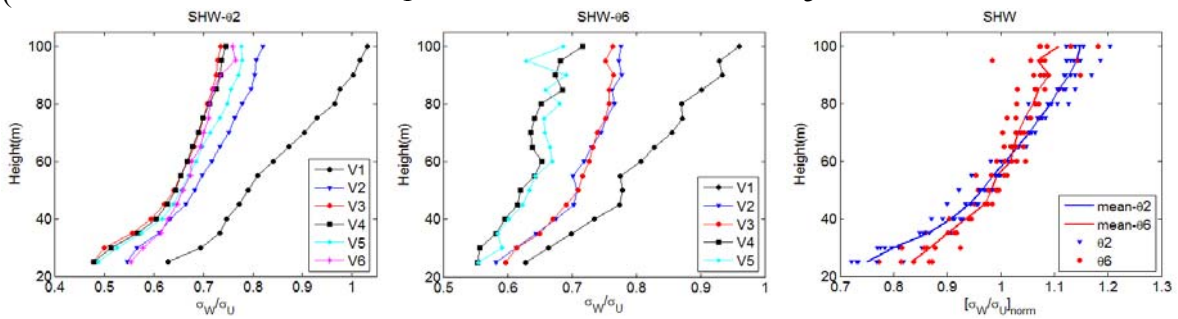

Figure 12. Correlations between the standard deviations of both vertical speed and horizontal speed with respect to different reference speeds in both θ2 (left) and θ6 sections (middle), and the correlations regardless of wind strength (right, the values are normalized by the MBL values).

In the above equation, h is the depth of the atmospheric boundary layer with the order of 1000m. But, the results under hilly terrains obtained in this study show significant differences. Figure 12 shows the variations of the ratio of σ_W/σ_U with respect to both height and reference wind speed. A best fit for the measurements using Equation 15 (other coefficients are still kept, and z and h are regarded as variables) finds the estimated h≈100m which is in the order of the characteristic height of upstream hills. Another point is that, according to ESDU[15], under neutral conditions all open flat terrains correspond to almost the same ratio of σ_W/σ_U irrespective of the nature of the terrain surfaces. But under hilly terrains, it is clear from the right picture in Figure 12 that the topographic effect can not be neglected. This is a feature of wind characteristics under hilly terrains as distinguished from those with open flat terrains.

4 CONCLUSIONS

This paper has analyzed the hill effects on near surface wind characteristics based on the field measurements from a Sodar profiler system. The longitudinal wind speed is found to be closely correlated to the forced convective flows. The θ2 azimuth section with upwind hills corresponds to downward flows (or negative vertical speed). The longitudinal mean wind speed in this section speeds up at higher altitudes and gradually departs from the log-law predictions. The θ6 section with downwind hills corresponds to upward flows. The longitudinal mean wind speed in this section also deviates from the log-law predictions and levels off along height at the upper alti-

tude range. The height where the log-law begins to fail to model the mean wind speed in both the sections decreases as the reference speed increases. The log-linear law is adopted to model the mean wind speed profiles. Results from the model agree well with the measurements. The effective standard deviations of wind speed in horizontal and vertical directions are also found to be closely correlated with each other in both sections. But the profiles in one section vary remarkably to those in the other section. The ratios of σ_w/σ_u in these two sections are different from those stipulated in the ESDU model for open flat terrains. A number of empirical estimators for both the mean wind speed profiles and the standard deviation of wind speed profiles are presented. The findings of this study can be used as reference for the determination of wind profiles under hilly terrain conditions.

5 ACKNOWLEDGEMENTS

The authors would like to express their gratitude to HKO for the provision of the wind data records and the permission of using the data for this study. The work described in this paper was supported by research grants from the Research Committee of City University of Hong Kong (Project No. 7002661 and 9667046).

A conditional analysis of roller vortices within the atmospheric log layer

G. A. Rosi, R. J. Martinuzzi, D. E. Rival

Department of Mechanical Engineering, University of Calgary, 2500 University Dr. NW, Calgary, Alberta, Canada

ABSTRACT: The scope of this work is a characterization of the fluctuations and near-ground roller vortices within the turbulent atmospheric boundary layer (ABL) at heights of approximately 5% of the ABL thickness. This height is comparable to a y+ value of approximately 100. To evaluate the roller vortices, a conditional-analysis technique is applied on a data set acquired on January 5th, 2012. This study begins with an evaluation of the ABL stability and thickness (δ). Subsequently statistical descriptors of the turbulent fluctuations are compared to those measured by Klebanoff [1] over a flat plate. The ABL data set is demonstrated to be neutral with a thickness of approximately 1000m. The statistical descriptors of the turbulent fluctuations of the data are found to qualitatively agree with values measured over a flat plate. From the conditional analysis, it is found that the centre heights of the roller vortices follow a Rayleigh distribution with a mean and standard deviation of 0.056δ and 0.027δ, respectively. However, the roller vortices concentrated around 0.05δ tend to have near-zero strength, while vortices above or below increase in strength. The concentration of near-zero strength vortices at 0.05δ is believed to be caused by the omission of the viscous core in the theoretical model.

KEYWORDS: Atmospheric turbulence, coherent structures, conditional analysis.

1 INTRODUCTION

Understanding turbulent fluctuations and coherent structures in the lower log layer of the atmosphere is valuable for several applications such as wind-turbine control, managing gusts during the takeoff and landing of aircraft, as well as wind loadings on large civil structures. Earlier research into atmospheric turbulence has generally focused on the time-averaged characteristics of the velocity fluctuations. For example, as demonstrated in Kaimal [2], the power spectra of the velocity fluctuations and their cross-correlations follow normalized curves that are functions of the Richardson number. Similar relations involving the fluctuation spectra have been determined and are well documented in various texts such as Lumley and Panofsky [3] and Kaimal and Finnigan [4].

The drawback of quantifying events in this manner is that no information regarding short-term coherent structures within the wind field is obtained. For this reason, methods such as Conditional Analysis and Proper Orthogonal Decomposition (POD) have recently been used to

investigate coherent structures directly. In meteorological studies, POD has provided significant results; see Wilson [5] and Lin et al. [6]. However, meteorological studies focus primarily on heights beyond 0.2δ. Furthermore, the coherent structures that are studied are on the order of δ, which are not of interest in the current study. In contrast, studies on canonical turbulent boundary layers (TBL) have investigated turbulent coherent structures on orders much smaller then the TBL thickness. For example, the properties of hairpin and horseshoe vortices are well documented [7] and have been measured experimentally by Schroeder et al. [8] and Adrian [9]. It has been shown that at 5% of the TBL thickness, i.e. the lower log layer, canonical TBLs are populated by both streak vortices and hairpin vortices; see Robinson [7] and Smith and Walker [10].

Given the breadth of research performed on canonical TBLs, demonstrating that ABLs share similarities with canonical TBLs would be extremely valuable for future wind-tunnel modelling. Scarabino et al. [11] attempted to demonstrate the similarities between ABLs and canonical TBLs by showing that both share similar coherent structures. Using data collected by Sterling et al. [12], velocity fluctuations of extreme gust events were classified into three groups and were then ensemble averaged. One of the ensemble groups exhibited vortex-like flow, which led Scarabino et al. [11] to fit a hairpin vortex model onto the ensemble average. In this regard the study had limited success: Although the hairpin-vortex model accounted for sharp changes in streamwise velocity, it failed to capture the simultaneous vertical fluctuations properly.

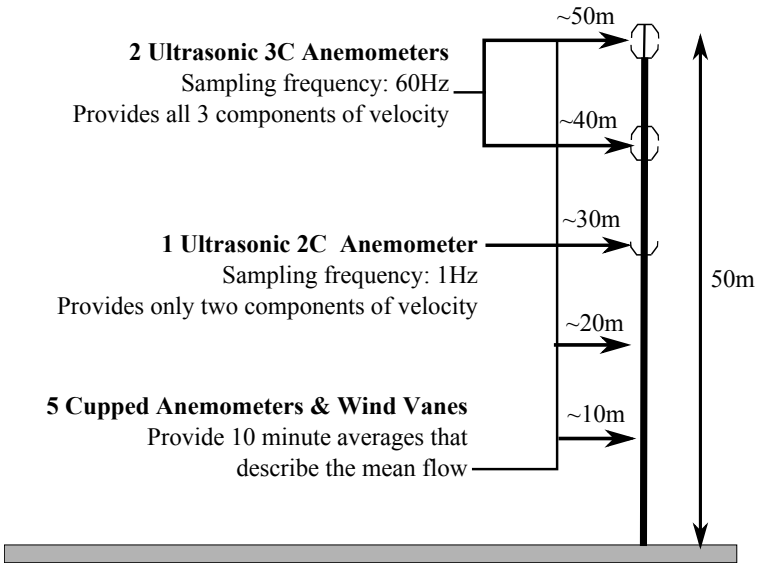
It is believed that the shortcomings of the hairpin-vortex model in Scarabino et al. [11] were due to an oversimplification since it was assumed that a gust event could be represented by a simple hairpin vortex. In reality, there are a wide range of structures within TBLs, thus resulting in much more complicated flow fields. It is argued that these coherent structures must be studied first in terms of their strength and orientation prior to investigating how they contribute to gust events. Thus, the current study takes a different approach than that in Scarabino et al. [11]. Rather than identifying gust events within the data and attempting to fit a certain coherent structure to each, events that meet specific criteria suggestive of a hairpin vortex are identified instead. Velocity fields are then determined for each specific event and compared to experimental data. In this way the height and strength of hairpin vortices within the lower log region of the ABL can be determined, statistically analysed and compared to those within canonical TBLs.

Since the structure of hairpin vortices is complex, it is assumed that such vortices can be simplified as two-dimensional rollers instead. This assumption is based on the following observations: (1) It is noted in Robinson [7] that the lifespan of transverse vortices is much longer than the lifespan of streamwise vortices; and (2) through experiments performed by Head and Bandyopadhyay [13] at $0 \leq Re_\theta \leq 10000$, it was found that the legs of hairpin vortices are around 100 wall units (y+) apart, which in the ABL translates to approximately 50m.

The current study compares properties of ABLs to those of canonical TBLs. First various statistical descriptors of turbulent fluctuations measured by a wind mast are compared to measurements taken over a flat plate. Subsequently a conditional analysis is used to identify hairpin-vortex events. The occurrence-frequency distributions of normalized circulation ($\Gamma/U_0\delta$) and normalized vortex-centre height (a/δ) are discussed, as well as the correlation between normalized circulation and normalized height. By assaying the reasonableness of the aforementioned results, the robustness of the model is then evaluated.

2 EXPERIMENTAL METHODS

For this investigation, a 2-hour long data set was acquired on January 5th, 2012 from a 50m wind mast erected on university land. The area is primarily rural. It is generally flat with a shallow depression of 5m depth upwind of the mast. A schematic of the wind mast, with the approximate positioning of its sensors, is provided in Figure 1a. A photograph depicting the mast and the surrounding terrain is shown in Figure 1b. The five cupped anemometers (CA) and wind vanes (WV), as well as the two-component ultrasonic anemometer, are all used to determine the mean wind speed and direction. Coherent structures are determined using the measurements taken by the two three-component ultrasonic anemometers (3CUS). The 3CUS sensors are located at 40m and 50m heights.



(a)

(b)

Figure 1: (a) A schematic of the wind mast with the approximate positioning of sensors indicated. (b) A photograph of the mast and surrounding terrain.

During the experiment the mean wind velocity profile varied considerably. The data was therefore split into 10-minute long sets during which the mean velocity remained fairly constant. The reference frames of the two 3CUSs were rotated so that the x-, y-, and z-axes were respectively oriented into the streamwise, vertical and lateral wind directions as determined by the WVs. This was performed independently for each 10-minute data set. Upon performing this rotation, the x-axis mean velocities measured by the 3CUS sensors were nearly equal to the velocity measured by the CA of corresponding height (mean discrepancy of $\pm$0.7m/s). The other two components measured essentially zero mean velocities (mean discrepancy of $\pm$0.5m/s). The mean values of all three components of the 3CUS sensors were subtracted from the respective component for each 10-minute data set. This modified data now represented the wind fluctuations in the longitudinal, vertical and lateral directions.

A condition suggestive of hairpin vortex impingement will now be presented. It is argued that a hairpin vortex be represented as an infinitely long potential vortex being convected towards the mast, as shown in Figure 2. The circulation of the vortex is Γ and the vortex centre sits at an arbitrary height $y = a$. Also the vortex is convected by the mean local velocity U_a

at the vortex-centre height. To account for ground effect, two counter-rotating vortices are positioned at heights $+a$ and $-a$. Figure 2 also shows the mast with the heights of the top and bottom ultrasonic sensors labelled as h_T and h_B, respectively. If Taylor's hypothesis is assumed to hold, then the vortex's shape should not change as it convects. This allows b to be set equal to $-U_a(t - t_R)$, where t_R is the instant the vortex centre has passed the mast.

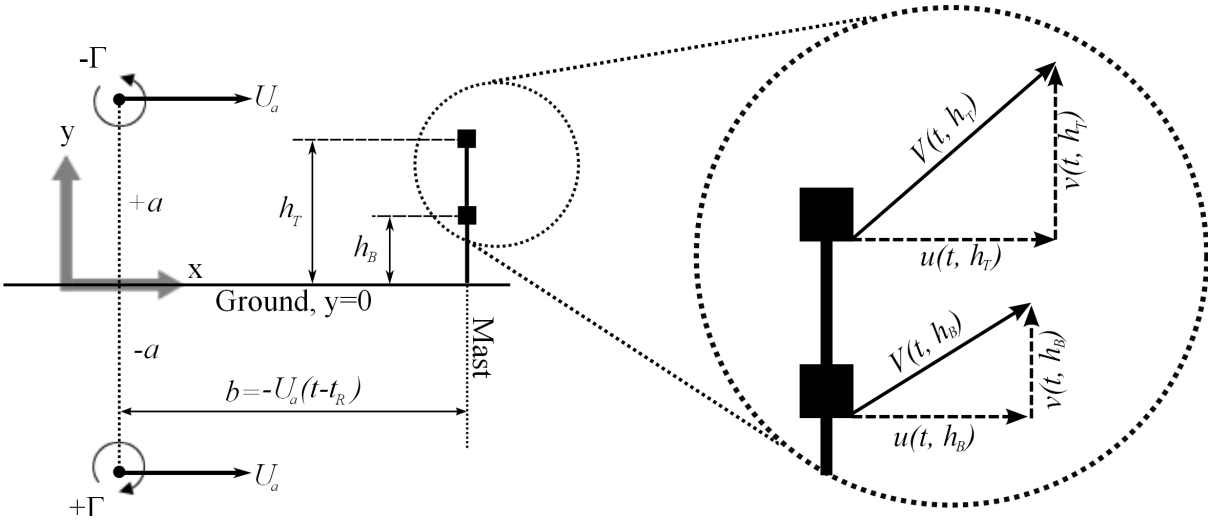


Figure 2: A potential line vortex of circulation Γ at an arbitrary height a being convected towards the mast at U_a (the mean wind velocity at height a). The vortex induces a fluctuation field V, comprised of a streamwise component u and vertical component v. Fluctuations from the mean velocity are measured by the two 3CUS sensors at heights h_T and h_B. A counter rotating vortex at $-a$ has been included to account for ground effect.

The fluctuation field generated by this vortex is given by u and v, which are the longitudinal and vertical fluctuations induced by the vortex, respectively. At the top and bottom 3CUS sensors, the vortex induces fluctuations of:

$$\vec{V}(t, h_T) = u(t, h_T)\hat{\imath} + v(t, h_T)\hat{\jmath} \tag{1}$$

$$\vec{V}(t, h_B) = u(t, h_B)\hat{\imath} + v(t, h_B)\hat{\jmath}. \tag{2}$$

If the current vortex is far from other vortices, then the fluctuation field is given by:

$$u(t, y) = +\frac{\Gamma(y-a)}{\pi((U_a(t-t_R))^2 + (y-a)^2)} - \frac{\Gamma(y+a)}{\pi((U_a(t-t_R))^2 + (y+a)^2)} \tag{3}$$

$$v(t, y) = +\frac{\Gamma U(t-t_R)}{\pi((U_a(t-t_R))^2 + (y-a)^2)} - \frac{\Gamma U(t-t_R)}{\pi((U_a(t-t_R))^2 + (y+a)^2)}. \tag{4}$$

The vortex-induced fluctuations at the sensors can be determined by replacing y with h_T and h_B in equations (3) and (4). If corresponding components are divided by one another, followed by setting t to t_R, equations (5) and (6) are determined:

$$\frac{u(0, h_T)}{u(0, h_B)} = \frac{a^2 - h_B^2}{a^2 - h_T^2} = F \tag{5}$$

$$\frac{v(0, h_T)}{v(0, h_B)} = \frac{h_T}{h_B}\left(\frac{a^2 - h_B^2}{a^2 - h_T^2}\right)^2 = \frac{h_T}{h_B}F^2, \tag{6}$$

where F is only dependent on the heights of the two 3CUS sensors and the vortex-centre height.

It is interesting to note that F is only negative when $h_B < a < h_T$. Also note that regardless of vortex-centre height, equation (6) is never negative, meaning that vertical fluctuations always occur in the same direction.

Equations (5) and (6) define a condition for identifying roller vortices. If a vortex centre passes the mast at time t_R, then the following must hold true at that instance as well:

$$\frac{v(t_R, h_T)}{v(t_R, h_B)} = \frac{h_T}{h_B}\left(\frac{u(t_R, h_T)}{u(t_R, h_B)}\right)^2. \tag{7}$$

By locating a time instance where (7) is satisfied, F is effectively known. From F, the values of a and Γ can be determined, thereby defining equations (3) and (4) completely. Finally equations (3) and (4) can be tested against the data time series in the immediate vicinity of t_R. If a roller in fact passes at t_R, then equations (8) and (9) must be true during the immediate time series:

$$\sigma_T = \overline{|u(t, h_T) - u(t, h_T)_D|} = 0 \quad \sigma_B = \overline{|u(t, h_B) - u(t, h_B)_D|} = 0 \tag{8}$$

$$\nu_T = \overline{|v(t, h_T) - v(t, h_T)_D|} = 0 \quad \nu_B = \overline{|v(t, h_B) - v(t, h_B)_D|} = 0, \tag{9}$$

where subscript D indicates fluctuations measured in the data set. Equations (8) and (9) will be evaluated over approximately $t_R \pm \frac{1}{2}T$, where T is the integral time scale of the fluctuations as determined from the data set. T is determined by integrating the autocorrelation functions of the turbulent fluctuations. It was determined that T for this data set is on the order of 1s. The details of how this was determined are not included in the current study. If equations (8) and (9) are nearly equal to 0, then the roller model predicts fluctuations of similar value to those in the data. Rollers must track fluctuation trends as well. For this reason, all roller events are manually checked to ensure that the immediate fluctuation trends are captured.

3 RESULTS & DISCUSSION

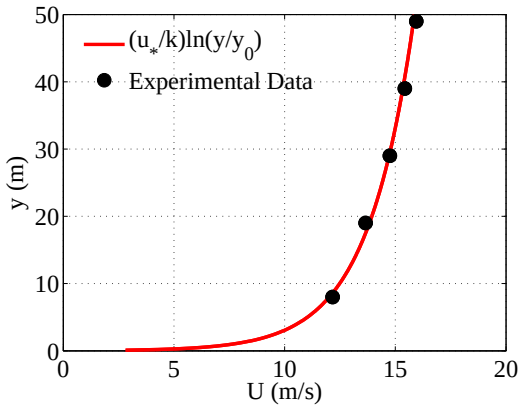
This section describes the ABL data set by evaluating important descriptors such as the stability, the thickness and the Reynolds number. Afterwards, the results of the conditional analysis are evaluated.

3.1 *Description of the ABL Data Set*

The stability of the ABL may be determined by analysing the mean velocity profile. In a neutral ABL, the mean velocity profile fits well onto the curve given by Kaimal and Finnigan [4]:

$$U(y) = \frac{u_*}{k}\ln\frac{y}{y_0}, \tag{10}$$

where y is the vertical distance from the ground, u_* is the friction velocity, k is the von Karman constant (approximately 0.4) and y_0 is the friction length. Both u_* and y_0 are determined from the curve fit. Figure 3a shows the mean velocity measurements taken by the cupped anemometers for the first 10-minute data set. The solid curve represents equation (10) fitted onto the mean velocity measurements. The friction velocities and roughness lengths for all 11 sets are provided in Figure 3b. The R^2 values are provided also, which are a measure of the quality of the fit. All the R^2 values for the 10-minute time sets exceed 0.97, indicating that equation (10) is a good descriptor of the mean velocity. Thus the ABL is presumably neutral. Also, the fact that the wind-velocity profiles are well described by a logarithmic fit indicates that the mast sits within the log region of the ABL.



(a)

Time Set	y_0 (cm)	u_* (m/s)	R^2
1	2.62	0.84	0.992
2	3.99	0.87	0.979
3	3.49	0.89	0.986
4	5.51	0.96	0.988

11	10.28	0.77	0.989

(b)

Figure 3: (a) The mean velocity profile for the first 10-minute set (14:50 to 15:00). (b) Roughness lengths, friction velocities and R^2 values for each 10-minute set as approximated by fitting the data to (10).

There are various methods to approximate the ABL thickness. For example, Blackadar and Tennekes [14] provides an approximation for δ of neutral ABLs based on friction velocity and Coriolis effects. The current study determines δ by comparing the ABL data to data collected from canonical TBLs over a flat plate. Cheng [15] states that the velocity profiles of TBL flow over a flat plate is classically represented as:

$$\frac{U}{U_0} = \left(\frac{y}{\delta}\right)^{\frac{1}{m}} \text{ where } m \approx \ln \frac{y_0}{0.2\delta}. \tag{11}$$

This provides an iterative method for determining the value of δ: Its value is first assumed; then the profile provided by equation (11) is compared to the experimentally measured profile normalized by U_0. A value of 1000m for δ provides reasonable agreement between equation (11) and the experimental data, as shown in Figure 4. The error bars in Figure 4 represent a single standard deviation in the observed results.

Figure 4 also shows various statistical descriptors of the turbulent fluctuations as measured by the 3CUS sensors (observed flow), as well as those measured in a canonical TBL over a flat plate by Klebanoff [1]. The statistical descriptors of the fluctuations for the observed flow and TBL flow share the same order of magnitude. However, the statistical descriptors for the observed flow and TBL flow often differ by approximately one standard deviation. The discrepancy between the observed flow and TBL flow may be due to the difference in Reynolds number. The TBL-flow data was collected at a Reynolds number $Re_x = 4.2. \times 10^6$ while the Reynolds number for this ABL data is approximately $Re_x = 4.3. \times 10^{15}$.

3.2 *Results of the Conditional Analysis*

The conditional analysis was performed on all eleven 10-minute data sets. 774 events were identified in which the roller model accurately tracked the fluctuations within an acceptable degree of precision. It was often found, however, that precision had to be compromised for the sake of accuracy. Table 1 quantifies the precision error of the roller model by providing the mean values of σ_T, σ_B, ν_T and ν_B. On average, the 50m 3CUS sensor was less precise then its 40m counterpart. This is likely because the turbulent intensities at 50m are greater then those at 40m.

Figure 5 shows the occurrence-frequency distribution of vortex-centre height a and circu-

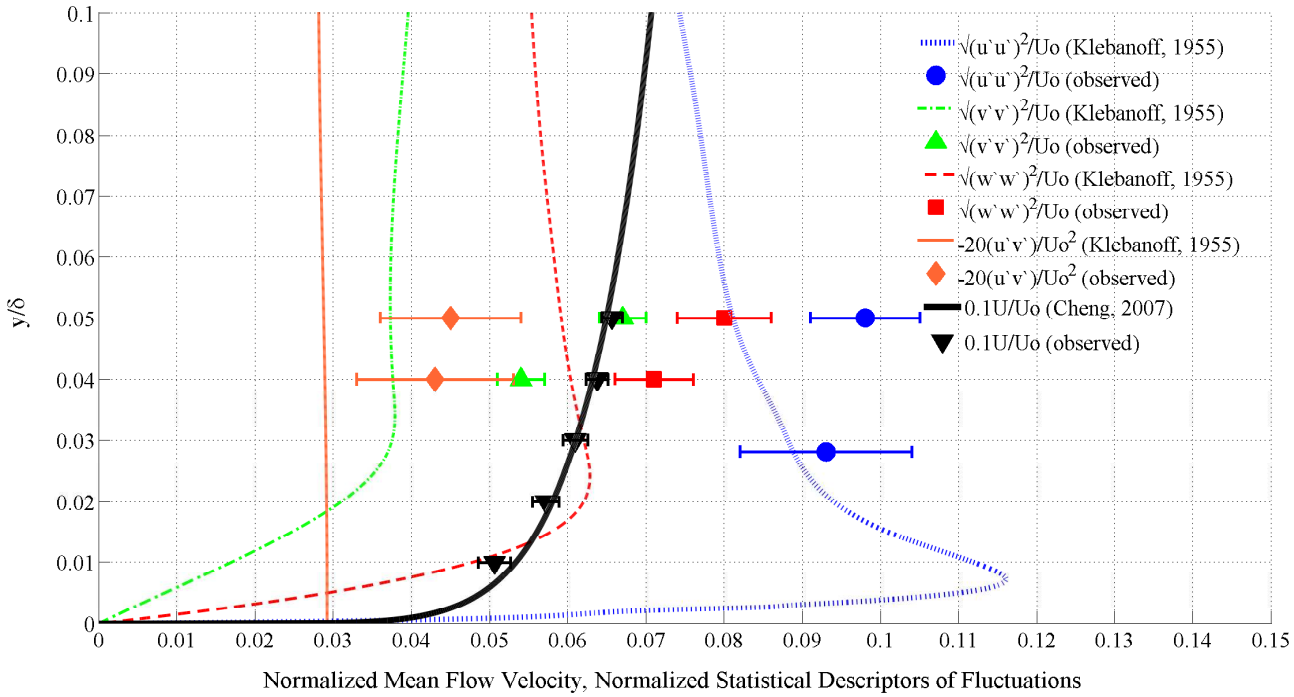

Figure 4: Theoretical and observed values for the velocity profile and its respective turbulent fluctuations.

σ_T (m/s)	σ_B (m/s)	ν_T (m/s)	ν_B (m/s)
0.772	0.561	1.093	0.610

Table 1: The mean precision error of the roller model in tracking the measured fluctuations. The precision error is evaluated for all eleven 10-minute sets. σ and ν refer to precision errors of the streamwise and vertical fluctuation components, respectively. Subscripts T and B refer to the top and bottom 3CUS sensors, respectively.

lation Γ normalized by δ and $U_0\delta$, respectively. The distribution of a resembles a Rayleigh probability distribution. The mean of a is 0.056δ, while the standard deviation of a is 0.027δ. In contrast, Γ appears normally distributed; its mean is $0.000U_0\delta$ while its standard deviation is $0.010U_0\delta$.

It is possible that the near-ground roller vortices have vortex-centre heights that follow the distribution shown in Figure 5a. Various studies performed on canonical TBLs have found similar distributions. From data of a numerical simulation of a canonical boundary layer ($Re_\theta = 670$) by Spalart [16], Robinson [17] found that spanwise vortices also follow a Rayleigh distribution with an average height of approximately 0.2δ. From experiments run at $Re_\theta = 1120$ Smith and Lu [18] also found that the vortex-centre heights follow a Rayleigh distribution with an average height of 0.06δ. Finally, from experiments Wu and Christensen [19] found that over a large Reynolds-number range ($4000 \leq Re_\theta \leq 11000$) the centre height of the spanwise vortices followed a Rayleigh distribution with a mean of approximately 0.06δ.

It seems unlikely that the circulation is normally distributed about 0. Wu and Christensen [19] found that the circulation of spanwise vortices followed a bimodal distribution about 0 ($Re_\theta = 8830$), while in Robinson [17] the circulation distribution was slightly skewed towards prograde vortices. Furthermore results from Wu and Christensen [19] demonstrate that pro-

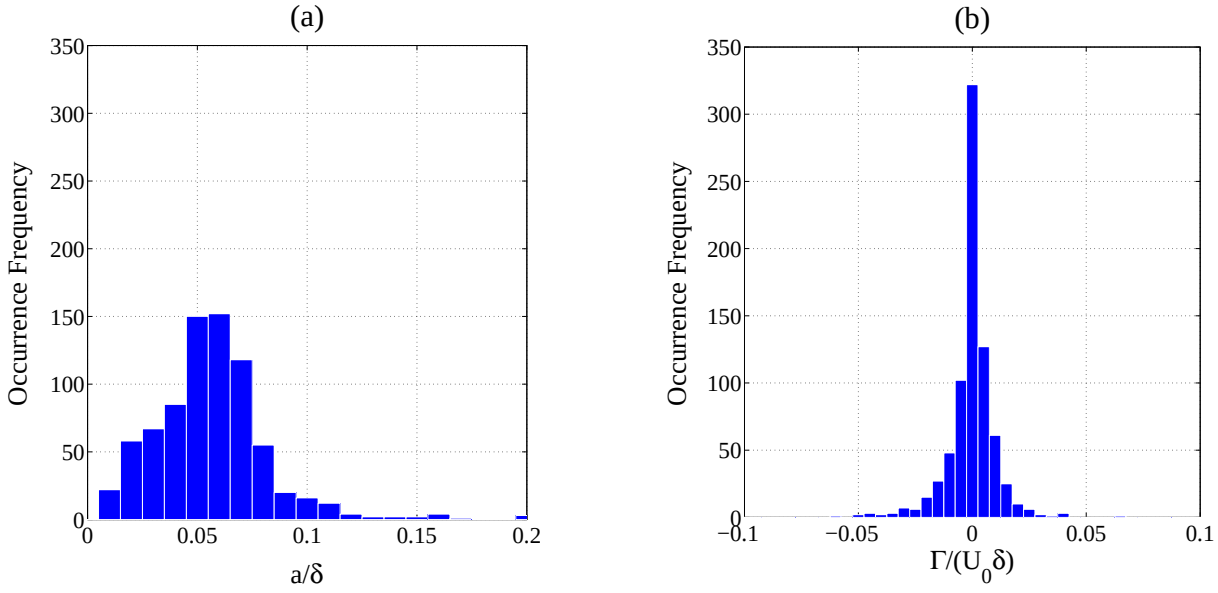

Figure 5: Occurrence-frequency distributions of (a) vortex-centre height a and; (b) circulation Γ for all eleven 10-minute data sets. Γ is normalized by $U_o\delta$, while a is normalized by δ. δ is assumed to equal 1000m, while U_0 is determined by evaluating equation (10) at 1000m.

grade vortices are more common near the shearing surface, while retrograde vortices are more common higher up in the boundary layer. Note that a prograde vortex causes a negative streamwise fluctuation below its centre while a retrograde vortex causes a positive fluctuation below its centre. Thus it would be expected for the circulation distribution in Figure 5b to be shifted to the right.

The zero mean in circulation is likely caused by shortcomings in the conditional model. One significant limitation in the model is the absence of a viscous core for the roller vortices. This may have caused the model to underestimate the circulation magnitude for the roller vortices concentrated at 0.05δ, the height at which the two 3CUS sensors are located. If a vortex-centre is at a similar height as the 3CUS sensors, then the sensors would possibly be within the viscous core. Being inside the viscous core would cause the conditional model to substantially underestimate the circulation. This is because the model does not account for the decrease in velocity inside the viscous core. Figure 6 shows normalized circulation plotted against normalized vortex-centre height, which in fact demonstrates that circulation tends to 0 as the vortex-centre height approaches 0.05δ. This supports the argument that neglecting the viscous core may have skewed the results. However, the circulation distribution determined by the current study may in fact be correct. Results from Wu and Christensen [19] demonstrate that as the Reynolds number is increased the ratio of prograde to retrograde vortices approaches unity.

4 CONCLUSIONS & RECOMMENDATIONS

The current study characterised the fluctuations and coherent structures within the atmospheric log layer. Hairpin-vortex structures were identified using a conditional analysis that modelled hairpin-vortices as infinitely long roller vortices convected towards the mast. For simplicity the roller vortices were assumed to be irrotational. It was found that the ABL data set qual-

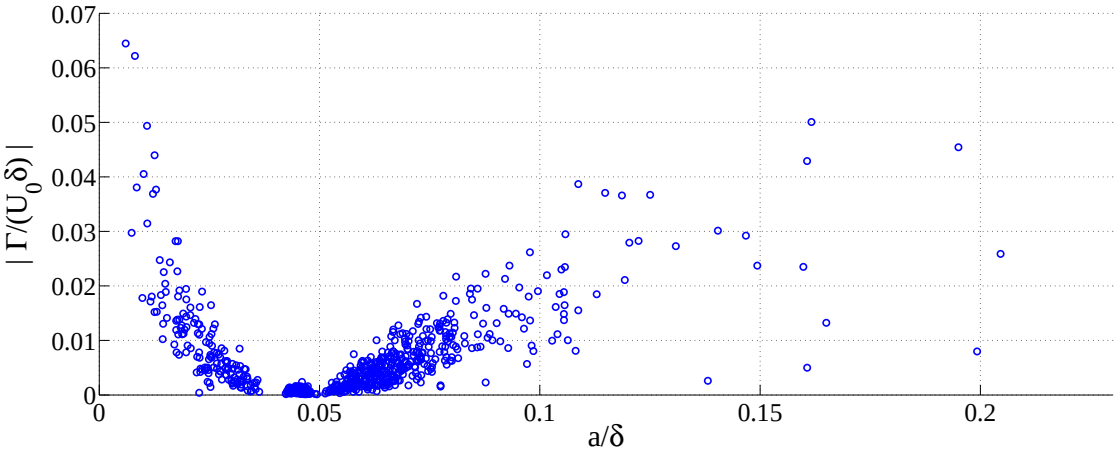

Figure 6: The magnitude of circulation Γ plotted against vortex-centre height a for all eleven 10-minute data sets. Γ and a are normalized as they were in Figure 5.

itatively agreed with statistical descriptors of TBL flow. The conditional analysis found that the occurrence frequency of vortex height followed a Rayleigh distribution, with a mean and standard distribution of 0.056δ and 0.027δ, respectively. The circulation followed a normal distribution with a mean and standard deviation of $0.000U_0\delta$ and $0.010U_0\delta$, respectively, with the bulk of the rollers measured around 0.05δ having circulations near zero. Despite the mean circulation of zero, the height distribution determined by the conditional analysis agreed with previous studies. The conditional model should be updated to account for the viscous core so as to accurately evaluate the vortex rollers when in proximity to the sensors.

ABSTRACT: We intend to use the WRF (The Weather Research and Forecasting Model） to prepare standard wind data at high altitude for the assessment of pedestrian wind environment, and also to investigate urban heat island phenomena. Before doing these investigations, it is necessary to confirm the prediction accuracy of WRF. In this study, the measured occurrence frequencies and vertical wind velocity profiles obtained by Doppler Soda at Minami-senju (inland area in Tokyo) were compared with those calculated by the WRF model. In order to well regenerate the vertical profile of wind velocity by WRF, appropriate surface roughness should be given to the WRF calculation. Thus, we used GIS data to appropriately classify land-use categories and to give a roughness length to the WRF calculation. The WRF calculation results using GIS data were compared with those of WRF using default values. The occurrence frequency and the vertical profiles of wind velocity calculated by WRF using GIS data agreed very well with those of the observation data. The calculated results of WRF using GIS were much better than those of WRF using default values.

KEYWORDS: WRF, vertical profile of wind velocity, occurrence frequency of wind velocity

1 INTRODUCTION

To assess the pedestrian wind environment around tall buildings based on occurrence frequencies of wind velocities we need reliable statistical wind observation data from near their construction sites. However, wind observatories are not always located near construction sites. Even if they do, the observation height is sometimes not high enough and the wind data are affected by surrounding buildings. Meso-scale simulation can be an alternative to direct observation. The authors intended to use the WRF (The Weather Research and Forecasting Model), a meso-scale simulation model, in order to prepare standard wind data at high-altitude for the assessment of the pedestrian wind environment. We also plan to use WRF for research on urban heat island phenomena, which is becoming serious in large cities in Japan. One of the effective countermeasures against heat island phenomena is to lead cool air of sea breeze into urban canopies. This strategy strongly depends on the vertical profile of wind velocity and the temperature of the sea breeze. Before doing these investigations using WRF, it is necessary to confirm how WRF can correctly regenerate the occurrence frequencies and vertical profiles of wind velocities. For this validation, observation data measured by Doppler Sodar in the Minami Senju district in Tokyo (Miyashita et al. 2002) were used. In order to well regenerate the vertical profile of wind velocity by WRF, it is considered that an appropriate surface roughness should be given to the WRF calculation. However, the default setting of WRF based on USGS (United States Geological Survey) expresses urban areas as only by one category and gives a uniform roughness length regard-

less of building densities and heights. Thus, we used GIS (Geographic Information System) data to appropriately classify urban land-use categories and to give roughness lengths to the WRF calculation. We conducted two cases of WRF calculations using a default setting and using GIS data, and the results were compared with the observation data.

2 OUTLINE OF CALCULATIONS

2.1 *Calculation Period, Initial and Boundary Conditions, Physics Scheme*

Calculations were carried out for a period of one month from May 1 to May 31, 2000. To set initial and boundary conditions we used FNL (Final) Operational Global Analysis data from the NCEP (National Center for Environmental Prediction). Table 1 gives an overview of the Physics Schemes used for these calculations.

Table 1: Physics Schemes

Physics scheme	microphysics	WRF 6 graupel class
	Longwave	Rapid Radiative Transfer Model
	Shortwave	Gudhia showtwave
	Surface layer	Monin-Obukhov (Janjic Eta) scheme
	Land surface	Noah land surface model
	Planetary boundary layer	Mellor-Yamada-Janjic scheme (2.5 level closure model)
	Cumulus	no
	Urban canopy	no

2.2 *Calculation Domains and Grid Intervals*

The calculations were conducted using three-stage, two-way nesting grids. The calculation domains and grid resolution are shown in Table 2 and Figure 1. The Minami Senju district, used for the comparison between observation and WRF calculations, is included in Domain 3.

Table 2: Computational Domain and Grid Resolution

	Domain (km) X×Y×Z	Grid Size X×Y×Z	Horizontal grid intervals (km)
Domain 1	450×450×20	50×50×60	9
Domain 2	180×180×20	60×60×60	3
Domain 3	60×60×20	60×60×60	1

※We used unequal intervals for the vertical grid and small intervals for areas near the ground surface.

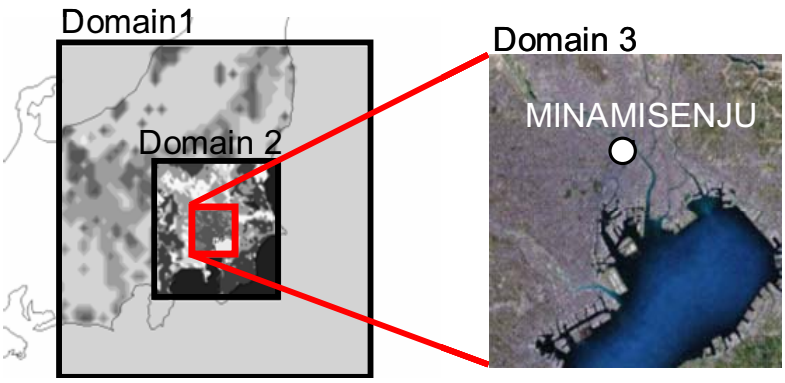

Figure 1: Computational Domain

2.3 *Setting Land-Use Categories and Ground-Surface Parameters*

Default setting of WRF employs the USGS's (United States Geological Survey) 24 categories of land use and their corresponding ground-surface parameters such as roughness length, albedo, and so forth. However, in the USGS, urban area is expressed by only one category and its roughness length is uniformly 0.8m regardless of building density and building height. Moreover, some areas that would be considered "urban" in reality are classified as pasture, grassland, and other categories in the USGS. Thus, the USGS does not sufficiently express the actual circumstances of Tokyo. For these reasons, we used the Digital Map 5000 and National Land Numerical Information Report (both referred to as "GIS" hereafter) published by the Ministry of Land, Infrastructure, Transport, and Tourism to appropriately classify land-use categories. Furthermore, we classified the urban area into three categories, "Low", "High", and "Commercial". We mainly used the Digital Map 5000, adding supplementary data from the National Land Numerical Information Report for places not covered by the former. The procedures for classifying land-use and determining ground-surface parameters are as follows.

Firstly, we netted the GIS in a 1km × 1km mesh, which is the same size as the grid in Domain 3 of the WRF calculation. Then, the area for each land-use category in each 1km×1km grid was calculated, and the land-use category occupying the largest area within each grid was determined to be a representative land-use category in the grid.

Secondly, we classified urban area into three categories to reflect the diverse urban configurations of Tokyo. (As described above, in the default setting of WRF with USGS, the urban area is expressed by only one category regardless of building density and building height.). We used land-use categories from the Digital Map 5000 and assigned them to three different urban categories: "Low," "High," and "Commercial". "General Low-Rise Residential area," "High-Density Residential area," and "Others" (including "Land for Public Facilities") in the Digital Map 5000 were assigned to the "Low" urban category; "Medium- and High-Rise Residential area" to the "High" urban category; and "Area for Commercial and Business Use" to the "Commercial" urban category. We totaled the areas occupied, respectively, by the Low, High, and Commercial category in each grid square, and the urban category with the largest area was determined to be a representative urban category for that grid square.

Finally, GIS land-use categories were corresponded to the USGS land-use categories, and surface parameters were determined as shown in Table 3. The USGS uses a uniform roughness length of 80cm for the urban area, but for this study we used 70cm, 100cm, and 150cm for Low urban area, High urban area, and Commercial urban area, respectively. We adopted these values

by referring to Grimmond and Oke (1999). Figure 2 shows land-use categories based on the USGS (Figure 2a) and the GIS (Figure 2b), which shows large differences between them.

Table 3: Land-use Categories and Surface Parameters

No.	USGS/SIB Land-Use Category	GIS Land-Use Category	Urban Category	Surface Z0 [cm]	Albedo [%]	Soil Moisture [%]	Surface Emmisivity [%]
1	Urban Land	House and Pablic Building	Low	70	15	10	88
			High	100			
			Commercial	150			
2	Dryland Cropland and Pasture	Farm	-	15	17	30	98.5
3	Irrigated Cropland and Pasture	Paddy Field	-	10	18	50	98.5

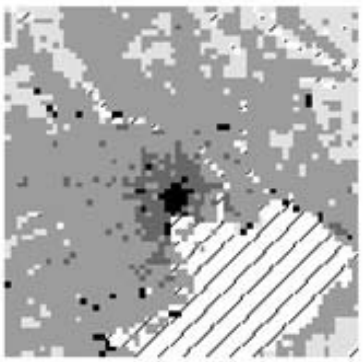
2a) USGS



2b) GIS

Figure 2: Land-use Categories in Domain 3

2.4 *Calculation Cases*

We carried out two kinds of calculations: one using the default setting of WRF with USGS (Case 1), and the other using the land-use categories and surface parameters based on GIS data as described in 2.3 (Case 2).

3 COMPARISON OF WRF-CALCULATED RESULTS WITH OBSERVATION DATA

3.1 *Occurrence Frequencies of Wind Velocities at High Altitude*

Figure 2 compares the probabilities of exceedance of mean wind velocity (10 minutes averaging 300m high) between the results of WRF and observation data. Case 1 and case 2 indicate WRF calculations using the default value and GIS data, respectively. The probability of exceedance of wind velocity calculated by Case 2 agreed very well with the observation data. The probability of exceedance calculated by Case 1 was higher than that of Case 2. However, the difference was not so large at this high altitude.

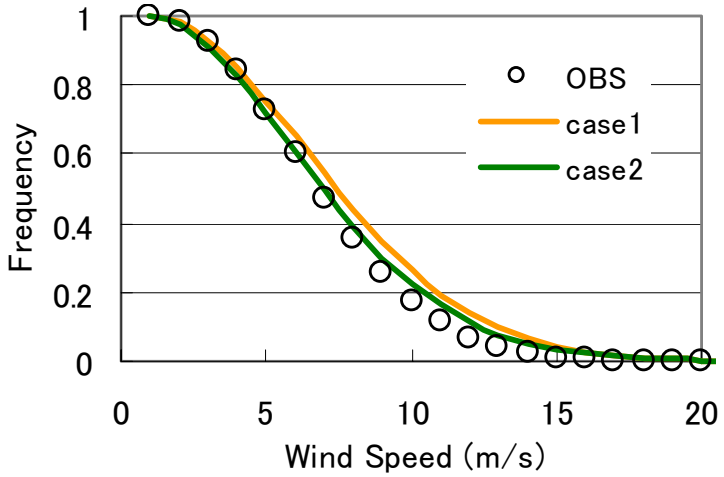


Figure 3: Probability of Exceedance for Mean Wind Speed

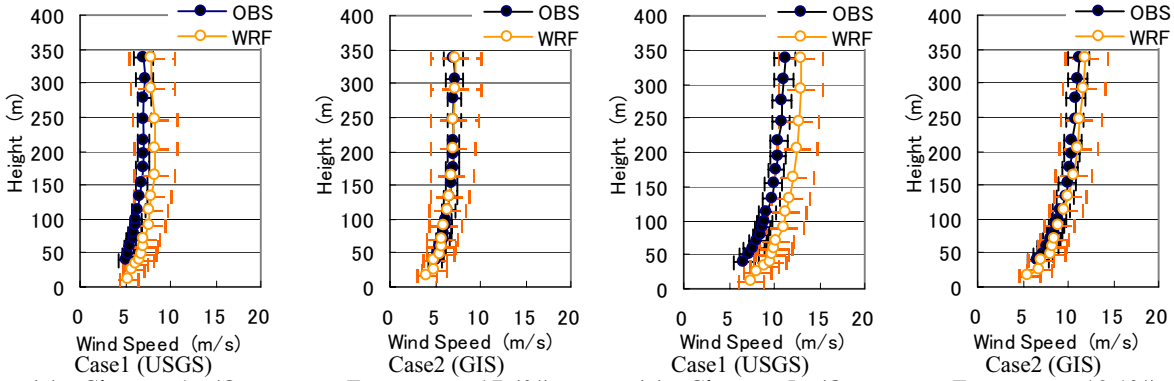
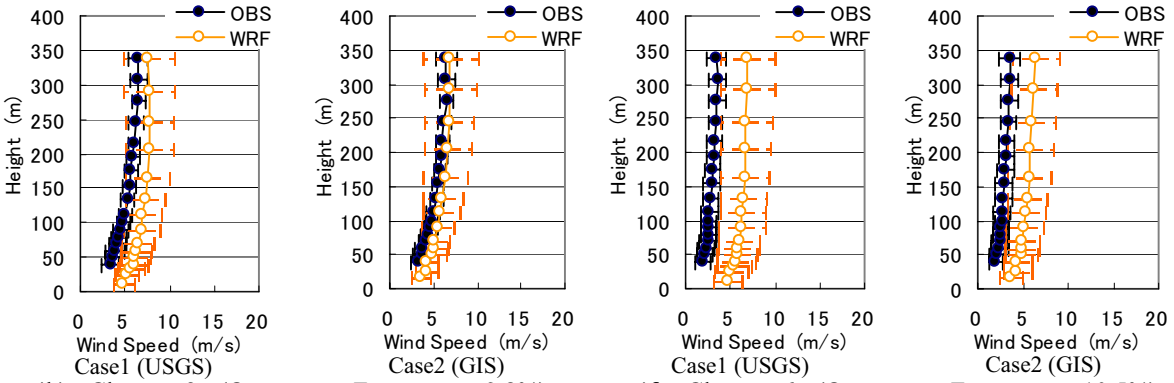
3.2 *Vertical Profiles for Mean Wind Velocities*

For this comparison, we firstly extracted southerly wind (wind direction=180° ±33° at 200m high) for both observation and calculation. Then the vertical profiles of wind velocity of the observation data were classified into eight clusters by cluster analysis. Corresponding clusters of calculated results were made so that each cluster at the same time of the observation data became the same cluster.

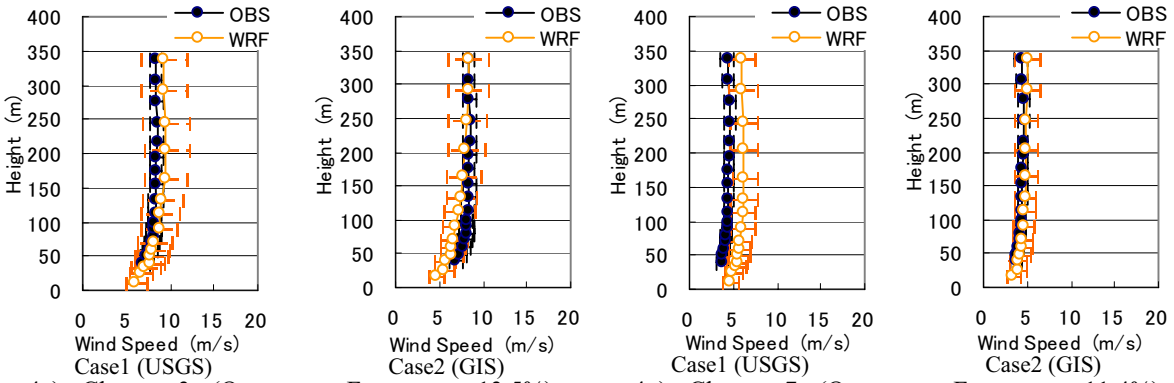
Figure 4 shows vertical profiles of wind velocities in the eight clusters. Averaged values ±1 σ (standard deviation) at each height in each cluster are plotted in the figures. The value shown in the caption for each cluster is the occurrence frequency for that cluster. Except for Figure 4f (Cluster 6), there is a pretty good match between observation and calculated results. In particular, Case 2 using GIS is remarkably close to the observation values. Case 1 using the default setting of USGS generally show higher values than the observation data. The calculated wind velocities for Case 6 do not correspond with observation data because Cluster 6 includes many data obtained during rainy weather. In both Case 1 and Case 2, during rainy weather the WRF calculation tends to produce a higher wind velocity than the observations.



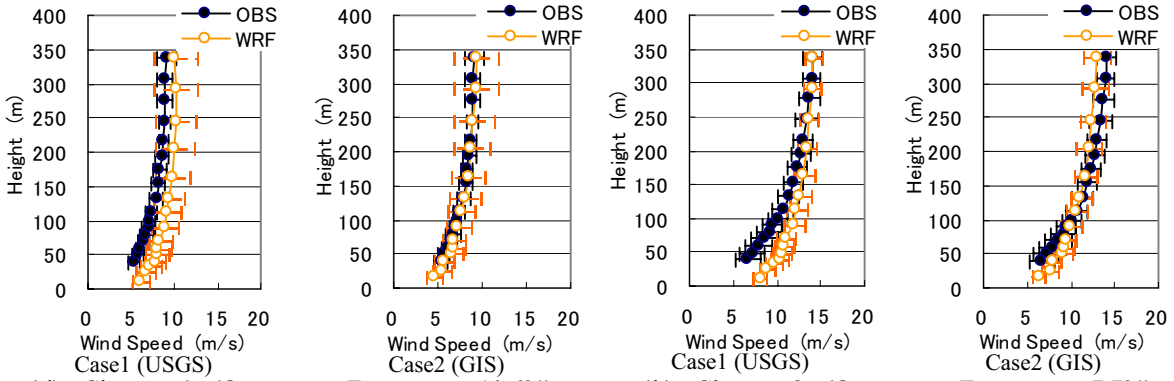
4a) Cluster 1 (Occurrence Frequency 17.4%) 4e) Cluster 5 (Occurrence Frequency 19.1%)



4b) Cluster 2 (Occurrence Frequency 9.8%) 4f) Cluster 6 (Occurrence Frequency 10.5%)



4c) Cluster 3 (Occurrence Frequency 13.5%) 4g) Cluster 7 (Occurrence Frequency 11.4%)



4d) Cluster 4 (Occurrence Frequency 10.6%) 4h) Cluster 8 (Occurrence Frequency 7.7%)

Figure 4: Vertical Profile of Mean Wind Speed

4 CONCLUSION

Two cases of WRF calculations were conducted using the default setting (Case1) and based on GIS-derived land-use categories and surface roughness lengths (Case2). The calculated results were compared with the observation data measured by Doppler Soda at Minami Senju. The calculated probabilities of exceedance of wind velocity at high altitude (especially Case2) corresponded very well with that of the observation. In addition, it was apparent that calculated vertical profiles of mean wind velocity of Case 2 were very close to those of the observation.

ABSTRACT: Structural damage resulting from strong winds associated with Typhoon Tokage (No. 23, 2004) was concentrated in Ogi City in Saga Prefecture located in northern Kyushu, Japan, even though Ogi City was more than 300 km from the typhoon's path. It may be because the winds that blow from mountains became stronger through the effect of downslope winds in stable conditions of the atmospheric layer. Here, we discuss our LES results of wind simulation in view of the effects of inflow wind profiles and grid resolutions. It was found that the simulated wind speeds became higher using the inflow winds experienced during the passing of Typhoon Tokage and the intensities of turbulence were larger using a fine domain resolution. It was confirmed that the results of the simulation help to explain how the convergence of wind speeds was affected by the local terrain and the weather conditions in Ogi City.

1 INTRODUCTION

Ten typhoons hit Japan in 2004. Figure 1 shows the paths of these typhoons and a close-up image of the routes of four typhoons that directly caused structural damage to the Kyushu area. Typhoon Tokage was unique because the associated damage was concentrated in Ogi City, which is located in Saga Prefecture in northern Kyushu, despite the fact that the city was more than 300 km away from the typhoon's path [1]. Residents in this region are familiar with the strong northwesterly winds that blow down from northern mountainous terrain every winter. The mountain-

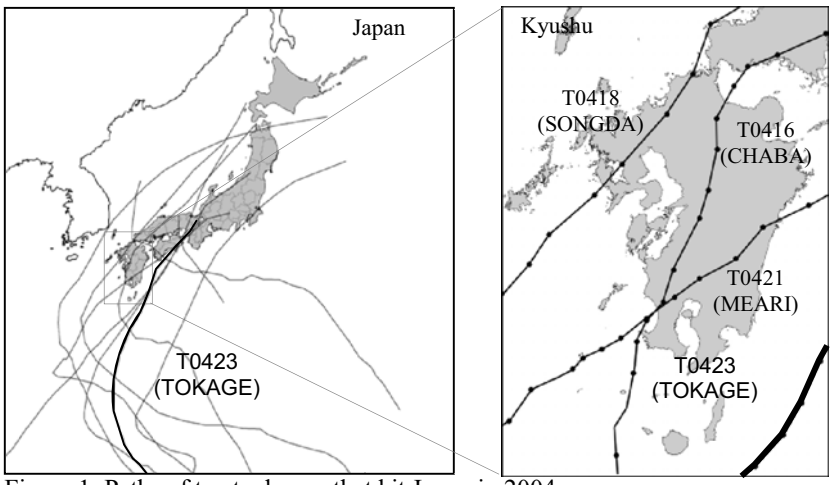

Figure 1. Paths of ten typhoons that hit Japan in 2004.

ous terrain of the area may have contributed to the strength of the northeasterly winds that were associated with Tokage. The authors focused on the effect of the mountainous terrain on the northerly winds blowing around Ogi City and examined the outbreak of strong winds during Typhoon Tokage using computational simulation. It is said that the atmospheric layer is in a neutral condition, when strong winds continue. However, the winds that blow from mountainous terrain may become stronger due to the effect of downslope winds in the stable conditions of the atmospheric layer. The effect of the upper atmosphere on strong downslope winds has been examined [2]. We have previously discussed the wind conditions in a neutral or stable condition of the atmospheric layer [3] and examined the effect of inflow wind profiles [4,5].

We are familiar with several CFD programs useful for carrying out local terrain analyses and wind assessment in and nearby urban areas. Although some attempts to predict hazardous strong winds over a wide area have been made in the past, few of them made use of records of observed strong winds.

In this paper, we discuss the effect of inflow wind profiles and grid resolutions on wind enhancement around Ogi City, where structural damage due to Typhoon Tokage was concentrated, using LES software [6] and refer to several sets of observed wind data gathered at NeWMeK sites [7].

2 FEATURES OF STRUCTURAL DAMAGE INFLICTED BY TYPHOON TOKAGE

Figure 2 shows the peak gust distributions found during Typhoon Tokage. Strong winds were measured around Ogi City in Saga Prefecture, which was located more than 300 km away from the typhoon's path. Figure 3 indicates the time evolutions of wind speed and direction measured

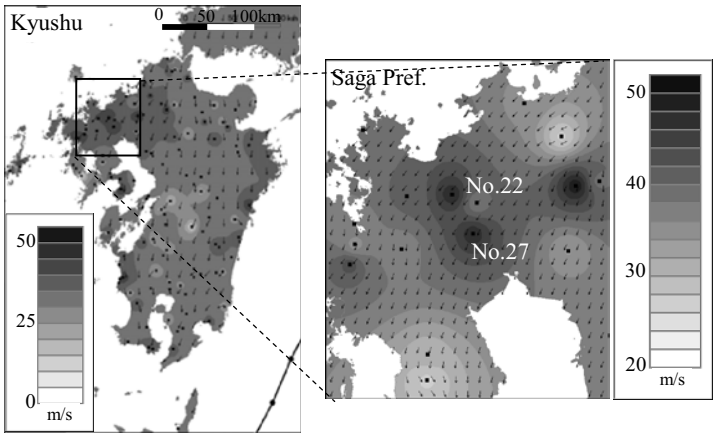

Figure 2. Peak gust distributions in Saga, Kyushu during Typhoon Tokage.

on October 20, 2004. The winds measured at NeWMeK observation point No. 27, located at the foot of the mountainous terrain, were stronger than those found at observation point No. 22.

Figure 4a illustrates the rate of residential damage experienced in Kyushu and in Saga Prefecture. As shown in the figure, structural damage was concentrated in Ogi City in Saga Prefecture. As indicated in Figure 4b, there is a shallow valley near the southward-facing slope of the mountains on the windward side of Ogi City. The concentration of structural damage found in this area may have resulted from the enhancement of strong winds by the mountainous terrain.

3 COMPUTATIONAL SIMULATION OF WIND FLOW USING LES SOFTWARE

We simulated the wind flows observed around Ogi City using LES software and NeWMeK data. In order to consider the significant details of complex terrain, the software employs a body-fitted coordinate grid system. The turbulence model uses large eddy simulation, and its governing equations are incompressible continuity equations and Navier-Stokes equations. The standard Smagorinsky model is applied to the sub-grid scale model.

The focal area was 18 km x 18 km x 5km, including the area of Ogi City, and is illustrated in Figure 5. Two computational domains using different grid resolutions were installed to compare simulated results. As shown in Figure 6a, the number of grid points in the x, y and z-directions for one domain was 91, 91 and 51 respectively. The other domain was divided into 161, 161 and 51 in the x, y and z-directions respectively, as indicated in Figure 6b. The buffer

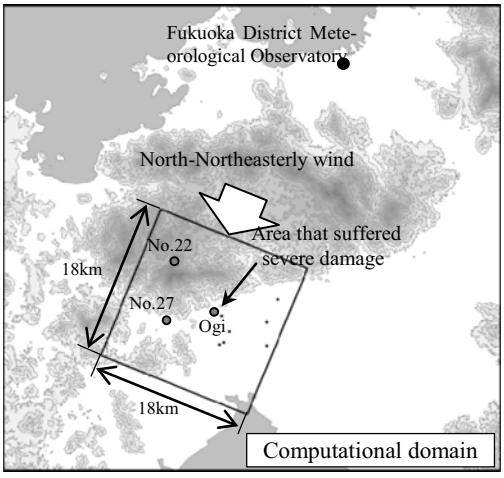

Figure 5. Focal area of simulation.

domain located in front of the inflow boundary was divided into 20, and the domain located behind the outflow boundary was divided into 10 for the purpose of making calculations under stable conditions. The minimum distance between grid points in the z-direction was approximately 3 m. The altitudes of the terrain were calculated based on a digital 50m-grid map provided by the Geographical Survey Institute. It was estimated that the wind blew from the north-northeast during the typhoon. The boundary conditions were as follows: an outflow based on the convection boundary condition, the free-slip condition for top and side boundaries, and the non-slip condition for ground and an inflow wind corresponding with the wind profile. No roughness was specified at ground level.

Two inflow wind profiles were used in this study. One of the inflow wind profiles was defined by the power law, using a power index of 1/7. The other was based on information gathered through upper-air observations carried out at the Fukuoka District Meteorological Observatory when Typhoon Tokage hit Kyushu. Figure 7 shows information about wind direction and wind speed that was gathered during the upper-air observations. The profiles of inflow wind in the following simulations were modified as shown in Figure 8. The Reynolds number was set at 10^4. The Froude number was set at 1000 to suit a neutral condition. The computation time unit was 0.002 seconds and the number of calculations was 20,000. The results of the second half of the calculations are discussed in the following section.

The results of the simulation were converted to actual scale using the maximum mean wind speed of 21.5 m/s, which was measured at observation point No. 22. We compared the simulated results under four different conditions as listed in Table 1.

Table 1. Simulation parameters.

4 RESULTS AND DISCUSSIONS

4.1 *Flow patterns for simulated winds*

Figure 9 shows the flow patterns for the simulated mean wind speeds at a height of about 10 m; charts a, b, c, and d illustrate the flows corresponding to the respective cases of Table 1. Each arrow in the figure indicates the vector of wind found at each focal point. The shallow valley was located to the windward side of the Ogi area which experienced severe damage. We found that winds converged here due to the mountainous terrain. The distributions of mean wind speeds at the foot of the mountainous terrain varied due to each condition resulting from the numerical resolutions and the wind profiles used in these simulations. As we compared Figures 9a and 9b using the coarse grid of 91 x 91, the wind speeds that were calculated based on inflow wind profiles during Typhoon Tokage were higher than those simulated using only the power index of 1/7, particularly in a plain to the east of the focal point, Ogi. The wind speeds resulting from the fine grid as shown in Figure 9c were higher than those using the coarse grid as indicated in Figure 9a using the same inflow based on the power index of 1/7. As shown in Figure 9d, the winds which were calculated based on inflow wind profiles during Typhoon Tokage using the fine grid of 161 x 161 converged markedly due to the shallow valley near the southward-facing slope of the mountainous terrain and a strong wind area was produced in the southeast of the focal point, Ogi.

Figures 10, 11 and 12 show the flow patterns of simulated mean wind speeds at the vertical section including observation points No. 22 and No. 27, and the focal point, Ogi. The locations of each section are shown in Figure 9a. As shown in Figure 10, the wind speed distributions on the leeward side of the mountainous terrain differ considerably depending on domain resolutions and inflow profiles. However, wind speeds at No. 22 located on the windward side of the moun-

tainous terrain are almost the same. Figures 11a and 12a indicate that the mean wind speeds were small at the foot of the mountainous terrain when inflow winds based on the power law were used in the coarse grid. Figures 11c and 12c illustrate that wind speeds become larger when using finer divisions. On the other hand, the mean wind speeds shown in Figures 11b and 12b were larger at observation point No. 27 and the focal point, Ogi, when we used the profiles of inflow winds based on upper-air information associated with Typhoon Tokage in the coarse grid of 91 x 91. As shown in Figures 11c and 12c, wind speeds became larger near observation point No. 27 and the Ogi area when using the finer division. Figures 11d and 12d illustrate that when inflow winds resulting from the typhoon were used, the simulated wind speeds became much larger at the foot of the mountainous terrain. As indicated in Figures 11b and 11d, it was found that the simulated winds flowed along the surface of the mountainous terrain at observation point No. 27 using the inflow winds during the typhoon. Similarly, as illustrated in Figures 10b and 10d, the simulated winds flowed along the surface of the ground around Ogi. As a result, the mean wind speeds at the foot of the mountainous terrain were significantly larger when inflow winds based on Typhoon Tokage were used.

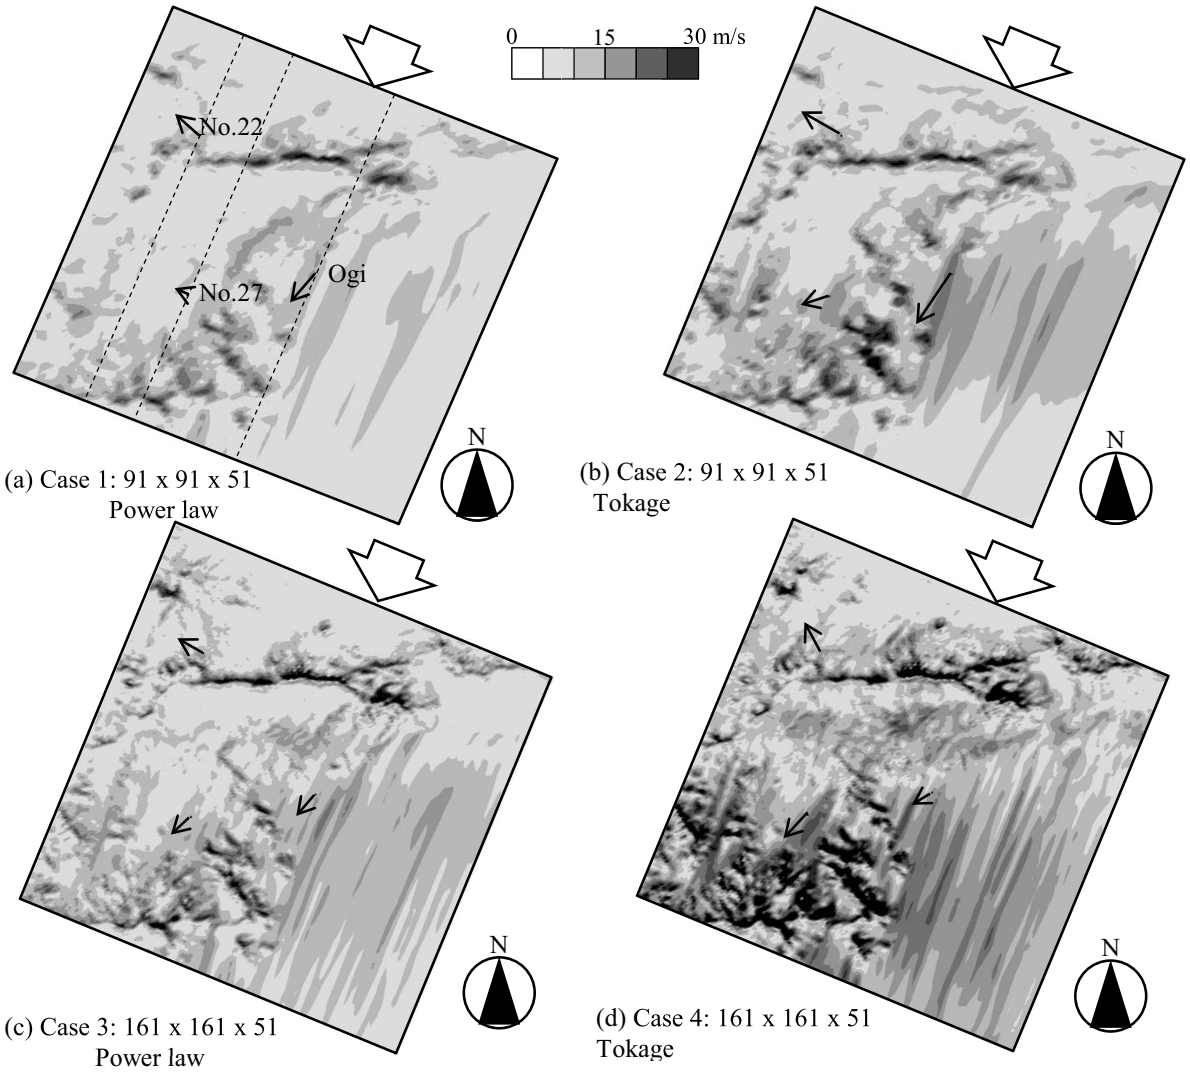

Figure 9. Flow patterns of simulated mean wind speed at a height of about 10m in square area of Figure 5.

4.2 *Simulated winds at observation points*

Table 2 describes mean wind speeds and directions, intensities of turbulence, and simulated peak gust speeds found at each focal point. The simulated wind speeds at the levels of 51m and 18m are shown in the table. These levels are the heights at which anemometers were installed. The intensities of turbulence are larger in the finer grid at both observation points. In particular, intensity of turbulence became large at No. 22 located at the summit of the mountainous terrain, using the profiles of inflow winds associated with Typhoon Tokage in the fine resolution.

Figure 13 indicates the recorded measurements and the numerical results at observation point No. 22. Charts a, b and c in Figure 13 include mean wind speed and direction profiles, and time evolutions of wind speeds and directions. The time scale of numerical computation was changed using the following formula.

$$t^* = \frac{\bar{t}}{H/U}$$

Here, the reference height H is 1,024m, the height of the mountain where observation point No. 22 was located, and the representative wind speed, U is 21.5 m/s recorded at observation point No. 22. The simulated time unit t* = 0.002 seconds, represents real time of approximately 1 second. Although the observed mean wind direction of wind during Tokage was northeast at observation point No. 22, the simulated winds blew from the east-northeast. Even though we expected that the simulated mean wind directions would correspond with the measured wind direction, the simulated directions disagreed with the measured value at No. 22. As shown in Figure 13c, although wind speed changed gradually in the simulation, high-frequency waves were not generated. Simulated maximum wind speed was 27.7 m/s in the coarse grid when inflow winds were based on the power law, and simulated speed was 28.9 m/s using the fine grid. Calculated maximum value was 30.4 m/s in the grid divided into 91 x 91, using inflow winds based on Typhoon Tokage, and speed was 38.2m/s in the grid divided into 161 x 161. Mean wind speeds, peak gust speeds, and intensities of turbulence recorded in the 10 minutes after 12:50 on Oct. 20 2004 are listed in Table 3. Peak gust speed of 34.2m/s at No.22 was observed during the period.

Figures 14a, b and c indicate mean wind speed and direction profiles, and time evolutions of wind speeds and directions at No. 27. Table 3 shows that mean wind speed was 23.8 m/s and

the mean wind direction at that time was north-northeast at No. 27 at the foot of the mountainous terrain. As shown in Figure 14a, mean wind speeds became larger in the case of the fine grid than the coarse grid. And mean wind speeds using inflow profiles during Typhoon Tokage were larger than using inflow winds based on the power law. Figure 14b shows that winds blew from the northeast and simulated wind directions corresponded with observed values. As indicated in Figure 14c, calculated wind speeds and directions were not able to generate fluctuations as large as those observed. But wind speed fluctuations were larger in the fine grid than in the coarse grid. Intensities of turbulence using the fine resolution are shown in Table 2. Simulated maximum wind speed when inflow winds were based on the power law was 31.9 m/s in the coarse grid, and 42.3 m/s in the fine grid. Calculated maximum value using inflow winds based on Typhoon Tokage was 15.9 m/s in the coarse grid, and 29.3m/s in the fine grid. Observed maximum value was 43.5 m/s at No. 27.

As a result, wind speeds in the simulation fluctuated greatly, using inflow winds based on upper-air information associated with Typhoon Tokage when compared with using inflow winds based on the power law. Based on these results, it seems that calculated wind speeds in the case based on the inflows associated with Typhoon Tokage corresponded to the observed values. Moreover, although high-frequency winds like those observed could not be generated in this calculation, intensities of turbulence became much larger using the fine calculation domain. Consequently, it seems that calculated peak gust speeds using the fine resolution corresponded more closely to actual observed values.

5 CONCLUSIONS

Residential damage due to strong winds associated with Typhoon Tokage (T0423) was concentrated in a specific small area around Ogi City, Saga Prefecture, which has mountainous terrain on the windward side. The flow patterns of wind speed around Ogi City were numerically simulated under two profiles of inflow winds. One of the profiles was defined by the power law and the other was based on upper-air observations measured by a nearby meteorological station. We compared CFD analytical results with coarse and fine grid resolutions in the target area using LES model simulation software. The following features were found:

1 The winds ran along the surface of the mountainous terrain and much stronger winds hit Ogi City when the measured inflow wind profile during Typhoon Tokage was used.
2 A strong wind area was produced in the southeast of the Ogi area based on the inflow winds associated with Typhoon Tokage.
3 Although fluctuating winds corresponding to the observed winds could not be generated using the LES computational technique in this study, the intensity of turbulence became larger using the fine resolution grid.
4 It seems that the calculated peak gust speeds using the fine resolution and the observed wind profile corresponded more closely to actual observed values.
5 The upper-air conditions resulting from the typhoon may also have played a role in causing the outbreak of much stronger winds.

ABSTRACT: Tornado-like vortices have been investigated by using LES turbulence model. The flow fields are visualized by virtual water vapor injected from the ground of the numerical model and the evolution from a single-celled vortex into a multi-vortex configuration is successfully reproduced. The flow fields as well as the force balance of four typical tornado configurations, weak vortex, vortex breakdown, vortex touch-down and multi-vortex are investigated. The definitions for the swirl ratio are summarized and the local corner swirl ratio is found to be robust and proposed to universalize the researches.

KEYWORDS: Tornado-like vortex, Swirl ratio, Flow fields, LES, CFD simulation.

1 INTRODUCTION

Tornadoes are one of the severe natural phenomenons and considered as the most violent storm on earth, which makes it important to take proper consideration of tornado-induced wind loads and tornado-borne missiles for wind resistant design of structures. Therefore, detailed information of the three-dimensional flow fields is necessary. Many researchers are motivated to observe the wind dynamics and collect the data in real tornadoes by using velocity and pressure instrumentation. However, due to the extreme danger faced by the observers, data collection for tornado's internal flow fields is still not much of a success. Reproducing tornadoes experimentally or numerically is therefore an alternative.

Laboratory simulations provide a safe, reproducible and controllable approach for the tornado-related researches. Mitsuta and Monji (1984) modified the simulator to provide the circulation by four small fans installed in the circulation chamber. Transition of a vortex from a one-cell to two-cell structure occurred throughout the whole convergence layer in their simulator. Haan et al. (2008) developed a large laboratory simulator with guide-vanes at the top to make the translation of the tornadoes reproducible. Most recently, Tari, P.H. et al. (2010) quantified both the mean and turbulent flow fields for a range of swirl ratios spanning from F0 to F2 scale by using the Particle Image Velocimetry (PIV) method. However, in view of the limitation of observation methods and the extremely complicated flow fields near the ground, it is difficult to make detailed three-dimensional measurements in the boundary layer which has been universally believed to be the most important region in the tornado-like vortices.

Recently, with the advancement in the computer technology, many numerical studies have been conducted. Nolan and Farrell (1999) explored the dynamics of axisymmetric tornado-like vortices. The internal swirl ratio as well as the vortex Reynolds number was defined. D.C

Lewellen et al. (2000) explored some tornado structures being expected to occur in nature. They defined the local corner swirl ratio and proposed the existence of a critical swirl ratio, at which the largest swirl velocity occurs very close to the ground. Ishihara et al. (2011) used LES turbulent model to simulate the flow fields of two types of tornado-like vortices and validated the model by comparing with laboratory simulators. The formation of one-cell and two-cell type vortices were investigated by examining axisymetric time averaged Navier-Stokes equations. However, among all the simulators the definition for the swirl ratio is not uniform and varies from one to another.

In this study, a numerical model representing the Ward-type tornado simulator is built and four typical types of tornado vortices are examined. The details of this model and the case settings are introduced in section 2 including its dimension, grid distribution and boundary conditions. In section 3 the three-dimensional flow fields as well as the force balance is provided. Section 4 proposes a universal definition of swirl ratio to unify the researches.

2 NUMERICAL MODEL

2.1 *Governing equations*

The governing equations employed in LES model are obtained by filtering the time-dependent Navier-Stokes equations as follows:

$$\frac{\partial \rho \tilde{u}_i}{\partial x_i} = 0 \tag{1}$$

$$\frac{\partial}{\partial t}(\rho \tilde{u}_i) + \frac{\partial}{\partial x_j}(\rho \tilde{u}_i \tilde{u}_j) = \frac{\partial}{\partial x_j}\left(\mu \frac{\partial \tilde{u}_i}{\partial x_j}\right) - \frac{\partial \tilde{P}}{\partial x_i} - \frac{\partial \tau_{ij}}{\partial x_j} \tag{2}$$

where $\tilde{u}_i$ and $\tilde{p}$ are filtered mean velocity and filtered pressure respectively. ρ is density, τ_{ij} is subgrid- scale stress and is modeled as follows:

$$\tau_{ij} = -2\mu_t \tilde{S}_{ij} + \frac{1}{3}\tau_{kk}\delta_{ij}, \quad \tilde{S}_{ij} \equiv \frac{1}{2}\left(\frac{\partial \tilde{u}_i}{\partial x_j} + \frac{\partial \tilde{u}_j}{\partial x_i}\right) \tag{3}$$

where μ_t is subgrid-scale turbulent viscosity, and $\tilde{S}_{ij}$ is the rate-of-strain tensor for the resolved scale.

Smagorinsky-Lilly model is used for the subgrid-scale turbulent viscosity,

$$\mu_t = \rho L_s^2 \left|\tilde{S}\right| = \rho L_s \sqrt{2\tilde{S}_{ij}\tilde{S}_{ij}}, \quad L_s = \min\left(\kappa\delta, C_s V^{1/3}\right) \tag{4}$$

where L_s is the mixing length for subgrid-scales, κ is the von Karman constant, 0.42, C_s is Smagorinsky constant, δ is the distance to the closest wall and V is the volume of a computational cell. In this study, C_s is determined as 0.032 based on Oka and Ishihara (2009).

When a wall-adjacent cell is in the laminar sublayer, the wall shear stress is obtained from the laminar stress-strain relationship as follows:

$$\frac{\bar{u}}{u_\tau} = \frac{\rho u_\tau y}{\mu} \tag{5}$$

If the mesh cannot resolve the laminar sublayer, it is assumed that the centroid of the wall-adjacent cells fall within the logarithmic region of the boundary layer, and the law-of-the-wall is employed:

$$\frac{\bar{u}}{u\tau_{\tau}} = \frac{1}{k}\ln E\left(\frac{\rho u_{\tau} y}{\mu}\right) \tag{6}$$

where $\bar{u}$ is the filtered velocity tangential to wall, u_{τ} is the friction velocity and the constant E is 9.793.

2.2 *Configurations and solution scheme*

In this study, a Ward-type simulator (Ward et al. 1972) is chosen and numerically simulated. The configurations of the numerical model are shown in Figure 1(a). Two significant geometry parameters are the height of the inlet layer, h, and the radius of the updraft hole, r_o, which are 200mm and 150mm respectively. The velocity profiles at the inlet are specified as below:

$$\begin{cases} U_{rs} = U_1\left(\dfrac{z}{z_1}\right)^{\frac{1}{n}} \\ V_{rs} = -U_{rs}\tan(\theta) \end{cases} \tag{7}$$

where, U_{rs} and V_{rs} are radial velocity and the tangential velocity at $r=r_s$, n equals to 7, the reference velocity U_1 and the reference height z_1 are set to 0.24m/s and 0.01m respectively through matching the velocity profile in the previous study by Ishihara et al. (2011), and θ is the degree of the inflow angle.

Considering the axisymmetry of tornado-like vortex, an axisymmetric topology method is adopted, see Figure 1(b). With an intent to investigate the turbulent features quantitatively in the vicinity of the center and the region near the ground, very fine mesh is considered in the convergence region. The total mesh number is about 7.8×10^6. Table 1 summarizes the parameters for the mesh and the system of the PC cluster used in this study.

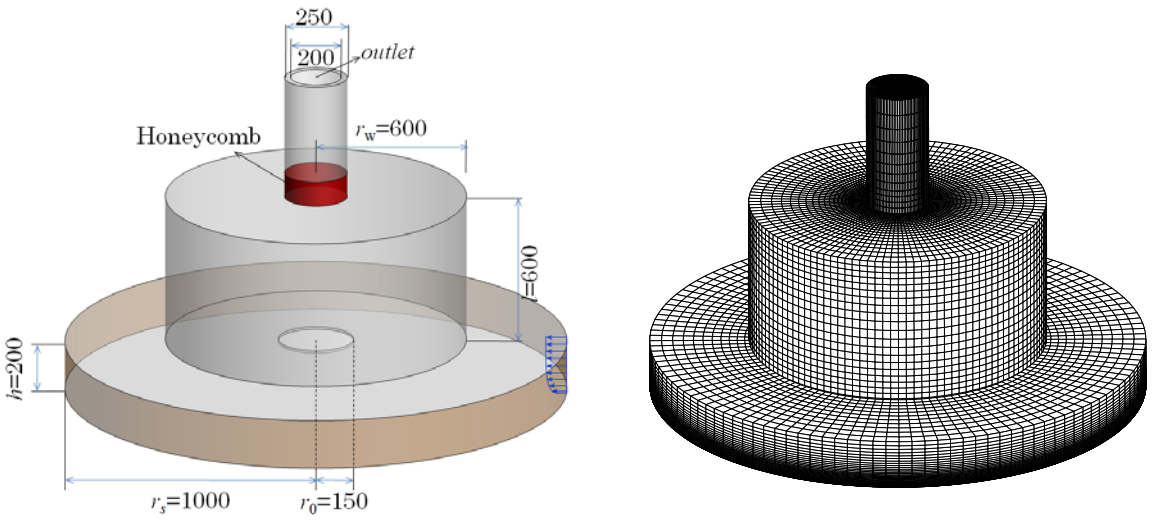

Figure 1. Geometry(a) and mesh(b) of the model.

Table 1. Parameters for the mesh and the system of PC cluster

Mesh size in the radial direction	1.0～25.0mm
Mesh size in the vertical direction	0.1～5.0mm
Mesh number	784200
CPU	Athlon 64 Processor3200, 2.01GHz
Number of nodes	8
CPU time for the case of S=2.44	150h

Finite volume method is used for the present simulations. SIMPLE (semi-implicit pressure linked equations) algorithm is employed for solving the discritized equations (Ferziger and Peric, 2002). The pressure at inlet of the convergence region is set to zero, and velocity at the outlet (0, 0, W_0) is given as (0, 0, 9.55m/s) to generate upward flow in the tornado. Three velocity components and the pressure are set as zero for the initial conditions.

2.3 *Swirl ratio definitions and Case settings*

In both the laboratory and the numerical simulators, a correlation has been found between the vortex structure and the swirl ratio. Various definitions for the swirl ratio have been proposed in the previous studies.

The swirl ratio has historically been defined as the ratio of angular momentum to radial momentum in the vortex, and expressed in the following forms:

$$S_{out}=\frac{\Gamma_\infty r_0}{2Qh},\ S_{out}=\frac{\Gamma_\infty}{2Qa}\ \text{and}\ S_{out}=\frac{\tan\theta}{2a} \tag{8}$$

where, $\Gamma_\infty$is the circulation at the outer edge of the convergence region, $\Gamma_\infty=2\pi r_s h V_\infty$, and a is the aspect ratio, $a=h/r_0$. In case the circulation is imposed by using guide vanes instead of rotating screen, the ratio of the circulation rate to the volume flow rate can easily be replaced by tanθ, where θ is the angle of the guide vanes.

In ISU tornado simulator by F. L. Haan Jr.(2008) the swirl ratio is specifically modified as:

$$S=\frac{r_c\Gamma_c}{2Qh}=\frac{r_c(2\pi r_c V_c)}{2Q}=\frac{\pi r_c^2 V_c}{Q} \tag{9}$$

in which, the circulation, Γ_c, is estimated using the multiplication of the maximum tangential velocity, V_c, and r_c, $\Gamma_c=2\pi r_c h V_c$, r_c is radius of maximum tangential velocity, V_c, in the quasi-cylindrical region.

D.C. Lewellen(2000) proposed a local corner flow swirl ratio, S_c. The specific form of the local corner flow swirl ratio is:

$$S_c=\frac{r_c^*\Gamma_\infty^{*2}}{\Upsilon} \tag{10-a}$$

in which, r_c^* is the characteristic length scale, calculated as $r_c^*\equiv\Gamma_\infty^*/V_c$, $2\pi\Gamma_\infty^*$ is the circulation per unit height in the outer region expressed as $2\pi\Gamma_\infty^*=2\pi V_\infty r_\infty$, Υ is the total depleted circulation flux flowing through the corner flow region, expressed as:

$$\Upsilon\approx 2\pi\int_0^{r_2} W(r,z_2)\,\Gamma_d(r,z_2)\,r\,dr \tag{10-b}$$

where, Γ_d is the depleted angular momentum and defined as $\Gamma_d=\Gamma_\infty-Vr$, r_2 is the radius safely outside of the upper-core region, z_2 is the height just above the corner flow.

Table 2. Case settings and accompany tornado vortex parameters.

Case	θ (°)	S_{out}	S	S_c	Re	Q(m^3/s)	V_c (m/s)	r_c (m)
Case1	46.8	0.4	0.02	0.71	1.6×10^5	0.30	10.72	0.014
Case2	58.0	0.6	0.06	1.59	1.6×10^5	0.30	9.84	0.024
Case3	64.9	0.8	0.12	2.36	1.6×10^5	0.30	9.11	0.035
Case4	69.4	1	0.23	2.93	1.6×10^5	0.30	9.62	0.047
Case5	76.0	1.5	0.34	4.16	1.6×10^5	0.30	10.99	0.054

Notes:

- Case1, Case2, Case4 and Case9 are four typical types of tornado configuration and are chosen for detailed flow field analysis.
- Previous case is the simulation carried out by Ishihara (2011).

In this study, the swirl ratio is increased through increasing the inflow angle. Nine cases are calculated systematically. The case settings as well as tornado vortex parameters for each case are illustrated in Table 2, in which Re is the Reynolds number defined as $Re=W_0D/\upsilon$, $D=2r_0$. It can be found the swirl ratio S_{out} tends to have a larger value compared with S. On the other hand, the local corner swirl ratio S_c shows the maximum value for the same corner flow pattern.

3 FLOW FIELDS CHARACTERISTICS

It is necessary to make the air flow visible and evaluate the vortex in a qualitative manner. For this purpose virtual water vapor is selected as the visualizing substance injected from the bottom of the model. The particles are not released until the flow fields are in the quasi-steady stage to eliminate the effect of the transit field solution.

As the value of the swirl ratio is increased, the vortex goes through various stages, as depicted in Figure 2. When S=0.02, we find the central core to have a smooth, laminar appearance. The core extends upward from the surface to the high elevation spreading radially slightly with height, shown in Figure 2(a). For S=0.06, a "vortex breakdown" occurs where the flow transitions from a tight, laminar vortex to a broader, turbulent state, see Figure 2(b). At S=0.23, the radius of the vortex core increases and the altitude of the breakdown decreases, as shown in Figure 2(c). The vortex breakdown is just above the boundary layer. A still further increase in swirl ratio to S=2.44 results in the breakdown being forced further toward the surface layer, see Figure 2(d). The core of the vortex expands substantially, leaving a relatively calm inner subcore. Concurrent with the expansion of the core the inner downflow penetrates to the lower surface, and in this particular snapshot, a family of several secondary vortices rotating about the main vortex is evident.

3.1 *Mean flow fields*

Quantitative analysis can be achieved by examining the distributions of the mean velocity components. In the following discussion, the maximum tangential velocity in the cyclostrophic balance region, V_c, will be used to normalize the flow fields. The radial distance is normalized by the core radius of the tornado vortex in cyclostrophic balance region, r_c.

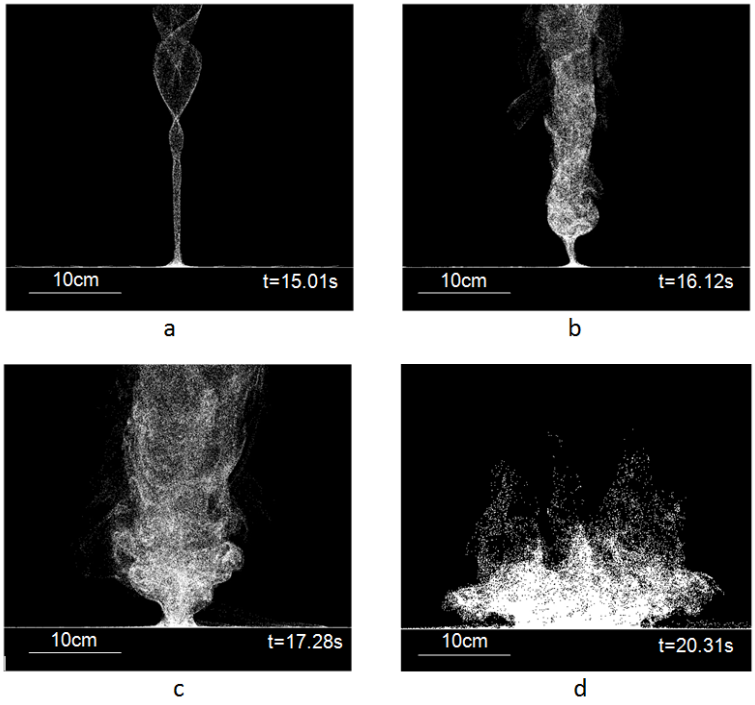

Figure 2. Flow visualization by injecting water vapor from the ground for four typical types of tornado-like vortices, (a) weak vortex, S=0.02, (b) vortex breakdown, S=0.06, (c) vortex touch-down, S=0.23, (d) multi-vortex, S=2.44.

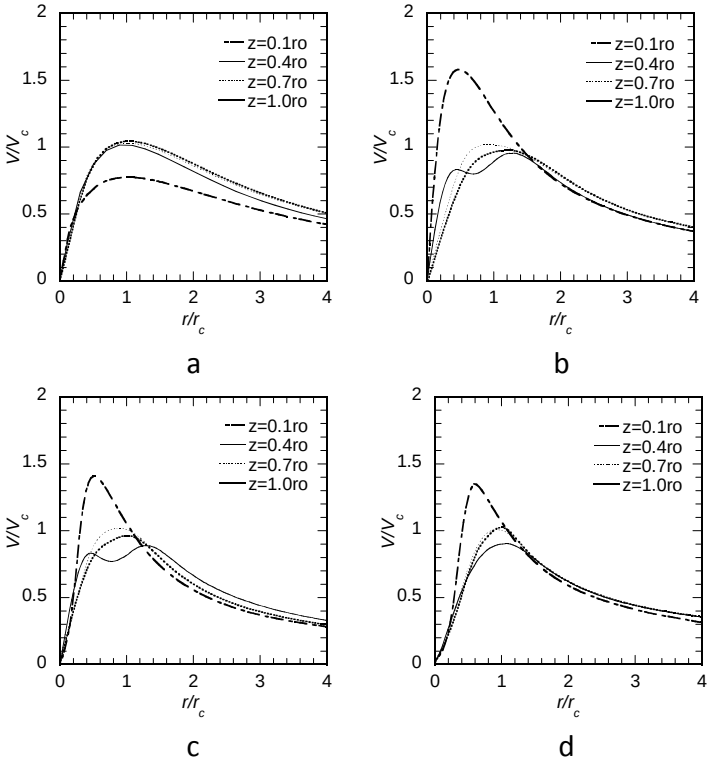

Figure 3. Radial profiles of the normalized tangential velocity for four typical types of tornado-like vortices, (a) weak vortex, S=0.02, (b) vortex breakdown, S=0.06, (c) vortex touch-down, S=0.23, (d) multi-vortex, S=2.44.

The radial profiles of the mean tangential velocity, V, versus nondimensional radial distance are shown in Figure 3(a). For the very low swirl ratio case, S=0.02, the mean tangential velocity field is apparently one dimensional except the layer very near the ground. The core radius, R, defined based on the location of the maximum tangential velocity at each elevation, is almost consistent. For S=0.06, the swirl overshoot appears at the surface layer with maximum tangential velocity being 1.6 times of V_c, and the core radius increases from $0.5r_c$ to $1.0r_c$ with height forming a funnel shape. Further increasing the swirl ratio to the stages of touch-down and multi-vortex, the ratio of maximum swirl velocity, V_{max}, to V_c is nearly a constant, varying in between 1.3 to 1.5, and the radial location of V_{max} changes very slightly, holding about $0.5r_c$.

3.2 *Force balances analysis*

The contributions from each term in Navier-Stokes equation can be calculated by force balances analysis. Ishihara, T. (2011) investigated the force balances of two typical stages by using the time-averaged axisymmetric Navier-Stokes equations. However, a systematic cross comparison for the force balances in various types of vortices is limited and deserved to be studied.

The time-averaged radial Navier-Stokes equation can be expressed as:

$$U\frac{\partial U}{\partial r}+W\frac{\partial U}{\partial z}-\frac{V^2}{r}=-\frac{1}{\rho}\frac{\partial P}{\partial r}-\left(\frac{\partial u^2}{\partial r}+\frac{\partial uw}{\partial z}-\frac{v^2}{r}+\frac{u^2}{r}\right)+D_u \tag{11}$$

The left hand side consists of the radial advection term, A_{ru}, the vertical advection term, A_{zu}, as well as the centrifugal force term, C_r. The right hand side of the equation is the radial pressure

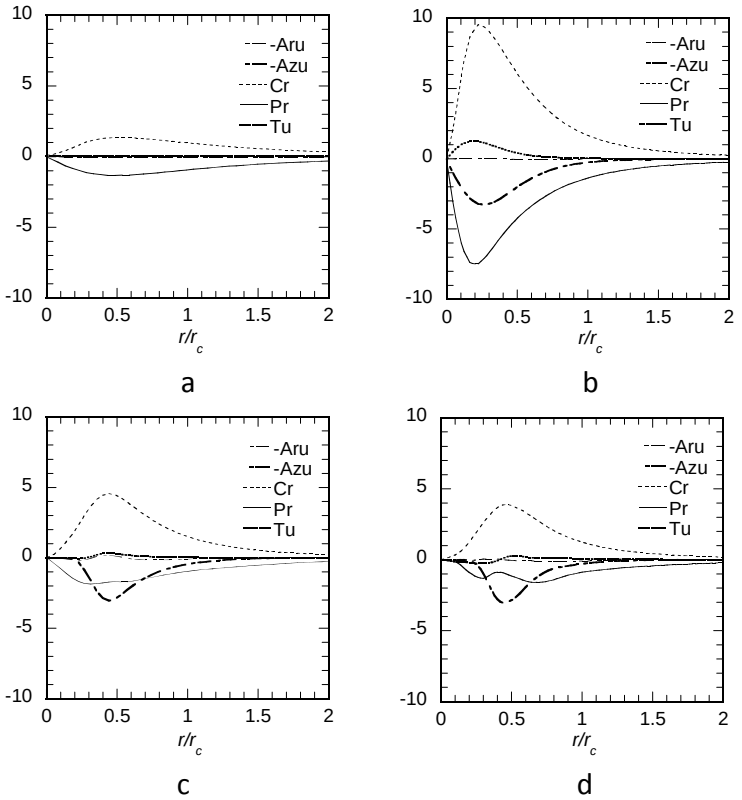

Figure 4. Radial force for four typical types of tornado-like vortices, (a) weak vortex, S=0.02, (b) vortex breakdown, S=0.06, (c) vortex touch-down, S=0.23, (d) multi-vortex, S=2.44.

gradient term, P_r, turbulent force term, T_u, and the diffusion term, D_u. The diffusion term, D_u, in the equation is small enough to be ignored compared with the other terms. u,v,w are root mean squares of the radial, tangential and vertical velocities.

Due to the slight change for the height of maximum tangential velocity, the terms in the radial momentum equations are computed at z=0.1r_o as a function of r/r_c for all the four stages, as shown in Figure 4. Examination of Figure 4(a) reveals that turbulence plays little role for weak vortex stage in the radial momentum balance. The centrifugal term and pressure gradient term are the significant portion of the total balance. Increasing the swirl to S=0.06, the flow evolves from laminar vortex to a turbulent state, followed by a significant change of the radial balance, as shown in Figure 4(b). The principle balance is in between the centrifugal term, pressure gradient term, turbulent term and vertical advective term. The emergence of the turbulent term is the manifestation of the unsteadiness of the flow fields. Figure 4(c) displays the terms in the radial balance for the case of vortex touch-down. The centrifugal term is mainly balanced by the pressure gradient term as well as the vertical advective term. However, different with the state of vortex breakdown, in some region the vertical advection term becomes more important than the pressure gradient term. Radial force balance for multi-vortex is presented in Figure 4(d), which is almost coincident with that for vortex touch-down.

4 PERFORMANCE OF LOCAL CORNER SWIRL RATIO

A pictorial approach is adopted to show how the surface intensification and the shape of the vortices change with the swirl ratio S_c, as illustrated in Figure 5, where U_{min} is the minimum averaged radial velocity, V_{max} is the maximum averaged tangential velocity, W_{max} is the maximum vertical velocity, r_{vmax} and h_{vmax} are the radius and height of the location of the maximum tangential velocity respectively. The parameters V_{max}/V_c, $-U_{min}/V_{max}$, W_{max}/V_{max} and the ratio of r_{vmax} to h_{vmax} are examined. The results of this study will be compared with the previous laboratory-scale numerical study by Ishihara et al. (2011) and the full scale numerical study by Lewellen et al. (2000). It is worth to be mentioned that the methods to obtain the angular momentum are different from one to another. In the previous study by Ishihara et al. (2011), the azimuthal momentum of the inflow is imposed by guide vanes, while in the present 8 cases the circulation is obtained directly from the velocity profile at the inlet boundary. For the full scale numerical model by Lewellen et al. (2000), the boundary condition is obtained from an inner nest of a thunderstorm simulation.

The ratio of the maximum averaged swirl velocity, V_{max}, to the maximum averaged swirl velocity in the upper cyclostrophic region, V_c, as a function of the local corner swirl ratio is demonstrated in Figure 5(a). Examining the set of present cases, the ratio increases sharply from the very low swirl ratio until S_c equals to around 1.6 where the pattern of vortex breakdown occurs and the distinct peak ratio reaches to about 1.7. For increasing the swirl ratio, the ratio of V_{max} to V_c decreases moderately and at last becomes almost a constant varying the values in between 1.3 and 1.5.

Figure 5(b) shows the ratio $-U_{min}/V_{max}$ as a function of the local corner swirl ratio. This ratio increases suddenly from the state of weak vortex, however, it is obvious that, except the very low swirl cases, $-U_{min}/V_{max}$ is insensitive to the swirl ratio and all the data are scattered about a central value 0.65. This near consistency is the indication of the dependency between the low-level radial overshoot and the swirl overshoot.

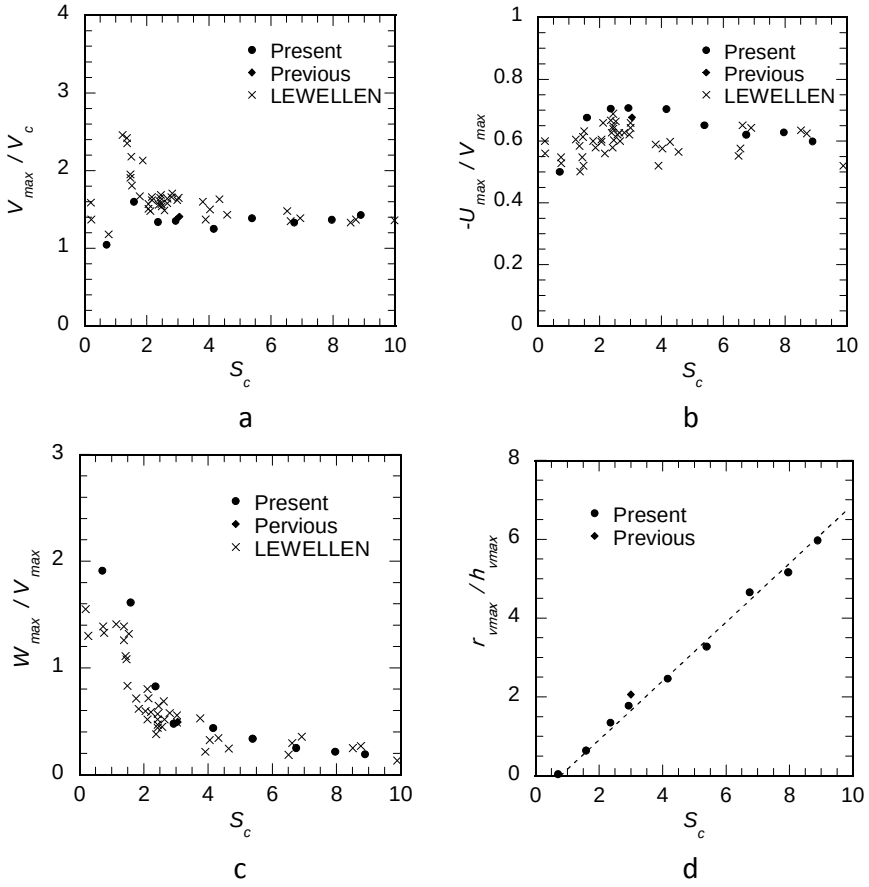

Figure 5. Summery surface intensification and the geometry of tornado vortices as a function of local corner swirl ratio, (a) the ratio of V_{max}/V_c, (b) the ratio of $-U_{min}/V_{max}$, (c) the ratio of W_{max}/V_{max} and (d) the aspect ratio of r_{vmax}/h_{vmax}.

The ratio W_{max}/V_{max} shows the maximum value, about 1.9, at the stages with very low swirl ratios, and decreases with increasing the swirl ratio, as demonstrated in Figure 5(c). The maximum vertical velocity is larger than the maximum tangential velocity until the vortex reaches to the touch-down state, after which the near consistency for the ratio W_{max}/V_{max} is observed with a central value of about 0.4.

A vortex aspect ratio defined as the ratio of r_{vmax} to h_{max} is applied to evaluate the structure of the flow in the vortex corner. As observed in Figure 5(d), the vortex aspect ratio increases linearly with S_c having a slope of about 0.7.

The values of V_{max}/V_c, $-U_{min}/V_{max}$ and W_{max}/V_{max} as a function of local corner swirl ratio obtained in Lewellen et al. (2000) and Ishihara et al. (2011) are also shown for comparison. Even though the present, previous and Lewellen's cases use different numerical models to generate the vortices, it is obvious that the results from different models exhibit the universally same tendencies. Therefore it can be argued that it is reasonable to universalize the researches by using the local corner swirl ratio.

5 CONCLUSIONS

The flow fields as well as the force balances of tornado-like vortices have been investigated by using the LES turbulent model in this study. Following summarizes the conclusions.

1. The visualized flow fields by the injected water fog from the ground successfully show the evolution from a single-celled vortex into a two-cell vortex configuration containing multiple subsidiary vortices.

2. The maximum normalized tangential velocity occurs at the stage of vortex breakdown, after which the maximum tangential velocity almost holds as a constant and the normalized radial location of V_{max} changes very slightly. Turbulence plays little role for weak vortex stage in the radial momentum balance. From the stage of vortex breakdown the force balance changes dramatically and the effects of turbulence emerge.

3. The values of V_{max}/V_c, $-U_{min}/V_{max}$ and W_{max}/V_{max} obtained from different simulators are plotted as a function of local corner swirl ratio and show good comparison. The vortex aspect ratio r_{vmax}/h_{rvmax} shows linear relationship with the local corner swirl ratio having a slope of about 0.7. Based on the consistency provided by the local corner swirl ratio, it is proposed to universalize the researches.

Generation of inflow turbulence using the local differential quadrature method

Tong WANG, Shu-yang CAO, Yao-jun GE

State Key Laboratory for Disaster Reduction in Civil Engineering, Tongji University, Shanghai 200092, China

ABSTRACT: Inflow turbulence plays an important role in the field of computational wind engineering. Whereas, generation of inflow turbulence through preliminary numerical simulation of a turbulent boundary layer using traditional low-order numerical algorithms usually can not yield satisfied results corresponding with the prescribed statistics, especially as the power spectral density for lack of high-frequency energy. This paper extends the traditional differential quadrature method (DQM) to the direct numerical simulation (DNS) of inflow turbulence based on the idea of localization with a common staggered mesh. This local DQM can be viewed, to some extent, as a generalized finite difference method whose weighting coefficients can be obtained from different interpolation base functions. It is found that the polynomial interpolation base functions and the Fourier expansion both perform well for the local DQM in modeling turbulence. This method is successfully applied to generate inflow turbulence and good results obtained. Comparisons show that the mean property and turbulence intensity can be well preserved and the high-frequency energy is efficiently improved with increasing the number of locally referenced points of the local DQM.

KEYWORDS: generation of inflow turbulence; the local differential quadrature method; high-frequency energy; turbulent boundary layer; interpolation base functions; DNS.

1 INTRODUCTION

The advent of high-speed computer and the development of accurate numerical algorithms have provided an important third approach — Computational Wind Engineering (CWE), in addition to theory analysis and experiment, for researchers to study the effects of air flow on structures which are usually located at the bottom of the turbulent atmospheric boundary layer (ABL). It is well known that the characteristics of the turbulent ABL vary with the land surface roughness, and that the wind-induced responses of structures are determined mainly by the interaction of the atmospheric turbulence and the released vortex of structures. So the imposed inflow turbulence at the inlet boundary has to satisfy the prescribed requirements, and also the turbulence statistics should not change a lot in the empty wind tunnel (Blocken, *et al.* 2007; Murakami 1998). Besides, in practice, estimating time history of dynamic wind load on structures by performing an unsteady LES heavily depends on the accurate inflow condition at every time step. Therefore, a crucial precondition to the above research activities using CWE is to generate appropriate inflow boundary conditions in accordance with characteristics of the turbulent ABL, i.e. generation of inflow turbulence, which has been a hot research topic in the field of CWE for the past two decades (Nozawa and Tumura 2002).

At present, several methods have been developed to generate inflow turbulence and can generally be classified into two types. The first one is to artificially generate time series of velocity fluctuations by performing an inverse Fourier transformation for the prescribed spectral densities, i.e. the so called “synthetic method” (Kondo, *et al.* 1997, Murayama, *et al*. 1999, Mathey, *at al.* 2006, Huang, *at al.* 2010). The other is to directly conduct preliminary simulation of a turbu-

lent boundary layer using computational fluid dynamics (CFD) (Lund, *at al.* 1998, Nozawa and Tumura 2002, Kataoka and Mizuno 2002, Tabor and Baba-Ahmadi 2009), simply denoted here as "direct method". A more comprehensive review of various methods commonly used for generation of inflow turbulence was given by Tabor and Baba-Ahmadi (2009) and Huang, *et al.* (2007) in which these methods were classified into three types, i.e. precursor database, synthetic method and recycling method. Here the precursor database and the recycling method are combined as the direct method because they are both based on CFD simulation. The synthetic method is relatively convenient and timesaving. And more importantly, the stochastic of its generated inflow turbulence can be guaranteed to satisfy the prescribed target characteristics. Kondo, *et al.* (1997) presented a method to deal with the divergence-free operation to ensure the continuity condition. Huang, *at al.* (2010) proposed a new inflow turbulence generator not only rigorously satisfying the divergence-free condition but also suitable for parallel computation. However, application of this method is limited by the fatal deficiency that its generated turbulent inflow data do not satisfy the Navier-Stokes equations. So the characteristics of the imposed inflow turbulence at the inlet can not be well preserved in the computational domain. In contrast, the direct method avoids this severe defect of the synthetic method, while requires a large computational load. Although the direct method has achieved great success in practice, it still has some defects, for example, it is relatively hard for the direct method to obtain satisfied results corresponding with the prescribed power spectral density for lack of high-frequency energy which is of great importance for analyzing the buffeting response of wind-sensitivity structures and for estimating wind energy utilization. This paper just focuses on the direct method as well as on the improvement to the high-frequency energy.

Generally, there are two approaches to enhance the high-frequency energy in CFD simulation of inflow turbulence. One is to use a fine grid, and the other using a high–precision algorithm which has been adopted in the present paper. The traditional high-order methods used in direct numerical simulation (DNS) of turbulence are compact finite difference, spectral and spectral elements methods. These methods are more accurate while not practical in CWE for their complexity and non-universality. This paper focuses on another high-order algorithm, the differential quadrature method (DQM) proposed by Bellman and Casti (1971). This method is highly accurate and conceptually simple, and has been reported to solve various problems of fluid mechanics. Nevertheless owing to the limitation of its quadrature rules, the traditional DQM has so far been used only for regular domain and laminar flows with a collocated mesh which commonly can not guarantee the continuity condition on boundaries and is prone to bring pressure oscillation. Sun and Zhu (2000) proposed an upwind local DQM to overcome some of the above difficulties. Shu, *et al*. (2003) developed a Local radial basis function-based differential quadrature (RBF-DQ) method, which is essentially a mesh-free approach, to expand its application. However, this method has never been used to turbulent flows and with a staggered mesh.

This paper extends the traditional DQM to turbulence simulation based on the idea of localization analogous to that of Sun and Zhu (2000), but with a common staggered mesh. An upstream grid number n_u and a downstream grid number n_d are introduced into the formulae of the present local DQM. By changing n_u and n_d, different upwind/central schemes of the local DQM can be obtained. Besides, the weighting coefficients can be calculated using different interpolation base functions. Two kinds of interpolation base functions, polynomial and Fourier, will be used and studied for turbulence simulation. Influences of several upwind schemes of the local DQM on high-frequency energy will also be investigated. In the next section, fundamentals of the traditional DQM and the local DQM are shown. Section 3 presents verification of this local DQM for turbulence modeling based on the channel flow. Then a recycling approach for generation of inflow turbulence used in this paper is introduced in Section 4. And Section 5 presents

and analyzes the numerical results of inflow turbulence generated using the present local DQM. Finally, some conclusions are summarized in Section 6.

2 THE LOCAL DIFFERENTIAL QUADRATURE METHOD

To roundly understand the local DQM, the traditional DQM is introduced. The idea of the traditional DQM is essentially an extension of the integral quadrature. It approximates an ordinary/partial derivative of a function with respect to a coordinate direction at a mesh point as the weighted linear sum of all the functional values in the whole domain along that direction. Details can be found in Shu (2000). Without losing generality, consider a one-dimensional function $f(x)$ defined in $[a, b]$. Using the DQM, the nth-order derivative of $f(x)$ with respect to x at a point x_i can be expressed as

$$f^{(n)}\left(x_i\right)=\sum_{k=1}^{N} w^{(n)}\left(i,k\right) f\left(x_k\right), \quad i=1,2,\ldots,N \text{ and } n=1,2,\ldots,N-1 \tag{1}$$

where $a=x_1<x_2<\ldots<x_{N-1}<x_N=b$ are the discrete grid coordinates which can be arbitrarily distributed in space, N the total grid number in x direction, and $w^{(n)}(i,k)$ the corresponding weighting coefficient which can be calculated from various interpolation base functions. For example, weighting coefficients of the first-order derivative can be calculated using the polynomial interpolation base functions, the so-called PDQ by Shu (2000), as

$$\begin{cases} w^{(1)}\left(i,k\right)=\prod\limits_{\substack{k=1\\k\neq i,j}}^{N}\left(x_i-x_k\right)\Big/\prod\limits_{\substack{k=1\\k\neq j}}^{N}\left(x_j-x_k\right), & \text{for } i\neq j \\ w^{(1)}\left(i,i\right)=-\sum\limits_{j=1,j\neq i}^{N} w_{i,j}^{(1)}, & \text{for } i=j \end{cases} \tag{2}$$

or using the Fourier series expansion, the so-called FDQ by Shu (2000), as

$$\begin{cases} w^{(1)}\left(i,k\right)=\dfrac{\pi}{2\left(b-a\right)}\prod\limits_{\substack{k=1\\k\neq i,j}}^{N}\sin\left[\dfrac{\pi\left(x_i-x_k\right)}{2\left(b-a\right)}\right]\Big/\prod\limits_{\substack{k=1\\k\neq j}}^{N}\sin\left[\dfrac{\pi\left(x_i-x_k\right)}{2\left(b-a\right)}\right], & \text{for } i\neq j \\ w^{(1)}\left(i,i\right)=-\sum\limits_{j=1,j\neq i}^{N} w_{i,j}^{(1)}, & \text{for } i=j \end{cases} \tag{3}$$

Weighting coefficients for higher order derivatives can be directly obtained by using the matrix multiplication approach,

$$\left[w^{(n)}\right]=\left[w^{(1)}\right]^{n} \tag{4}$$

It can be seen from the above statement that the traditional DQM is, in fact, a global method because it connects the derivative of a function with respect to a coordinate direction at a given point with all the functional values along that direction in the computational domain. Just as stated in the first section, the traditional DQM is limited to regular domain and laminar flows on a collocated mesh because of its global quadrature rule. In order to extend its application, Sun and Zhu (2000) introduced the idea of localization combined with the upwind mechanism. Next, we will show a local DQM analogous to but different from that of Sun and Zhu (2000).

Unlike the traditional DQM, derivative of a function with respect to a coordinate at an internal point is expressed as a weighted linear sum of the function values at partial grid points rather

than at all the grid points along that coordinate direction. In details, consider an internal point x_i, the derivative of $f(x)$ with respect to x at this point can be expressed as a weighted linear sum of the function values at q grid points near x_i along the x direction, that is to say

$$f^{(n)}(x_i) = \sum_{k=1}^{q} w^{(n)}(r,k) f(x_{i-r+k}) \tag{5}$$

where $q=n_u+n_d+1$; n_u and n_d are the upstream grid number and the downstream grid number, respectively, and they should satisfy $n_u \geq 1$, $n_d \geq 0$ and $n_u \geq n_d$; The number r can be determined in terms of velocity $u(x_i)$ as follows

$$r = \begin{cases} n_u + 1 & u(x_i) \geq 0 \\ n_d + 1 & u(x_i) < 0 \end{cases} \tag{6}$$

It is clear that if $n_u > n_d$, an upwind scheme is obtained, and $n_u = n_d$ corresponds to a central scheme. Fig. 1 illustrates the grid distribution of the local DQM as $n_u=3$ and $n_d=2$.

Figure 1. Grid points used in the local DQM as $n_u=3$ and $n_d=2$

The difference of the present local DQM from that of Sun and Zhu (2000) just lies in the formula of r. In Sun and Zhu (2000), r is determined by

$$r = \begin{cases} q/2+1 & q \text{ is even, } u(x_i) \geq 0 \\ q/2 & q \text{ is even, } u(x_i) < 0 \\ (q+1)/2+1 & q \text{ is odd, } u(x_i) \geq 0 \\ (q+1)/2-1 & q \text{ is odd, } u(x_i) < 0 \end{cases} \tag{7}$$

Evidently, the local DQM of Sun and Zhu (2000) just has upwind schemes, besides the upwind grid number is larger than the downstream grid number by only one or two corresponding to the even or odd q, respectively. So the present local DQM is relatively more general.

It has to be indicated here that the weighting coefficient $w^{(n)}(r,k)$ in Eq. (5) should be calculated from the referenced q grid coordinates x_j ($j=i-r+1,\ldots,i-r+q$) rather than from the N grid coordinates x_j ($j=1,\ldots,N$) using Eq. (2) or Eq. (3). Besides, when an internal point x_i locates its position near the boundary, there may not be enough grid points to introduce upwind or central mechanisms. Then one should adjust n_u and n_d to guarantee that the referenced points are not outside the computational domain, and this treatment will inevitably compromise the accuracy near the boundary. However, this problem will not be considered in the present paper.

The formula (5) is just the present local DQM which imposes the differential quadrature rule on a local domain rather than on the whole domain. Actually this method can be considered, to some extent, as a generalized high-order finite difference method for the weighting coefficients can be obtained by using various interpolation base functions. For example, if the polynomial interpolation base functions are used, the local DQM is identical with the highest-order, i.e. (q-1)th, finite difference scheme according to the demonstration of Shu (2000). And if the Fourier expansion is used, the local DQM is similar, to some extent, to the spectral element method. In

addition, because the differential quadrature rule is used locally, the staggered mesh can also be introduced. From this point, the local DQM is similar to the FDM and FVM except the values of weighting coefficients and the approach to calculate them.

3 VERIFICATION OF THE LOCAL DQM

In this section, the above local DQM is applied to model the channel flow at Re_τ=180 to check its validation for turbulence simulation. Two kinds of interpolation base functions, polynomial and Fourier expansion, are used to calculate the weighting coefficients to study the effects of different base functions on numerical results. For convenient, the above two cases are denoted as "local PDQ" and "local FDQ", respectively, for short. The governing equations used here, and also hereafter for generation of inflow turbulence, are the three-dimensional unsteady incompressible Navier-Stokes equations in Cartesian coordinate,

$$\begin{cases} \nabla \cdot \mathbf{V} = 0 \\ \mathbf{V}_t + (\mathbf{V} \cdot \nabla)\mathbf{V} + \nabla p/\rho = \nu \nabla^2 \mathbf{V} \end{cases} \tag{8}$$

where $\mathbf{V}=\{u,v,w\}^{\mathrm{T}}$ is the velocity vector, p the pressure, ρ the density and v the kinematic viscosity coefficient. A common staggered mesh is introduced: the pressure p is defined in the center of the cell, and the velocities u, v and w are defined on the surface center of the cell normal to x, y and z axis, respectively.

The traditional fractional step method is applied to solve the above equations. And the local DQM shown ahead is only used to discretize the convection terms in space while calculating the intermediate velocities, and the viscous terms are spatially discretized by the three-point second-order central difference scheme. In time, the first-order explicit Euler scheme is used for the unsteady terms, the second-order Adams-Bashforth scheme for the convection terms and Crank-Nicolson for the viscous terms.

The computational domain is $2\pi\times2\times\pi$ in longitudinal (streamwise), vertical (wall-normal) and spanwise direction, respectively, with a coarse mesh, 65×65×65. Uniform grid is used in the streamwise and spanwise direction, and unequal in vertical direction. The vertical grid size varies gradually from 0.005 (y^+=0.9) near the wall to 0.064 (y^+=11.5) at the center of the channel. Boundary conditions here are: a periodic condition for the streamwise and spanwise directions, a non-slip boundary condition for the upper and bottom floors.

Fig. 2 and Fig. 3 show the calculated mean velocity profiles and *root-mean-square* (*rms*) of velocity fluctuations using the local PDQ and the local FDQ, respectively, compared with numerical data of Del Alamo and Jimenez (2003).

Three central schemes, CS3(n_u = n_d =1), CS5(n_u = n_d =2) and CS7(n_u = n_d =3), and three upwind schemes, US4(n_u =2, n_d =1), US6(n_u =3, n_d =2) and US8(n_u =4, n_d =3), are considered for the local DQM. Because the Reynolds number here is not very large, there is no distinct unphysical oscillation while using central schemes. The time step, Δt, for the local PDQ is specified as 0.0001 and 0.00005 respectively for the upwind and central schemes. For the local FDQ, Δt is fixed as 0.00005 for all schemes, and it is hard to obtain convergent results using a larger time step as that of PDQ.

As shown in Figs. 2 and 3, the results of the present local DQM have a good agreement with those of Del Alamo and Jimenez (2003) obtained by using the spectral method, though the present grid mesh is much coarse. It should be indicated here that CS3 and US4 of the local PDQ are identical with the traditional three-point second-order central difference and the four-point third-order upwind difference, respectively. It is clear that the present results are improved efficiently with increasing the number of referenced points, and the central schemes are more accu-

rate than the upwind schemes for possessing the least numerical diffusion. Comparisons between Fig. 2 and 3 indicate that the local PDQ and the local FDQ yield almost the same mean-velocity profiles, while some discrepancy for *rms* of velocity fluctuations. So it can be concluded that the local DQM is applicable for the turbulence simulation.

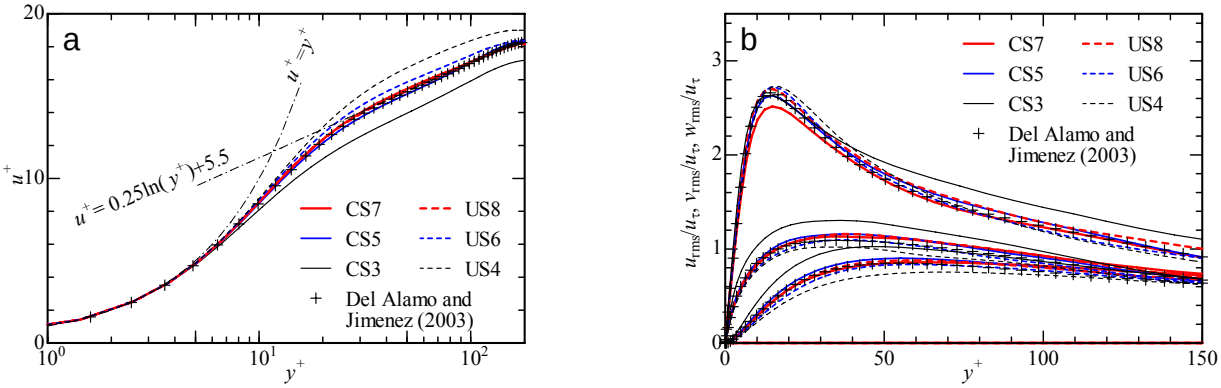

Figure 3. Numerical results of the local FDQ for the channel flow at Re_τ=180: (a) Mean-velocity profiles; (b) *rms* of velocity fluctuations

4 APPROACH FOR GENERATING INFLOW TURBULENCE

The most widely used direct method for generation of inflow turbulence is the recycling method in which the velocity in a downstream plane is extracted and rescaled for the inflow boundary. In this method, the region used to generate turbulence is usually referred to as ‘‘driver region’’, and the second region that we are interested in is usually referred to as ‘‘main region’’. Lund, *et al.* (1998) first proposed this rescaling recycling method to generate developing turbulent inflow data for LES. Kataoka and Mizuno (2002) simplified Lund’s method by assuming that the boundary layer thickness is constant within the driver section. Nozawa and Tumura (2002) extended Lund’s method to a rough-wall boundary layer flow using a roughness block arrangement. For simplicity, the simplified recycling method proposed by Kataoka and Mizuno (2002) is adopted in this paper to generate inflow turbulence, and its detailed process is shown in Fig. 4.

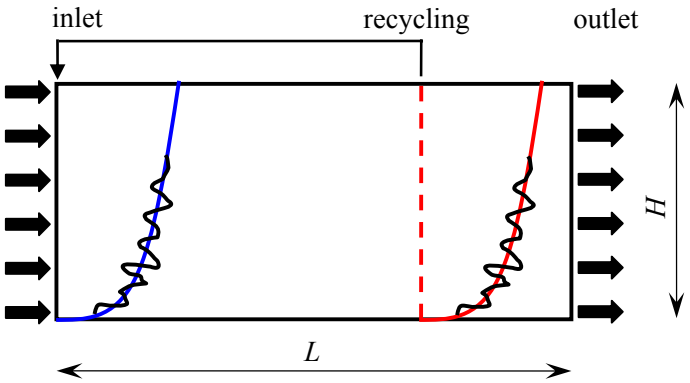

Figure 4. Sketch map of Kataoka's recycling method

A mean velocity profile is prescribed at the inlet, and only the fluctuating part is directly extracted from the recycling station to the inlet boundary without rescaling. The velocity components at the inlet are given as follows,

$$\begin{cases} u_{\text{inlt}}(y,z,t) = \langle u \rangle_{\text{inlt}}(z) + \phi(\eta) \times \{ u(y,z,t) - \langle u \rangle(y,z) \}_{\text{recy}} \\ v_{\text{inlt}}(y,z,t) = \phi(\eta) \times \{ v(y,z,t) - \langle v \rangle(y,z) \}_{\text{recy}} \\ w_{\text{inlt}}(y,z,t) = \phi(\eta) \times \{ w(y,z,t) - \langle w \rangle(y,z) \}_{\text{recy}} \end{cases} \tag{9}$$

where the subscripts denote the values at the inlet (inlt) and the recycling (recy) station, and $\langle \bullet \rangle$ represents a time-averaged value. $\langle u \rangle_{\text{inlt}}$ is set as the prescribed velocity profile. The added damping function $\phi(\eta)$ blocks the velocity fluctuation from developing in the free stream. Kataoka (2008) gave the damping function as

$$\begin{cases} \phi(\eta) = \dfrac{1}{2}\left\{ 1 - \tanh\left[\dfrac{8.0(\eta - 1)}{0.82 - 0.4\eta} \right] \Big/ \tanh(8.0) \right\} \\ \eta = y/\delta \quad (\delta : \text{boundary layer thickness}) \end{cases} \tag{10}$$

Other boundary conditions are: a convection outflow boundary condition for the outlet, a free-slip boundary condition for the ceiling, a non-slip boundary condition for the bottom and a periodic condition for the spanwise boundary.

5 GENERATION OF INLFOW TURBULENCE USING THE LOCAL DQM

Generation of inflow turbulence using traditional low-order numerical algorithms usually suffers the difficulty of bad statistics, especially as the power spectral density for lack of high-frequency energy. An efficient approach to solve this defect is to use a finer mesh which consequently results in a large computational load. Another efficient way is to use high-order methods. In this section, the local DQM will be used to generate inflow turbulence at two relatively high Reynolds numbers, $Re_\theta \approx 1120$ and 1460, based on the recycling approach presented in Section 4. At these high Reynolds numbers, it is hard for the central schemes of the local DQM to obtain convergent results because of large numerical oscillation. In addition, the local PDQ and the local FDQ have almost the same behavior in turbulence simulation just as shown in Section 3. So, only upwind schemes of the local PDQ are used here, which undoubtedly introduce some nu-

merical diffusion. However, our focus will mainly be put on preservation and the high-frequency energy.

5.1 *Details for the calculation*

It is assumed that the boundary layer thickness is constant in the recycling section from the inlet to the recycling station (Kataoka and Mizuno 2002), so the streamwise length of the recycling section can not be very large. Referring to the work of Kataoka and Mizuno (2002) and Kataoka (2008), the streamwise length of the recycling section is specified here as δ, and the whole computational domain is L=1.5δ in flow direction, H=1.6δ in vertical direction and 1.2δ in spanwise direction. A relatively coarse mesh, 50×90×40 in streamwise, vertical and spanwise direction, is generated. Uniform grid is used in the streamwise and spanwise direction, and unequal in vertical direction. The vertical grid size varies from 0.0012δ near the wall to 0.078δ at the ceiling. The discretization schemes are the same as those of Section 3 and the same staggered mesh is used. The damping function of Eq. (10) is applied.

Two different mean-velocity profiles of power law are prescribed at the inlet boundary with exponent α=0.21 and 0.17 for Re_θ≈1120 and 1460, respectively.

5.2 *Results and comparisons*

Fig. 5 shows the calculated mean-velocity profiles at several positions, x/δ=0.25, 0.75 and 1.25, in streamwise direction compared with target ones, numerical data of Jimenez, *et al.* (2009) at Re_θ≈1100 and experimental data of DeGraaff and Eaton (2000) at Re_θ≈1430.

Only three upwind schemes, US4(n_u =2, n_d =1), US6(n_u =3, n_d =2) and US8(n_u =4, n_d =3), are considered here . As shown in Fig. 5, the calculated mean-velocity profiles of the above three schemes all have a good agreement with the target one while the discrepancy becomes a little larger at downstream. As a whole, the mean-velocity profile is well preserved in the computational domain.

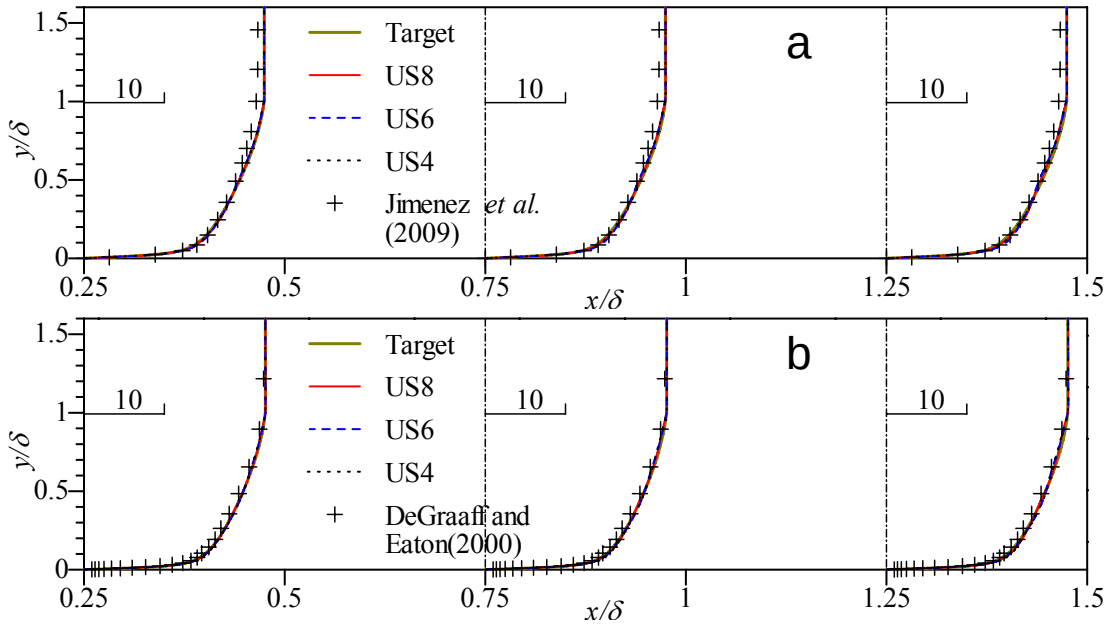

Figure 5. Calculated *rms* profiles: (a) α=0.21 and Re_θ≈1120; (b) α=0.17 and Re_θ≈1460

Fig. 6 shows the calculated *rms* of the streamwise velocity fluctuation in wall unit, u_{rms}/u_τ, compared with the numerical results of Jimenez *et al.* (2009) at $Re_\theta \approx 1100$ and experimental data of DeGraaff and Eaton (2000) at $Re_\theta \approx 1430$. Like the mean velocity, the profile of *rms* can also be well preserved in the computational domain. However, all the three upwind schemes overestimate *rms* within the height of δ and underestimate it above this height. Good agreement is shown for the higher order scheme, US8, although there is a large discrepancy in the outer region. This may attribute to the selection of the damping function. In our trial calculations, it is found that the *rms*, especially in the outer region, heavily depends on the selection the damping function. However, we are not going to discuss this problem, because our focus is not here.

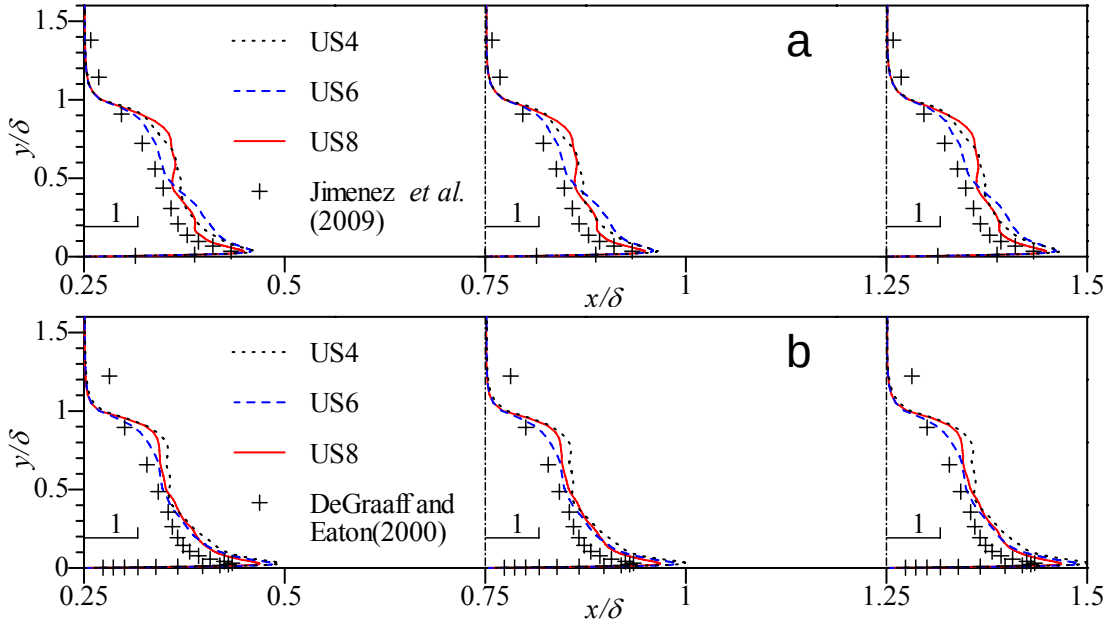

Figure 6. Calculated *rms* profiles: (a) α=0.21 and $Re_\theta \approx 1120$; (b) α=0.17 and $Re_\theta \approx 1460$

From the above results and comparisons, it can be concluded that the recycling method based on the local DQM can generate relatively satisfied mean and *rms* results. Besides, this method has a good preservation which may mainly attribute to the short streamwise length of the computational domain.

Fig. 7 shows the power spectral densities of the along-wind velocity fluctuation at x/δ=0.75, y=0.075δ ($y^+ \approx 32$) and z/δ=0.6 for Re_θ=1120 and at x/δ=0.75, y=0.075δ ($y^+ \approx 43$) and z/δ=0.6 for Re_θ=1460, compared with the Karman spectrum. The data of US4 follows the Karman spectrum until $n\delta/U$=2.3, US6 until $n\delta/U$=3.5 and US8 until $n\delta/U$=4.3 for $Re_\theta \approx 1120$. The improvement of high-order schemes to the high-frequency energy is remarkable. And similar conclusions can be obtained for $Re_\theta \approx 1460$. This can also be obtained from the corresponding time histories of the along-wind velocity as shown in Fig. 8.

Only one second, from 6 to 7, of the time history is presented in Fig. 8 for a clear show. Mean velocities of the three time histories are almost the same. It can be seen clearly from Fig. 8 that the curves become smoother and smoother with decreasing the order of the local PDQ from US8 to US4. It means that smaller vortex can be represented using higher-order schemes of the local DQM at the same mesh.

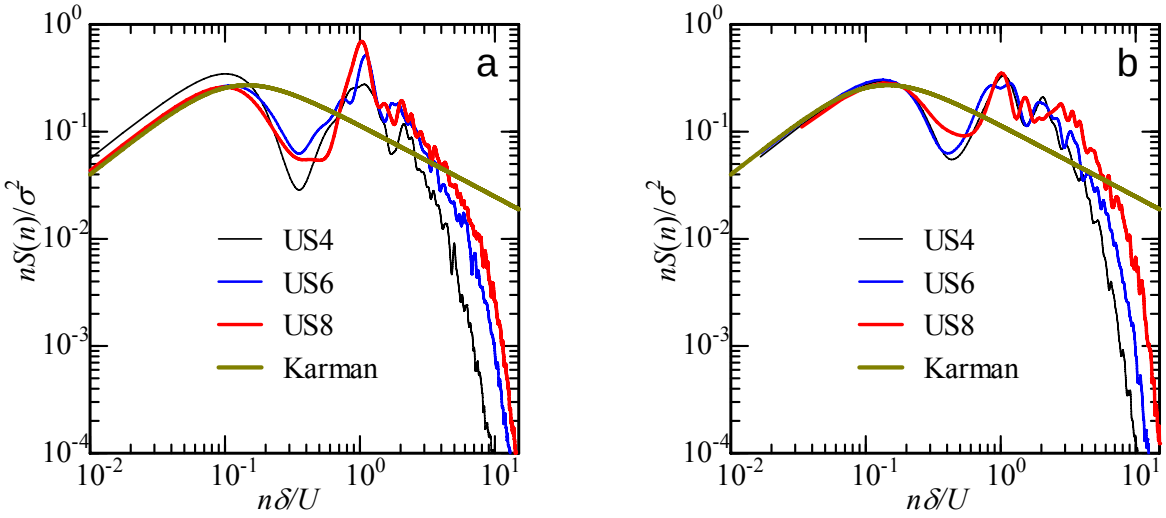

Figure 7. Calculated power spectral densities: (a) α=0.21 and Re_θ≈1120; (b) α=0.16 and Re_θ≈1460

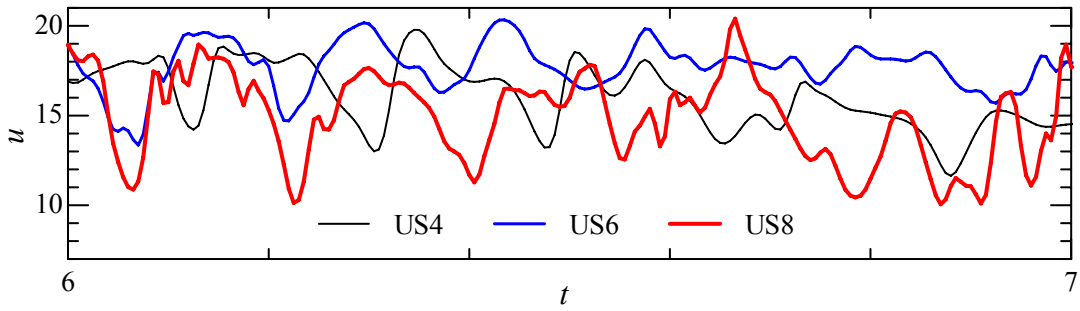

Figure 8. Time histories of the along-wind velocity for Re_θ≈1120 at x/δ=0.75, y/δ=0.056, and z/δ=0.6

6 CONCLUSIONS

In this paper, a local DQM is developed from the traditional global DQM based on the idea of localization combined with a common staggered mesh, different from existing ones. This method can be viewed as a generalized finite difference method. An upwind grid number and a down-stream grid number are introduced into the formulae of this local DQM. Different upwind/central schemes of the local DQM can be obtained by changing these two numbers. The local PDQ whose weighting coefficients are obtained by polynomials and the local FDQ whose weighting coefficients calculated by the Fourier expansion are both applied to the channel flow with several upwind/central schemes. Results indicate that the local PDQ and the local FDQ both perform well, and the central schemes are more accurate than the upwind ones for possessing the least numerical diffusion. Finally, the local PDQ is successfully applied to generate inflow turbulence with several upwind schemes. The mean properties and turbulence intensities can be well pre-served in the computational domain. With increasing the referenced grid number, the high-frequency energy is efficiently enhanced.

ABSTRACT: Under the actions strong wind over the sea, rough waves may roar and interfere wind flows. The flows may become extreme complicated and fluctuated and incur unusual response for structures in this region. The strong interfered performances of wind flows near sea surface by rough waves are investigated by using the 3-D LES (Large-Eddy-Simulation) numerical simulation technique. The research results indicate that the numerical simulation results are basically consistent with those by wind tunnel experiments. The difference can not be avoided and the major causes are presented. With the interference of wave, the wind flows fluctuated intensely, and the unsteady characteristics is very significant, which largely dependent upon the wave shapes. The apparent influential region by wave ranges from the wave crest to 15 times of wave height downwind horizontally and 4 times of wave height upward vertically.

KEYWORDS: 3-D LES; sea wave; aerodynamic interference; numerical simulation

1. INTRODUCTION

On the extreme (such as once every hundred years) climatic conditions, under the actions of strong wind, wild sea waves (crest may be higher than 8m, or even more) may appear. The combined effects from wind, waves and currents will have an extremely negative impact on bridges and/or offshore platforms. Wave velocity is generally lower than the wind speed, thus the wave can be regarded as an obstacle, and it will influence the downwind flow field characteristics, especially for the roaring wave, its impact is very significant, may lead to very complex wind flow field. The turbulence intensity and wind angle of attack, etc. may be completely different with the normal wind field. Therefore, unusual impact from the interfered wind flows may construct the terrible threat to the artificial structures. However, only a few researches have been carried out in references and/or documents [1-4]. Exhaustive investigations on this issue should be further conducted

In order to study the influence of wind interfered by rough waves on bridge and/or offshore platform, it is necessary to investigate the characteristics of wind flow downwind of the wave beforehand. Wind tunnel test and numerical simulation are both applicable, and the latter one is expounded and the results are compared with by the former one in this study. The properties are analyzed and summarized, and some conclusions are drawn.

2. WAVE SHAPE

For actual sea waves, enormous forms can be observed and it is impossible to investigate all of them. In this study, only the extreme cases are concerned. The waves with 8m height are considered as the examples. For such fairly rough waves, the shape is relatively simple and the distance between two wave peaks is very long (maybe longer than 500m). So for the high waves, it is rarely to observe several accompanied peaks, and one single wave may usually emerge. For the sea waves, two simplified shapes are selected and quantified with scale of 1:40. Certainly, the influence of more types of wave shapes and even groups of waves on wind flows can be studied with similar methods.

Wave shape type 1: certain function curve, x=exp(0.25*z), y=(normpdf(0,4,x), plot(x,y) ($3 \le x \le 9.9$). The shape can be achieved through stretching or panning the curve in both horizontal and vertical coordinates, and the width and height are 30cm and 20cm, respectively.

$$y = \frac{689.6552}{(0.3255x+4)\sqrt{2\pi}} e^{\frac{-8}{(0.3255x+4)^2}} - 21.7241 \quad (5.7849 \le x \le 24.2151)$$

Wave shape type 2: The probabilistic density function of standard normal distribution, and the interval of X axis is[-2.5, 2.5]. The shape can be realized through the curve, and the width and height are 60cm and 20cm, respectively.

$$y = 50\frac{1}{\sqrt{2\pi}} e^{\frac{-x^2}{288}} \quad (-30 \le x \le 30)$$

The graphs of two wave shapes are plotted in Fig.1.

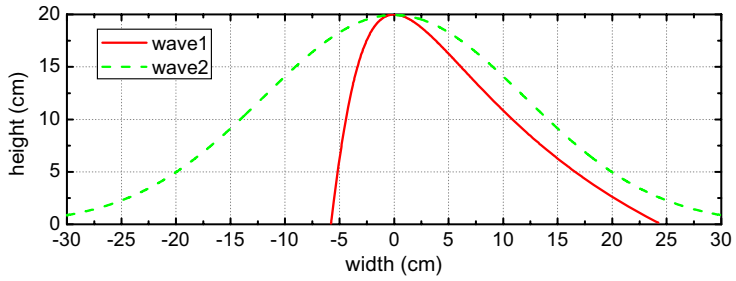

Fig.1 Wave shape graphs

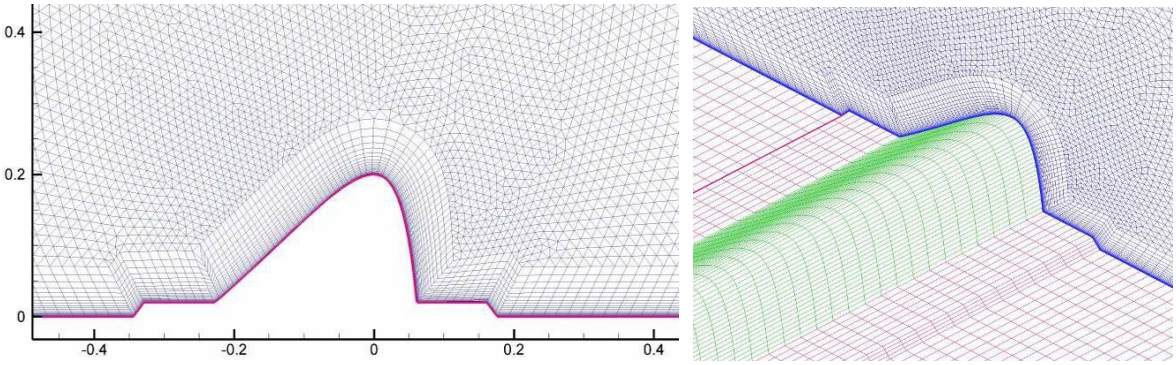
3. NUMERICAL SIMULATION MODEL

3.1 *Geometric modeling and meshing*

The geometric ratio is 1:40 for numerical modeling, and the three-dimensional computational domain is taken as 26m (length) × 2.5m (height) × 1m (Width). The horizontal distance between wave crest and inlet is 8m, and the outlet is 18m apart from the crest. The model is 0.2m high. The computational domain for Wave 1 meshes is shown in Fig. 2, and the triangle unstructured mesh is adopted. Boundary layer mesh is used for Near-wall region meshing to ensure the requirements of stable numerical solving on the wall boundary layer. The boundary layer height of the first grid is 0.0002m. Owing to the fact of two-dimensional segmental rigid computational model, the statistical average of the flow maybe assumed in the spanwise direction, and it is divided into 30 grids. The total volume mesh number is about 1,230,750. The sketch maps of 2-D and 3-D local computational domain and meshgrids are shown in Fig.2 For Wave 2, it is similar to that of wave 1 using the same modeling approaches, and the total volume mesh number is about 1,619,430.



(a)2-D local grids sketch (b)3-D local grids sketch

Fig.2 Computational domain and meshgrids

3.2 *Computational parameters*

The3-dimensional Large Eddy Simulation model is utilized for numerical analysis. The spatial discretization can be realized using central difference, and the velocity pressure coupling maybe solved using the SIMPLE (Semi-Implicit Method for Pressure-Linked Equations) algorithm based on decoupling idea. The convergence criterion for Iterative calculation is set to be the non-dimensional root mean square residual decays below 10^{-4}.

The boundary conditions for the numerical model are respectively set as follows: the inlet flow velocity is smoothly 10m/s (It need to be mentioned that the Reynolds number effect may exist, which is not considered for limitation of the context length); the outlet flows are completely developed; the top surface is free boundary; the side surface is symmetric boundary; the model surface and sea level is no-slipping wall boundary, and the standard wall function is adopted; the time interval of calculation step is 0.005s; when the flow field become stable, the calculation time is 15s, and the steps are 3000.

4 RESULTS AND ANALYSIS

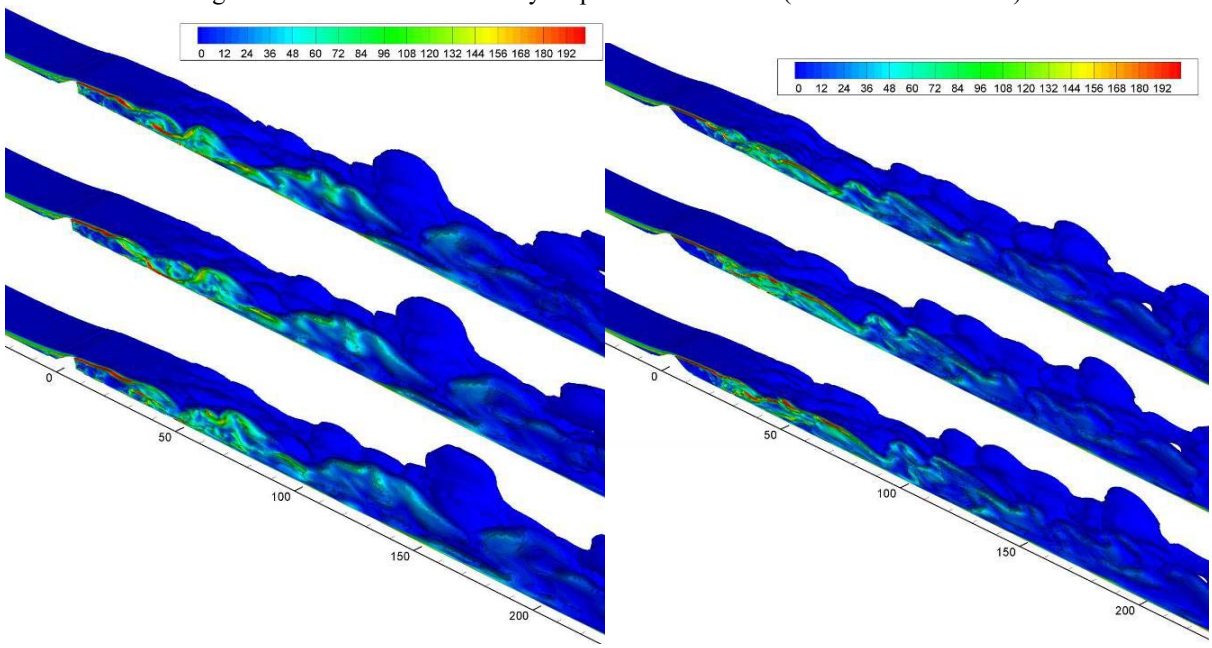

Fig. 7 Instantaneous 3-D vorticity maps at different time (Time interval: 0.05s)

From Fig.3, it can be seen that:

(1) In front of sea wave, in the region of 3-4m upside of sea surface level, the wind velocity behaves obvious difference, and the major causes may include two aspects: on one hand, air is viscous and one boundary layer is inevitable in which the velocity increase from zero to be 10m/s; on the other hand, owing to the obstacle effect from wave, the velocity near the sea surface is relatively lower. For the influence extent from the above two aspects, it can be analyzed by means of the following two techniques: no wave, i.e. remove the wave; the wave is set at the entrance of flows. In the region outside of 40m in front of wave, the wave effect is negligible, and the gradient flows property is similar, which may be mainly caused by the first reason. For the region behind wave and the distance maybe about 30m, the mean velocity is almost zero when the height is lower than wave crest. It may be considered as a "stagnant water area". When the mean velocity is negative, it may be regarded as a "backwater area". Such backwater area can be detected in the region from 35-70m behind the wave. Behind this area, the boundary layer thickness increase owing to the obstacle effect of wave.

(2) For the two heights of 30cm and 40cm, the numerical results are higher than those of experimental ones. For the two heights of 50cm and 60cm, the numerical and experimental results are almost identical. The reasons maybe provided as follows. The wind tunnel laboratory walls are not absolutely smooth, and the testing points are apart from the flow inlet entrance. Therefore, thicker boundary layer appears. Whereas, the smooth wall modeling is utilized for CFD numerical simulation. Thus, the results difference near the wall region is comparatively

apparent. In addition, differences between the wind tunnel test model and numerical simulation model can not be avoided. The testing model may be relatively rough than the computational ones. Such influence may become weaker with the distance farther from the wave, and the results tend to be more close to each other.

From Fig.4, it can be observed that:

(1) For the mean wind velocity of horizontal flow, the numerical simulation results are higher than those of wind tunnel test ones. The closer to wave and the closer to sea surface, the apparent difference. In such regions, the flow fields are more complicated, and the result accuracy is relatively unsatisfactory for both wind tunnel test and numerical simulation.

(2) For the mean wind velocity of vertical flow, in a very wide region behind the wave, the value is negative. The results difference between the numerical computation and wind tunnel test is very obvious in the region that near the wave. The vertical velocity is almost negligible when the distance is 150m far from the wave. The numerical results trend of two types of waves is almost similar.

(3) For the mean angle of incidence, the results from numerical computation and wind tunnel test are relatively close for wave 2. The numerical simulation results are comparatively higher. For wave 3, the results from two methods are distinct. The major cause is the complex flow fields and extreme fluctuation near the wave, and the accuracy is difficult to be ensured for both wind tunnel test and numerical simulation.

(4) For the mean static pressure, the numerical simulation results are lower than those of experimental ones, and the difference is more obvious for wave 3. The systematic error may happen for testing apparatus and/or numerical calculation.

(5) For the standard deviation of all parameters, the numerical simulation results are lower than those of experimental ones. The major cause may include the following two aspects. The experimental instruments and signals are inevitably interfered and contaminated by a large variety of noises. The testing conditions (eg. roughness, turbulence, and so on) can not be so realistic as the numerical simulation. In addition, the wind tunnel width is 3m, while the wave model length is 2.5m, and the more obvious 3-D around flow effect may be incurred.

From Fig.5-Fig.7, it can be detected that:

Except the region that close to wave, the interfered wind flows by two waves are fundamentally similar in other regions. All calculation conditions are basically identical. Although the wave shape is different, the wave height is the same and the configurations are smooth and a bit similar. Two complicated flow fields can be detected: one is the “stagnant water area” that locates in the interval from wave crest to 30m downwind; the other is the “backwater area” that locates in the interval from 30 to 80m downwind of the crest, and the height is within 1.5 times of the wave height. For bridge deck, the height may be higher than this area. With the interference effects of wave, the angle of incidence may deviate from zero to the formidable values, which may bring a challenging threat to the safety of bridge.

5 CONCLUDING REMARKS

The strong interfered performances of wind flows near sea surface by rough waves are investigated by using the 3-D LES numerical simulation technique. The research results indicate that the numerical simulation results are basically consistent with those by wind tunnel experiments. The difference can not be avoided and the major causes are presented. With the interference of wave, the wind flows fluctuated intensely, and the unsteady characteristics is very significant, which largely dependent upon the wave shapes. The apparent influential region by wave ranges from the wave crest to 15 times of wave height downwind horizontally and 4 times

of wave height upward vertically. So if the bridge deck and/or offshore platform are located such a region, adverse wind effects may incur and more comprehensive researches on wind-resistant performance of bridge and/or offshore platform are strongly recommended to be conducted.

Appropriate shape of boundary transition section of terrain model for mountains-gorge bridge site

Peng Hu*, Yongle Li, Haili Liao

Department of Bridge Engineering, Southwest Jiaotong University, Chengdu, China

ABSTRACT: To study the appropriate boundary transition section shape of terrain model for mountains-gorge bridge site, a kind of transition curves was derived based on the theory of flow around cylinder with ideal fluid, took an ideal 2D platform terrain as an analysis model to comparatively analyze the flow separation behavior and distribution characteristics of average wind field after airflow flowed along the transition section between curve transition section with equivalent angle of 30° and ramp transition section with included angle of 30° by CFD commercial software FLUENT 6.3, and the total flow transition length of different curve transition sections was also compared. The result shows that when air flows along the curve transition section with equivalent angle of 30°, the distribution characteristics of wind velocity field after airflow flowed along the transition section are much closer to the distribution characteristics of reference wind velocity field than that when airflow flows along the ramp transition section with included angle of 30°, and its total flow transition length is also the relative shortest. The research conclusions could provide some references for the terrain model studies of wind characteristics over the mountains-gorge bridge site.

KEYWORDS: mountains-gorge; terrain model; transition section; bridge site; wind characteristics; CFD

1 INTRODUCTION

When air flow over the mountains-gorge terrain, the air will subject to the blocking, uplifting and separating effects by the mountains, and the air will also subject to the channeling effect and blocking effect by the gorges. For long span bridge in the mountains-gorge terrain, wind characteristics over these bridge sites are very complex, which have a great difference compared with the bridges in the sea or river. There will be a large error if study the wind characteristic of these bridge sites according to the conventional regulation and stipulation (2004). In addition, it is difficult to have experience references from others because the complex of bridge sites terrain and every bridge sites has its own inherent characteristics. With development of the west regions of China, more bridges located in mountains-gorge terrain will be built due to the complex terrain in these regions and the limits of the transport line grade. Therefore, the study on the wind characteristic over bridge site in complex terrain is very urgent and necessary.

The calculation of complex flow over mountains-gorge terrain in practical applications is a difficult task to complete. Theoretical studies are limited by the inherent difficulties to treat real hill or mountains-gorge geometries and boundary conditions and it is also limited by the complexity of the model equations that try to mimic the most important physical phenomena present in the atmospheric boundary layer. Whereas field experimental campaigns are extremely expensive to be carried out and easily affected by environment condition which become a real urgent problem to be solved. A more feasible procedure to analyze the problem is the wind tunnel test method and numerical simulation method, but there is a specific problem in modeling a mountains-gorge terrain model in the wind tunnel test method and numerical simulation method: for the mountains-gorge terrain, it usually has a large elevation

difference everywhere, naturally, there will exist a distance (Δh, as shown in Fig.1) between the terrain model boundary and the wind tunnel floor (or the bottom of the computational domain in numerical simulation method) for the limited terrain area considered in one test, and the air would be separated from the model boundary if the there was no transition section from the wind tunnel floor to the terrain model boundary. In order to let the air flow over the terrain "smoothly", Hu et al. (2006) studied the wind characteristic parameters of a bridge across the V shape valley by terrain model wind tunnel test, and adopted a transitional additional terrain to let the air flow over the terrain model; Chen (2008) also adopted this method in another long span bridge in mountains-gorge terrain. Maurizi (1998) discussed the wind flow over a mountainous area at an altitude of 1000m above sea level, and used a ramp additional terrain with a maximum slope of 10% to let the air flow over the mountainous terrain. Although the transitional additional terrain and the ramp additional terrain have a simple form, the problem is that whether they are valid as a boundary transition section shape to let the air flow over the terrain smoothly.

The undisturbed wind field is usually taken as the reference wind field in wind tunnel tests. In an objective manner, when the inlet air flow over the appropriate boundary transition section, the air should keep the same characteristics as the reference wind field, so the undisturbed wind field will show more representative to act as the reference wind field in further studies. Comprehensive consideration of the boundary transition section in the wind tunnel and the numerical simulation methods, two principles that the appropriate boundary transition section should be satisfied: a) the air should keep the same characteristics as the reference wind field when the air flow over the transition section, and air separation could not occur at the end of the transition section; b)the length of the air flow from the starting point of the transition section to the point that the air get stable is fully short, because a longer transition section will further reduce the model scale factor as the test section of a wind tunnel is limited; besides, for the numerical simulation method a longer transition section also increase calculation region size and computational cost.

To study the appropriate boundary transition section shape of terrain model for mountains-gorge bridge site in wind tunnel test and numerical simulation test, in this paper, a kind of transition section curves was derived based on the theory of flow around cylinder with ideal fluid, took an 2D platform terrain as an analysis model to comparative analyze the flow separation behavior and distribution characteristics of wind velocity field after air flowed along the transition section between curve transition section and the ramp transition section by CFD commercial software FLUENT 6.3, and the total flow transition length of different curve transition section shapes were also compared. The research conclusions could provide some references for the terrain model studies of wind characteristics over the mountains-gorge bridge site.

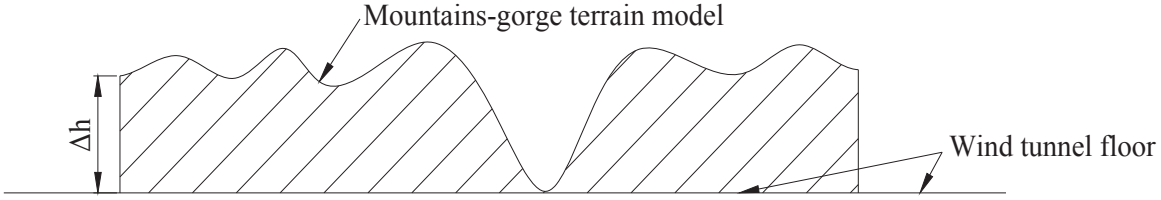

Fig.1 Distance between the terrain model boundary and the wind tunnel floor

2 TRANSITION SECTION CURVES BASED ON IDEAL FLUID AROUND CYLINDER THEORY

The undisturbed reference inlet air can be regarded as a uniform rectilinear flow, and its vertical wind velocity is zero. Therefore, the vertical wind velocity of the flow at the starting and end points of the transition section should also be equal to zero. When the air flow over

the transition section, except for the flow near the wall is subjected to the influence of air viscosity, the airflow could be taken as the potential flow in other large regions. Based on the theory of flow around cylinder with ideal fluid, the stream function and the wind velocities are given as follows:

$$\psi = U_\infty y\left(1-\frac{a^2}{x^2+y^2}\right) \tag{1}$$

$$u = \frac{\partial \psi}{\partial y} = U_\infty\left[1+a^2\frac{y^2-x^2}{\left(x^2+y^2\right)^2}\right] \tag{2}$$

$$v = -\frac{\partial \psi}{\partial x} = -U_\infty a^2\frac{2xy}{\left(x^2+y^2\right)^2} \tag{3}$$

where ψ is the stream function; U_∞ is the inference wind velocity, a is the radius of the cylinder; u、v are the longitudinal velocity and vertical velocity, respectively; x、y are the corresponding coordinate of the flow, as shown in Fig.2.

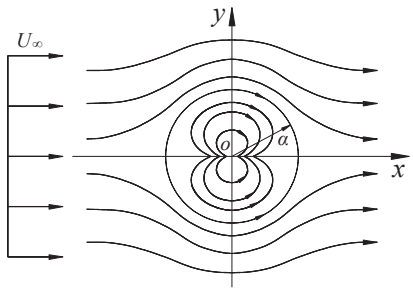

Fig.2 Flow around cylinder with ideal fluid

It can be seen from Eq. (3) that, when $x=0$ or $x=\pm\infty$, the vertical wind velocity v is equal to zero. According to the nature of stream function, each streamline can be regarded as a wall without influence the initial flow field. Therefore, the streamline can be taken as the shape of transition section, and its starting and end points are just the coordinate points of which vertical wind velocity is zero in Fig.2. Note that, the transition section may have an indefinite length if take the coordinate point $x=\pm\infty$ at the end point of the transition section. Therefore, to satisfy the length requirements of transition section, the Eq. (1) can be rewritten as:

$$\begin{aligned}\psi &= U_\infty y\left[1-\frac{a^2}{y^2}\cdot\frac{1}{1+(x/y)^2}\right]\\ &= U_\infty y\left[1-\frac{a^2}{y^2}\cdot\sum_{n=0}^{\infty}(-1)^n\left(\frac{x}{y}\right)^{2n}\right]\\ &= U_\infty y\left\{1-\frac{a^2}{y^2}\left[1-\left(\frac{x}{y}\right)^2+\left(\frac{x}{y}\right)^4-\left(\frac{x}{y}\right)^6+\left(\frac{x}{y}\right)^8-\left(\frac{x}{y}\right)^{10}+\cdots\right]\right\}\end{aligned} \tag{4}$$

From the perspectives of practical applications and further researches, retaining only the first five terms in Eq.(4), and the corresponding stream function and the vertical wind velocities as given as:

$$\psi_5 = U_\infty y - a^2 U_\infty \frac{1}{y} + a^2 U_\infty \frac{x^2}{y^3} - a^2 U_\infty \frac{x^4}{y^5} + a^2 U_\infty \frac{x^6}{y^7} - a^2 U_\infty \frac{x^8}{y^9} \tag{5}$$

$$v_5 = -\frac{\partial \psi_5}{\partial x} = -2a^2 U_\infty \frac{x}{y^3} + 4a^2 U_\infty \frac{x^3}{y^5} - 6a^2 U_\infty \frac{x^5}{y^7} + 8a^2 U_\infty \frac{x^7}{y^9} \tag{6}$$

Let the vertical wind velocity in Eq. (6) equal to be zero, and then it leads to:

$$\begin{cases} x_1 = 0.778y \\ x_2 = 0 \end{cases} \tag{7}$$

where x_1、x_2 can be taken as the x-coordinate value of starting and end points of the transition section, respectively. Substituting Eq. (7) into Eq. (5) yields:

$$\begin{cases} y_1 - \dfrac{0.673a^2}{y_1} = \dfrac{\psi_5}{U_\infty} \\ y_2 - \dfrac{a^2}{y_2} = \dfrac{\psi_5}{U_\infty} \end{cases} \tag{8}$$

where y_1、y_2 are the corresponding y-coordinate value of starting and end points of the transition section, respectively, and the value of y_1、y_2 can be obtained from Eq.(8):

$$\begin{cases} y_1 = \dfrac{m + \sqrt{m^2 + 2.692a^2}}{2} \\ y_2 = \dfrac{m + \sqrt{m^2 + 4a^2}}{2} \end{cases} \tag{9}$$

where $m=\psi_5 / U_\infty$.

Hence, the starting coordinate point (x_1, y_1) and end coordinate point (x_2, y_2) are all determined via Eqs. (7) and (9). Since the length of the air flow from the starting point of the transition section to the point that the air get stable must be fully short. Therefore, the length of transition section also should be fully short. For the shortest transition section (refer to the projected length), in other words, its equivalent slope k_0 (shown in Fig.3), which can be expressed as Eq. (10), must be maximum.

$$k_0 = \frac{y_2 - y_1}{x_2 - x_1} = \frac{y_2 - y_1}{0.778y_1} \tag{10}$$

Substituting Eq. (9) into Eq. (10) yields:

$$k_0 = 1.285\left(\frac{\sqrt{m^2 + 4a^2} - \sqrt{m^2 + 2.692a^2}}{m + \sqrt{m^2 + 2.692a^2}} \right) \tag{11}$$

And when $m \to -\infty$, the maximum k_0, denoting by k_{0max}= 0.624, which is independent of the value of a. Usually, the height of transition section is approximately equal to the height of the terrain model boundary, denoted by h_0, thus, $h_0 = y_2 - y_1$, according to the Eqs. (9) and (11), the relation between a and m can be obtained as follows:

$$\begin{cases} \dfrac{m+\sqrt{m^2+4a^2}}{2}-\dfrac{m+\sqrt{m^2+2.692a^2}}{2}=h_0 \\ 1.285\left(\dfrac{\sqrt{m^2+4a^2}-\sqrt{m^2+2.692a^2}}{m+\sqrt{m^2+2.692a^2}}\right)=k_0 \end{cases} \tag{12}$$

It should be noted that, the above equations are all derived based on the potential flow theory, therefore, in the actual viscous fluid, the value of k_0 need to adjusted, but the value of k_0 must smaller than $k_{0\max}$= 0.624. When the values of h_0 and k_0 are determined, then the values of a and m can be obtained by solving the Eq.(12), next substituting h_0 and k_0 into the Eq. (5) yields the following form of transition section curve:

$$y-\frac{a^2}{y}+\frac{a^2x^2}{y^3}-\frac{a^2x^4}{y^5}+\frac{a^2x^6}{y^7}-\frac{a^2x^8}{y^9}-m=0 \tag{13}$$

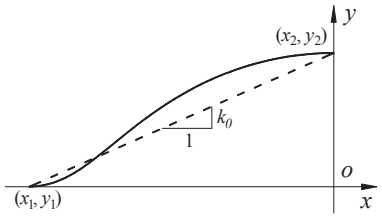

Fig.3 Equivalent slope of curve transition

3 WIND CHARACTERISTICS BETWEEN CURVE TRANSITION SECTION AND RAMP TRANSITION SHAPES

The references (Hu et al. 2006; Chen et al. 2008) both adopted the ramp transition section, but the applicability of the ramp transition section to the boundary transition section for the mountains-gorge bridge site terrain model needs to be validated. Therefore, the flow separation behavior and distribution characteristics of wind velocity field between the curve transition section and the ramp transition section are compared in the next.

3.1 *Numerical model*

In order to focus on the flow characteristics of different transition sections, the terrain model was simplified to a 2D platform terrain with the height of 0.385m, and the same two transition sections are ser at the two ends of the platform terrain. The total length of transition sections and the platform terrain is 18.0m. Since the ramp transition section with a angle of 30° could satisfy the practical engineering (Hu et al. 2006), so the curve transition section with the equivalent slope of 0.58 (corresponding equivalent angle is 30°) are chosen to be compared. Using the parameters of h_0 =0.385m and k_0 =0.58, the specific form of curve transition section can be obtained by Eqs.(12) and (13), and it is given as Eq.(14). Besides, an empty domain model with no transition sections is also presented to serve as a basic reference model, it could judge which transition section is better when the air flow over the transition section. The 2D platform terrain model and different transition sections are shown in Fig.4.

$$y-\frac{21.298}{y}+\frac{21.298x^2}{y^3}-\frac{21.298x^4}{y^5}+\frac{21.298x^6}{y^7}-\frac{21.298x^8}{y^9}+15.968=0,\quad (0.664\le x\le 0) \tag{14}$$

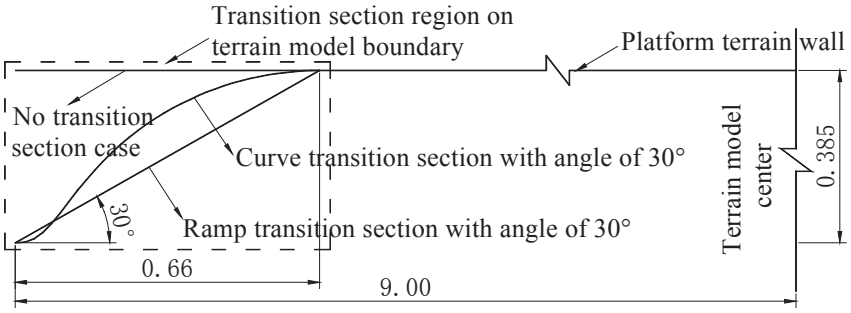

Fig.4 Terrain model and different transition section shapes (dimensions are given in m)

3.2 *Boundary conditions and analysis parameters*

The length from the center of terrain model to the inlet and outlet boundaries are 35.0m and 55.0m, and the height of the domain is 15.0m, satisfying the requirement of blocking ration smaller than 3% (Bekele and Hangan 2002). The domain is discretized by structured meshes and the height from the center of the wall-adjacent cell to the bottom wall is 0.0005m. As a result, the total number of meshes is 700,000. The boundaries are shown in Fig.5, in which the inlet velocity is 10.0/s and the turbulence intensity is 0.5%. In this investigation, the CFD commercial software FLUENT 6.3 is employed, and the flow is supposed to be incompressible and steady. When choosing the discretization schemes for the governing equations, the SIMPLEC algorithm is applied to the pressure-velocity coupling, the second order interpolation scheme is used for pressure, and the second order upwind scheme is adopted for moment and turbulence properties. The values set for the inlet boundary are used to initialize the flow field, and the scaled residuals for all variables are set to be 10^{-6}. For the no transition section case, the height of the domain is 14.615m (=15m-0.385m), and the corresponding inlet velocity is set to 10.263m/s (=10×15/14.615m/s).

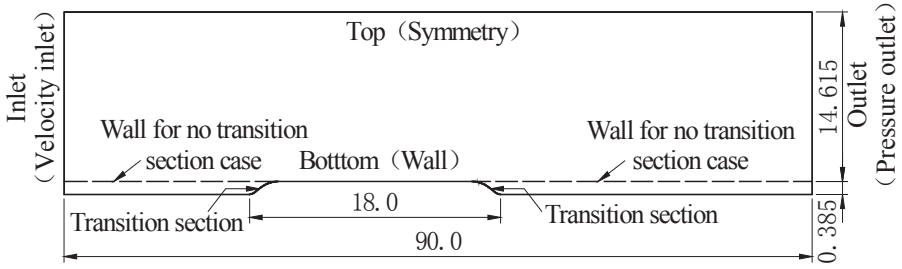

Fig.5 Schematic diagram of computational domain and boundary conditions (unit: m)

3.3 *Comparison of flow separation behavior*

Flow separation can lead to a thicker boundary layer or a more unstable flow; therefore, an appropriate boundary transition section should avoid the flow separation. Fig.6 compares the wall shear stress between the curve transition section with equivalent angle of 30° and the ramp transition section with an angle of 30°. It can be seen from the figure that the wall shear stress of curve transition section and the ramp transition section are all smaller than zero at the starting point (x=-9.0m), which indicates that the flow separation is occurred. Furthermore, at the end point (x=-8.34m) of the transition section, only the wall shear stress of the ramp transition section is also smaller than zero, so flow separation is also occurred at this position for the ramp transition section. Fig.6 also shows the wall shear stress of no transition section case, the wall shear stresses of curve transition section are closer to those of

no transition section case, which implies that the flow characteristics near the wall for the curve transition section are more close to those of no transition section.

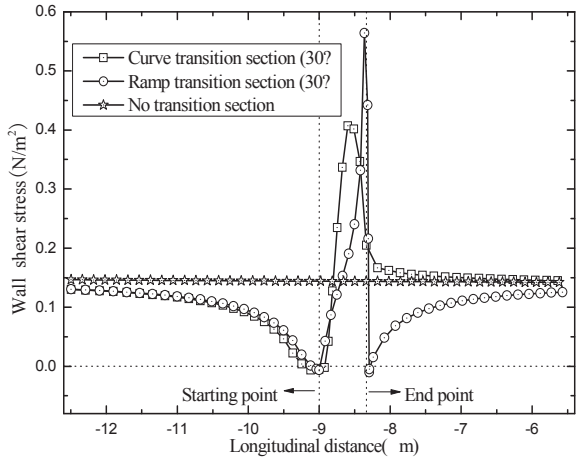

Fig.6 Distributions of wall shear stress

3.4 *Distribution characteristics of wind field after air flowed over the transition section*

When air flows over the transition section, the characteristics of the air, such as the velocity and wind attack angle, will inevitably change. For different transition sections, the distribution characteristics of wind field will have great differences. A reasonable treatment is to adopt the normalization value. The normalized wind velocity profiles at the end point of the two transition sections and the middle of the platform terrain are shown in Figs.7 and 8, the wind velocity at the end point of the ramp transition section accelerate greatly, which has a great difference from that of no transition section case. However, the wind profile of the curve transition section is more close to that of the no transition section case. In Fig.8, the wind profile of the curve transition section is also more close to that of the no transition section case than the ramp transition section, which indicates that the distribution characteristics of wind field after the air flowed over the transition section is more similar to those of the no transition section case.

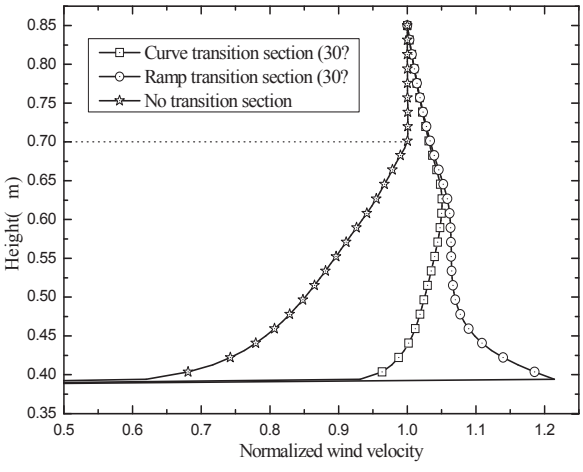

Fig.7 Normalized wind velocity profiles at the end of transition section

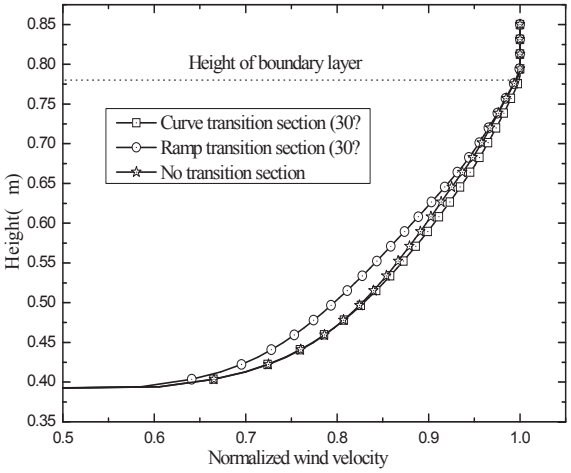

Fig.8 Normalized wind velocity profiles at the middle of terrain model

In order to investigate the normalized wind velocity from the end point of the transition section to the middle of the platform terrain, a term of "relative normalized wind velocity difference (denoted by γ)" is introduced:

$$\gamma = \sum_{h>0.385}^{h=H} \frac{\left| v_h / v_H - v_{0h} / v_{0H} \right|}{v_{0h} / v_{0H} \cdot N} \tag{15}$$

where H is the height of the boundary layer; v_h is the velocity at the height of h from the wall; v_{0h} is the velocity at the height of h from the wall for the no transition section case, v_H is the velocity at the boundary layer, v_{0H} is the velocity at the boundary layer for the no transition section case, and N is the numbers of the points from the wall to the boundary layer. Therefore, the relative normalized wind velocity difference γ along the terrain with different transition sections are shown in Fig.9, with the position near the middle of the platform, the value of γ are all close to that of no transition section case, however, the curve transition section is more closer to the no transition section case than the ramp transition section in the value of γ.

In order to investigate the wind attack angle from the end point of the transition section to the middle of the platform terrain, similarly, the wind attack angle at different transition sections are shown in Fig.10. It can be seen from the figure that the change law of wind attack angle is similar to the relative normalized wind velocity difference γ. Furthermore, the normalized wind velocity difference and the wind attack angle of curve transition section in Figs. (9) and (10) are faster to be stable as the no transition case. Therefore, the total flow transition length of the curve transition section is shorter than that of the ramp transition sections.

As discussed above, the normalized wind velocity difference and the wind attack angle of curve transition section is closer to the no transition section case than those of the ramp transition section, which indicates that the curve transition section is more suitable to be a boundary transition section in the complex terrain.

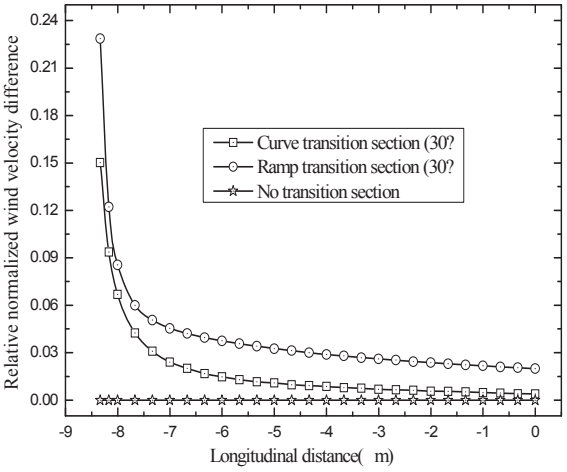

Fig.9 Distributions of average relative normalized wind velocity difference after airflow flowed along the transition section

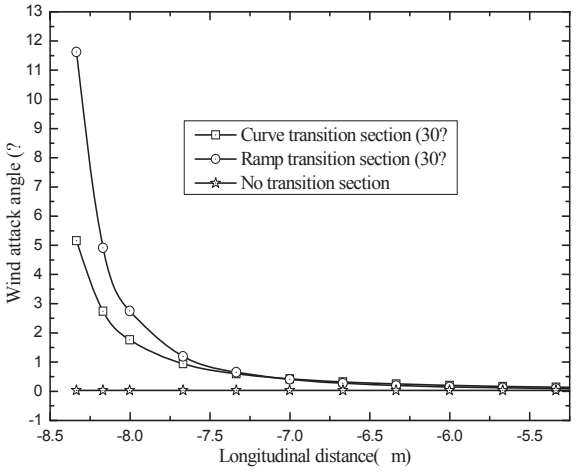

Fig.10 Distributions of average wind attack

4 WIND CHARACTERISTICS AMONG DIFFERENT CURVE TRANSITION SECTION SHAPES

In order to consider the different curve transition section shapes, the two other curve transition sections with equivalent angle of 20°and 10° are added in this study case, the different curve transition sections are shown in Fig.11.

Fig.12 shows the wind velocity profiles at the middle of the terrain for different curve transition sections, the different wind velocity profiles all have high concordance with each other. Since the wind velocity along the vertical direction for different curve transition

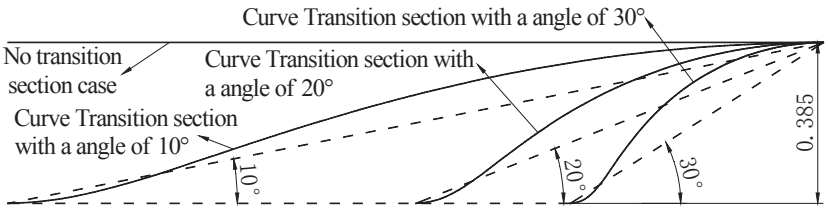

Fig.11 Different curve transition section shapes (dimensions are given in m)

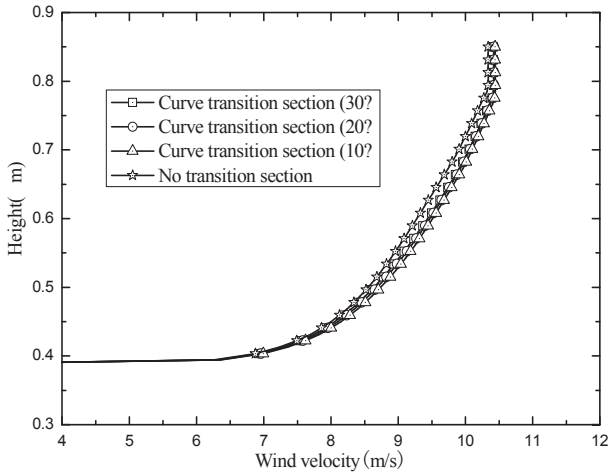

Fig.12 Wind velocity profiles at the middle of terrain model

sections can be probably different. Therefore, a term of "relative wind velocity difference (denoted by α)" is introduced:

$$\alpha = \frac{|v_h - \eta v_{0h}|}{\eta v_{0h}}, \quad \eta = \frac{14.615}{15 - y} \tag{16}$$

where y is the height from the bottom of the domain, η is the velocity ration factor, which is introduced to consider the different domain height between the model with transition sections and the model with no transition section (shown in Fig.5). The relative wind velocity difference α and the wind attack angle along the transition section and the platform terrain at the height h=0.05m are shown in Fig.13 and 14. It can be seen from the figures that the values of relative wind velocity difference α for different curve transition sections are all decrease first, then increase and then decrease again, but with the position near the middle of the platform, these values are all consistent with the no transition section case. However, it should be noted that the curve transition section with equivalent angle of 30° is faster to be stable as the no transition case. Similarly, the change law of wind attack angle is similar to that of the relative wind velocity difference, as shown in Fig.14. Through the analysis of change laws of relative wind velocity difference and the wind attack angle, it could be concluded that the total flow transition length of curve transition section with equivalent angle of 30° is shorter than those of the other curve transition sections with equivalent angle of 20°and 10°.

5 CONCLUSIONS

To study the appropriate boundary transition section shape of terrain model for mountains-gorge bridge site, a kind of transition section curves were derived based on the theory of flow around cylinder with ideal fluid. Through the analysis of different transition

sections including the curve transition sections and ramp transition section, some main conclusions are given as follows:

(1) Air separation occurs when the air flow along the ramp transition section, while it does not occur when the air flow along the curve transition section.

(2) The relatively normalized velocity profile and the wind attack angle of air flow along curve transition section are closer to those of no transition section case than air flow along the ramp transition section.

(3) The total flow transition length of the curve transition section with equivalent angle of 30° is shorter than the other curve transition sections with equivalent angle of 20°and 10°.

(4) The curve transition section with equivalent angle of 30°could be applied to the boundary transition section shape of the mountains-gorge terrain model in wind tunnel test and numerical simulation test.

Inflow turbulence generation for LES of wind flow around bluff body

B.W. Yan[a], Q.S. Li[a]

[a] *Department of Civil and Architectural Engineering, City University of Hong Kong, Hong Kong*

ABSTRACT: Large eddy simulation (LES) has been widely applied in wind-related problems. A key issue to ensure obtaining accurate results by LES is to generate an appropriate inflow field satisfying the physical wind characteristics in the atmospheric boundary layer (ABL). The methods adopted in this study for inflow field generation include two statistical methods (the random flow generation method (RFG) and the synchronizing random flow generation method (DSRFG) and a numerical method (the recycling method). These inflow generation methods are used to predict the wind effects on the Commonwealth Advisory Aeronautical Council (CAARC) standard tall building. The computational results show that all the three methods can reproduce the time-averaged velocity and turbulence intensity profiles quite well at the building position. However, the RFG method is incapable of generating fluctuating velocity satisfying the prescribed von Karman spectrum, and the DSRFG method yields random flow field satisfying the target spectrum at the inlet, while the recycling method generates the streamwise velocity fluctuation quite well at the inlet. The mean pressure coefficients on the front surface of the building are accurately predicted by all the inflow turbulence generators (the three methods), and the pressure coefficients distribution patterns on the side and back surfaces are well predicated, while some discrepancies still exit between the numerical results and wind tunnel measurements. All the RMS pressure coefficients obtained by the inflow turbulence generation methods fall in the range of wind tunnel data, illustrating that the effects of turbulence characteristics on the wind-induced pressures on the tall building are reproduced to some extent.

KEYWORDS: inflow turbulence generation; CFD, LES; bluff body; wind effect

1 INTRODUCTION

Large eddy simulation (LES) has been developed since the 1960s. But, its application to industrially relevant problems has only recently become available as LES requires sufficiently powerful computing resources. With developments of computational fluid dynamics (CFD) techniques, LES has been widely applied to simulate turbulent flows of engineering interest. In computational wind engineering (CWE), LES has become a powerful tool which has been applied in the predication of wind effects on buildings and structures, wind flow characteristics and topographical effects, wind fields in densely-arranged cities and atmospheric environments [1]. For the application of LES in atmospheric boundary layer, a very important issue to enable the LES techniques to obtain accurate results is to generate a physically appropriate flow field as an inflow boundary condition (inflow turbulence) satisfying prescribed spatial and temporal wind characteristics, since inaccurate generations of inflow turbulence can result in inaccurate simulation results of wind effects on buildings and structures. Several inflow turbulence generation techniques have been proposed in the past decade. They can be classified into three categories: synthetic method, precursor simulation, and recycling method.

The simplest method is to superimpose the random noise with proper turbulence intensity on the measured mean velocity distribution. But, such a method requires sufficient field measurement information from ground to the gradient height, which is usually not available, and this method ignores the cross-correlations between velocity components, namely Reynolds stresses

and spatial relations in turbulence structures. And the Lack of the spatial information can be solved by taking considerable settling distance to simulate the entire upstream region before the mean flow reaches the equilibrium boundary layer. Instead of using the problem-dependent settling distance, the recycling method was introduced by Spalart [2] using the periodic boundaries to reduce the settling distance. This method was further developed by Lund et al. [3] who introduced the rescaling idea to specify a precise inlet profile satisfying the prescribed shear stress and momentum thickness. Kataoka and Mizuno [4] simplified Lund's rescaling method using the constant boundary layer thickness in place of the similarity laws of the boundary law. Nozawa and Tamura [5] further developed Lund's method for generation of boundary layer conditions. Their method is similar to the method employed in wind tunnel tests to simulate boundary layer conditions. Liu and Pletcher [6] indicated that the position of the recycling and rescaled plane could cause a difficulty resulting from the coupling of the initial and inflow condition which will influence the computational cost, and they proposed a modification to Lund's method by using dynamically positioned recycling plane according to instantaneous flow properties. All the above mentioned methods demand an auxiliary LES computation with streamwise periodic boundaries to specify a fully developed inlet profile for the flow around complex geometries as the starting point. For the synthetic methods, one common way is to obtain the velocity fluctuations from an inverse Fourier transform of prescribed spectrum which follows the prescribed power spectrum density and spatial correlations. This method was initiated by Hoshiya [7], then developed by Iwatani [8], and Kondo et al. [9]. Another synthetic approach is based on proper orthogonal decomposition (POD) and linear stochastic estimation (LSE) in combination with the simultaneously measured fluctuating velocity obtained by hot wire probes or stereoscopic particle image velocimetry (SPIV) conducted by Perret et al.[10]. The methods based on the variant of spectral method for generation of an isotropic continuous flow field were further developed by several researchers including Smirnov et al. [11], Klein et al. [12], Batten et al. [13] and Huang et al. [14]. Smirnov et al. [11] superimposed turbulence length scale and time scale into the basic model proposed by Kraichnan [15] to generate an isotropic divergence-free fluctuating velocity field with the target length scale and time scale, and they realized the inhomogeneous and anisotropic turbulence characteristics through a scaling and orthogonal transformation of the resulted flow field with a given anisotropic velocity correlation tensor. Huang et al. [14] further developed the Kraichnan's approach to establish a general inflow turbulence generation method capable of generating a spatially correlated turbulent flow field satisfying any target spectrum including the von Karman spectrum through the discretizing and synthesizing procedures. Another method, the precursor simulation, was conducted to run a separate precursor calculation of an equilibrium flow to generate a library of turbulent database that can be reintroduced into the main simulation. Although the method demands extra computational efforts and cost to establish the database, the inflow field should possess the main characteristics of turbulence structures including temporal and spatial fluctuations and a reasonable energy spectrum.

2 INFLOW TURBULENCE GENERATION METHODS

The methods adopted in this study are the random flow generation method by Smirnov et al. [10] and the discretizing and synthesizing random flow generation method by Huang et al. [14], and the recycling and rescaling method based on Kataoka's research works [4].

2.1 *Random flow generation method (RFG)*

The spectral synthesizer in the Fluent code is based on the RFG method modified by Smirnov et al. [11]. The method can be used to generate fluctuating velocities which are computed by synthesizing a divergence-free velocity vector field from the summation of Fourier harmonics on the basis of the input turbulence boundary conditions. In the implementation of the Fluent code, the number of the Fourier harmonics is fixed to 100 [16].

2.2 *Discretizing and synthesizing random flow generation (DSRFG)*

Another approach employed in the study is DSRFG, which is based on Kraichnan's method to establish a general inflow turbulence generator capable of generating a spatially correlated turbulent flow field satisfying any target spectrum including the von Karman spectrum. A brief formulation of the method is presented below [14].

$$u(x,t)=\sum_{m=k_0}^{k_{\max}} u_m(x,t)=\sum_{m=k_0}^{k_{\max}}\sum_{n=1}^{N}\left[\, p^{m,n}\cos(\tilde{k}^{m,n}\cdot\tilde{x}+\omega_{m,n}t)+q^{m,n}\sin(\tilde{k}^{m,n}\cdot\tilde{x}+\omega_{m,n}t)\right] \tag{1}$$

where $p^{m,n}=\dfrac{\varsigma\times k^{m,n}}{\left|\varsigma\times k^{m,n}\right|}\sqrt{a\dfrac{4E(k_m)}{N}}$, $q^{m,n}=\dfrac{\xi\times k^{m,n}}{\left|\xi\times k^{m,n}\right|}\sqrt{(1-a)\dfrac{4E(k_m)}{N}}$, $\tilde{x}=\dfrac{x}{L_s}$, $\tilde{k}^{m,n}=\dfrac{k^{m,n}}{k_0}$, $\left|k^{m,n}\right|=k_m$,

$\omega_{m,n}\in N(0,2\pi f_m)$, $f_m=k_m\times U_{avg}$, ς and ξ are the vector form of ς_i^n and ξ_i^n. L_s is the turbulence integral length scale which denotes the two-point spatial correlation. a is a random number uniformly distributed between 0 and 1. U_{avg} is the average velocity at the reference height. N =100 (sampling number for each wave number k_m).

The artificial velocity fluctuations generated by the turbulence generation method will be resolved by the grid which is commonly chosen to be the spatial filter in LES. This means that the artificial velocity will be transformed into velocities and SGS viscosities through the chosen SGS model. For this reason, the grid scale between the main building and the inlet of the computational domain should be fine enough to enable most of the artificial velocity fluctuations generated at the inlet can be resolved and then acting on buildings.

2.3 *Recycling method*

The recycling and rescaling method is based on the approach proposed by Kataoka and Mizuno [4], which is a simplified version of Lund's method. In the modified method, the development of the boundary layer thickness is neglected and treated as constant and the mean velocity profile is fixed at inflow. As shown in Figure.1, the approach is to extract instantaneous velocity fluctuations from the recycled station and reintroduce the rescaled fluctuations at the inlet in an auxiliary simulation of a zero pressure gradient boundary layer, which is denoted as driver section. The auxiliary simulation is spatially developing through the rough wall surface, and generates its own inflow conditions which make the approach convenient for an existing inflow–outflow computational domain that can be converted to the inflow turbulence generator after a sequence of simple operations. The coupled inlet and recycling plane are defined as "pseudo-periodic condition", and the periodic boundary conditions in the streamwise direction are appropriate for fully developed flow without a need for a development section. In this study, the inflow generation calculation in the driver region is synchronized with the main simulation in the main domain (shown in Figure.2). The velocity fluctuation was generated based on Kataoka's method [4], and the rough wall surface is realized with the cubic roughness elements arranged in the streamwise direction.

L is the width of the cubic roughness element while G is the center distance between the neighboring roughness elements. In this case, G is chosen as $5L$, and such an arrangement gave a roughness density λ=8.0%. In addition, the generation of the Gaussian random perturbations is superimposed in the top region at the inlet for the recycling method in the auxiliary computation since the lower turbulence intensity generated by the recycling method was observed in recent study. The velocity components prescribed at the inlet following Kataoka's method [4] are given as follows:

$$
\begin{aligned}
u_{inlt(y,z,t)} &= \langle u \rangle_{inlt}(z) + \phi(\theta) \times \{u(y,z,t) - \langle u \rangle(y,z)\}_{recy} \\
v_{inlt(y,z,t)} &= \phi(\theta) \times \{v(y,z,t) - \langle v \rangle(y,z)\}_{recy} \\
w_{inlt(y,z,t)} &= \phi(\theta) \times \{w(y,z,t) - \langle w \rangle(y,z)\}_{recy}
\end{aligned} \tag{2}
$$

The following damping function [16] was adopted to restrict the velocity fluctuations from developing for the unstable conditions.

$$
\phi(\theta) = 0.5 \left\{ 1 - \frac{\tanh\left[\dfrac{8.0(\theta - 1.0)}{-4.0(\theta - 0.3) + 0.7} \right]}{\tanh(8.0)} \right\} \tag{3}
$$

where $\theta = z / \delta$, δ is the boundary layer thickness.

3 BUILDING MODEL, COMPUTATIONAL DOMAIN, MESH ARRANGEMENT AND BOUNDARY CONDITIONS

3.1 *Building model*

In this study, the selected building is the Commonwealth Advisory Aeronautical Council (CAARC) standard tall building. The building shape is rectangular prismatic and its full-scale dimensions are: sides 30.8 m by 45.72 m and height 183.88 m with density 160 kg/m^3 and natural frequency 0.2 Hz. As introduced by Melbourne [18], the building is flat-topped, without parapets, and the external surfaces are flat without mullions or other geometric disturbances. Since

the 1970s, the building model has been intensively investigated in various wind tunnels as a standard model to study the wind effects on tall buildings and several wind tunnel measurements about this building model were reported [19,20].

3.2 *Computational domain*

A 1:250 scale rigid model of the CAARC building is considered in this study. The main computational domain is shown in Fig.2. The Reynolds numbers involved in the simulations is the same as that in the wind tunnel experiment conducted by Obasaju [19] in British Maritime Technology (BMT) Environmental Wind Tunnel. As shown in Fig.2, the computational domain covers 30*B* (*B* is the breadth of the building model) in the streamwise direction, 17*B* in the spanwise direction and 2*H* (*H* is the height of the building model) in the vertical direction. The blockage ratio of the computational domain is nearly 3% which is regarded as acceptable in CWE community. In consideration of the periodic boundary in the spanwise direction, the size of the across-wind dimension is chosen to be at least twice the size of the largest eddy.

3.3 *Mesh arrangement*

For the auxiliary driver section using the recycling method, structured mesh arrangement is applied to discretize driver section, and for the need of capturing the turbulence generated by the roughness elements, the grid points are clustered near the cubic element surfaces and the ground neighborhood. About 1.2×10^6 mesh elements are used in discretizing driver section.

For the mesh arrangements in the main region, the structured mesh is used in the domain far from the building model and the unstructured mesh is adopted near the building model surfaces, since the Fluent code [16] is capable of dealing with both structured and unstructured grids. The advantages of this kind of mesh arrangement are capable of refining the grid distribution in the building surface neighborhood and avoiding excessive grid-stretching and reduce the total grid number in the main region. On the surfaces of the building model, a boundary layer with 20 grids is adopted and the first grid height next to the building surface is chosen as *B*/1000 and a growth factor 1.05 so that the near-wall grid y^+ ($y^+=\rho uy/\mu$) is in the order of unit. Finally, the total grid number in the main region is almost 1.5×10^6.

3.4 *Boundary conditions*

In order to obtain better agreement between wind tunnel experiment and numerical results, the inflow boundary conditions adopted in this study is identical as that in the wind tunnel experiment of Obasaju [19]. The log law wind speed profile of the atmospheric boundary layer simulated in the wind tunnel study of Obasaju [19] is given as follows:

$$\frac{U}{U_\tau}=2.5\ln(\frac{Z-D}{Z_0}) \tag{4}$$

where U_τ is friction velocity, D is the zero plane above ground, and Z_0 is the surface roughness length parameter. The parameters chosen in the present numerical simulation are U_τ=14.5m/s, D=10 mm, Z_0=1.3 mm. The inlet wind speed corresponding to the building height is U_H=14.5 m/s.

As discussed by Tominaga et al. [21], the influence of inflow turbulence for the LES was extremely important. Hence the turbulence intensity profile should be properly reproduced for the accurate simulation of the wind effects on the tall building. The profiles of the mean wind speed and turbulence intensity are shown in Fig.3.

For the case using the inflow turbulence generated by the recycling method, pseudo-periodic boundary conditions are used in the streamwise directions, and the velocity inlet is used for the cases using other inflow generation methods. For all the cases, the periodic boundary conditions are used in the spanwise direction, with all properties being equal at equivalent points on pairs of periodic boundaries which means the distance between the two periodic boundaries

must be such that two-point correlations are zero for all points on a pair of periodic boundaries. This denotes that the distance should be chosen to be at least twice the size of the largest eddies so that the effect of one boundary on the other is minimal. A symmetry condition (vanishing vertical derivatives of the streamwise and spanwise velocity components, as well as vanishing vertical velocity) at the top boundary of the computational domain is adopted. For the LES simulation, outflow boundary conditions are less troublesome, and the familiar zero gradient boundary condition is used for all the variables normal to the outflow boundary. For all the surfaces of the cubic roughness elements, the building model and the ground, the boundary conditions are set to be no-slip wall boundary (u=v=0) which is appropriate for the velocity components at solid walls.

4 IMPLEMENTING AND NUMERICAL SETUP

4.1 *Subgrid-scale turbulence model*

The subgrid-scale (SGS) turbulence models in Fluent code employ the Boussinesq hypothesis as in the RANS models. The simple model was firstly built on Prandtl's mixing length model and it is assumed that we can define a SGS viscosity μ_{SGS} in terms of one length scale and one velocity scale, as suggested by Smagorinsky [22]. However, the Smagorinsky model is purely dissipative which is not particularly appropriate for the high Reynolds number bluff body flows. Germano et al. [23] conceived a procedure in which the Smagorinsky model constant, C_S, is dynamically computed based on the information provided by the resolved scales of motion. The dynamic procedure thus obviates the need for users to specify the model constant C_S in advance. In this study, the dynamic Smagorinsky-Lily model is adopted as the default subgrid-scale turbulence model, and the C_S obtained by the dynamic Smagorinsky-Lilly model varies in time and space over a fairly wide range. In Fluent code, C_S is clipped between zero and 0.23 by default to avoid numerical instability [16].

4.2 *Solution strategy*

The solver for incompressible flow in Fluent code employs an algorithm which belongs to a general class of methods called the projection method [24]. In the projection method, the governing equations are solved sequentially. The pressure velocity coupling method chosen for the present simulation is SIMPLC (Semi-Implicit Method for Pressure-Linked Equations Consistent) algorithm [25], which is one of variants of the basic SIMPLE algorithm. For LES, second-order or higher-order discretisation techniques are needed, because upwind differencing, which was standard practice in early CFD computations with RANS turbulence modelling, is far too diffusive and generates large truncation errors. The bounded central difference, a default convection scheme for LES in Fluent code, is used to discretize the convective terms of momentum equations for its relative low diffusivity. The central differencing is also applied to discretize the diffusion term. The time derivative is discretized using the second order backward differences and the spatial discretization is treated implicitly. The non-linear terms produced by fully-implicit discretization of the convection term is solved by an iterative process. The Green-Gauss cell based method is used for numerical approximation of pressure gradients. In order to obtain numerical solutions that are statistically converged quickly, steady RANS model had been used before the LES was performed. In other words, the results of the RANS simulation were adopted to be the initial solutions of the LES.

A 12CPUs workstation was used in parallel for the LES. With consideration of the accuracy of the LES and computational expenses, it was decided to adopt 0.025 seconds per time step for the computations and the convergence criterion for the scaled residuals within one time step is less than 1×10^{-4}.

5 RESULTS AND DISCUSSIONS

5.1 *Wind characteristics*

Velocity values are taken at the building model position for all the inflow generation methods to validate the characteristics of the generated velocity field when the main domain is computed with the building model filled with additional computing grid points.

In this section, the time-averaged longitudinal velocity and turbulence intensity profiles at the building model position are compared with the target profiles. As demonstrated in Figure.3, the time-averaged velocity and turbulence intensity profiles are reproduced quite well. For the mean velocity profile, all the methods reproduce the variations of velocity in vertical direction quite well, while that generated by DSRFG is slightly higher in the ground neighborhood and lower at the top in comparison with those by the other methods and the target profile. For the turbulence intensity profile, all the three methods generate reasonable results, although there are some discrepancies between the target values and the predictions generated by the RFG and the recycling method which reproduce lower turbulence intensity at higher elevations. Particularly, the turbulence intensity reproduced by the recycling method can impose the random perturbation at the top inlet in the auxiliary driver section for the inflow turbulence generation.

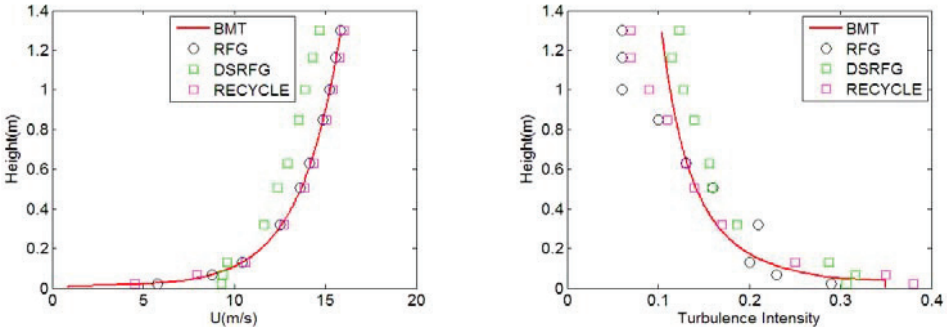

Figure.3 Mean velocity profile and turbulence intensity profile at the building position

The velocity values reproduced by DSRFG at the inlet of the main region are considered herein. In Fig.4, the wind velocity spectral curves at the inlet and the building model position are displayed, which were obtained by two power spectral density estimators: Welch estimator and Yuler-Walker estimator. The spectra of u, v and w velocity fluctuations at the inlet demonstrated in Figs.4(a)~(c) are found to be predicted well in comparison with the target Karman spectrum, while the spectra of three velocity component fluctuations at the building model position (shown in Figs.4(d)~(f)) illustate relatively large discrepancies in the frequency range larger than 1 Hz. Such a decay of the power spectral density in the relatively higher frequency range was reported to be caused by the grid resoluation [4]. Therefore, it is necessary to refine the grids distributed between the building surfaces and the inlet to minimize the decay of the ernergy contained in the high frequency range.

As discussed in [14] and shown in Figs.5(a)~(c), the velocity component fluctuations generated by RFG are incapable of simulating wind velocities satisfying the von kaman spectrum. Actually, there are obvious discrepancies between the simulated spectra and the target spectra. In particular, the energy contained in the high frequency range is neglected by RFG and such a spectrum is called Gaussian spectrum. For the longitudinal velocity fluctuating component, the spectrum simulated by the recycling method is found to follow the target von Karman spectrum until the frequency reaches to 0.2 Hz, while the energy contained in the higher frequency range shows some discrepancies compared with the von Karman spectrum. Such a decay in the high frequency range may be attributed to the restriction of the grid resolution.

5.2 *Wind loading on the building model*

The incident wind flow considered in this study is normal to a side of the building model surface. Fig.6 shows the mean and RMS pressure coefficients at the 2/3 height of the building model, as demonstrated in Fig.6, which were obtained by the present LES and wind tunnel tests. It can been seen that the mean pressure coefficients on the windward face calculated by the three inflow generation methods are nearly the same as those of differet wind tunnel experiments. For the side and back faces, the mean wind pressure distribution patterns predicted by different inflow turbulence generation methods are consistent with those of various wind tunnel experiments. For RMS pressure coefficients shown in Fig.6, not only obvious discrepancies exit between the numerical predictions and the wind tunnel test data, but also among the model experimental results. As discussed by Li and Melbourne [26, 27], the reasons for the discrepancies of RMS pressure coefficients among different wind tunnel experiments can be attributed to the different turbulence intensity and turbulence integral length scale values or profiles of approaching wind flows as well as blockage ratio encountered in the model tests.

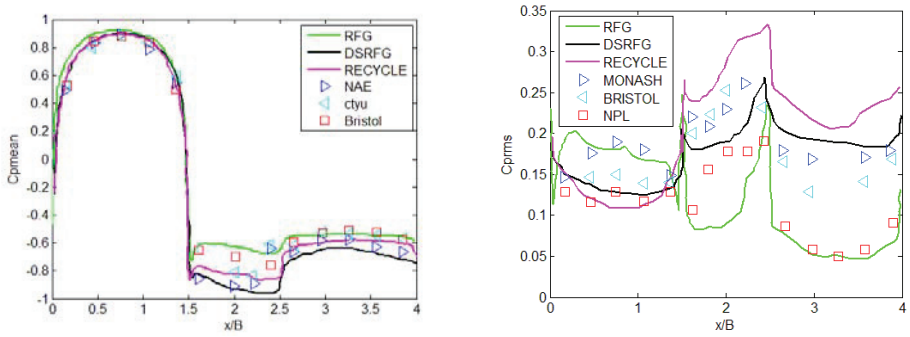

Figure.6 Mean and RMS pressure coefficients at 2/3 height of the building model

As shown in Fig.6, the fluctuating pressure coefficient distribution shapes calculated by the three inflow turbulence generation methods are similar while the distribution predicted by DSRFG is enveloped by the wind tunnel experimental measurements. This illustrates that DSRFG can provide more accuarte predictions of the wind loading on the tall building than the other two methods.

6 CONCLUSIONS

In this study, we focused on examining the performance of three methods (DSRFG, RFG and the recycling method) for inflow turbulence generation. The computational results showed that all

the three methods can reproduce the time-averaged velocity and turbulence intensity profiles at the building position quite well. The spectra of random wind velocities reproduced by DSRFG showed good agreement with the target spectrum at the inlet and that of the longitudinal velocity simulated by the recycling method is similar to the von-Karman spectrum. However, RFG is incapable of generating fluctuating velocity satisfying the prescribed von Karman spectrum. The velocity spectra at the building position simulated by DSRFG and the recycling method are affected by the grid resolution between the windward surface of the building and the inlet. The lower grid resolution may result in fast decay of wind velocity spectra in the high frequency range. In order to verify the accuracy of the wind loading predication by the three methods, the time-averaged and RMS pressure coefficients distributed at the 2/3 height of the CAARC building were compared with available wind tunnel test data obtained by several labs. It was found that the mean pressure coefficients on the front surface of the building were accurately predicted by all the three inflow generation methods and the pressure coefficient distribution pattern on the side and back surfaces were also well predicated. All the RMS pressure coefficients obtained by the three inflow turbulence generation methods fall in the range of the model test data by various wind tunnel experiments, verifying that the effects of turbulence characteristics of approaching wind flows on the building surface pressures were reproduced to some extent. It was shown through the comparison that DSRFG can provide more accuarte predictions of the wind loading on the tall building than the other two methods.

7 ACKNOWLEDGEMENT

The work described in this paper was fully supported by a grant from the Research Grants Council of Hong Kong Special Administrative Region, China (Project No: CityU 117709) and a grant from City University of Hong Kong (Project No. 7002615). The authors would like to thank Dr. Shenghong Huang of the University of Science and Technology of China for helpful discussions.

Turbulence simulation in wavelet domain based on Log-Poisson model: univariate and multivariate wind processes

Chao Yin[a], Teng Wu [a], Ahsan Kareem [a]

[a]*Nathaz Modeling Laboratory, University of Notre Dame, Notre Dame, IN, USA*

ABSTRACT: The wind in atmospheric boundary layer is characterized as turbulent flow at a high Reynolds number. The complexity in turbulence is mainly from its nonlinear and multi-scale structure. This paper simulates the wind process utilizing the wavelet domain based on the Log-Poisson model where both multi-scale structure and the intermittency could be properly represented. Following simulating a univariate process, a methodology for simulating multivariate processes is also established, where a correction technique based on the coherence of the wavelet coefficients at each scale is utilized. The resulting simulation follows the characteristic features of the sample record and offers a more realistic simulation than the spectral representation based methods.

KEYWORDS: Turbulence; non-Gaussian; wavelet; Log-Poisson model; multivariate processes

1 INTRODUCTION

The wind process in atmospheric boundary layer is characterized as turbulent flow at a high Reynolds number. A physical origin of the complexity in turbulence is due to the nonlinearity controlled by the Navier-Stokes equations. As a result, turbulent flows are naturally described based on the statistics theory. Typically, turbulent fluctuations are assumed to be Gaussian. Conventional wind process simulation, such as spectral representation, is based on this assumption. Another physical origin of the complexity in turbulence is due to the multi-scale property resulting from nonlinear interactions, where the turbulence are better described utilizing the statistics of velocity difference at two locations compared with that of velocity fluctuations at a single location. As a strong discontinuous nature of turbulence, internal intermittency seems only changing the velocity statistics slightly (a broad banded probability density distribution (PDF) compared to Gaussian distribution), while it has significant effects on the statistics of the velocity difference (a considerably larger tail PDF compared with Gaussian distribution).

In order to take into account the effects of intermittency, several phenomenological models have been introduced in the literature, such as Log-normal and other multifractal models. Obviously, the conventional wind process simulation cannot take intermittency into account. On the other hand, these random cascade models are convenient to be incorporated in the wavelet based simulation[1,2]. Specifically, the recently developed Log-Poisson model[3], which is claimed to be able to reveal the physical mechanism of the intermittency phenomenon, is utilized in this study. As a result, the intermittency will be preserved in the simulated turbulence utilizing wavelet domain. The boundary condition effects on the energy containing (EC) range and the non-local relationship between the scales in the multiplicative cascade process of the inertial subrange are included in the simulation. In addition, the wavelet domain also facilitates to include non-stationary feature in the simulation often observed in atmospheric turbulence. Based on this developed framework, univariate and multivariate wind process simulation schemes are proposed and their efficacy is demonstrated by examples.

2 ANALYSIS OF WIND PROCESS

Conventional strategies of simulating wind processes are usually restricted to the second-order statistics with implied Gaussian assumption. These strategies can be generalized by Karhunen-Loeve (K-L) expansion and numerically realized with the Galerkin Scheme [4]. The generalized Gaussian process simulation scheme is given as[5]

$$V(\theta,t) \approx \sum_{k=1}^{N} \lambda_k \xi_k(\theta) \phi_k(t) \approx \sum_{k=1}^{N} \lambda_k \xi_k(\theta) \left[\sum_{m=1}^{N} d_m^{(k)} \psi_m(t) \right] \tag{1}$$

where θ is the original random variable; $V(\theta,t)$ is the target random process with respect to time *t*; $\{\lambda_k\}$ are the eigenvalues of K-L expansion; $\{\xi_k(\theta)\}$ is the identical independent distribution (*i.i.d*) standard Gaussian sequence; $\{\phi_k(t)\}$ are the eigenfunctions corresponding to $\{\lambda_k\}$; $\{d_m^{(k)}\}$ are the coefficients corresponding to the prescribed truncated orthogonal basis $\{\psi_m(t), m=1,2,\cdots N\}$. Suppose Fourier basis is selected, the simulation is equivalent to the spectral representation. On the other hand, the simulation can be extended to the nonstationary Gaussian process if wavelet basis is selected[5].

A typical turbulent flow field is not necessarily Gaussian as demonstrated by some experimental data[e.g.,6]. Specifically, the PDFs of velocity differences at the inertial scale exhibit a significant longer tail than Gaussian distribution, which is related to the intermittency in turbulence. Conventional schemes based on the second-order statistics are insufficient to describe such a non-Gaussian process. On the other hand, since typical dynamical information in turbulence is contained in the scaling quantities, based on which the wavelet coefficients are generated, wavelet expansion utilizing higher-order statistics is an appropriate tool to analyze and simulate such a multi-scale process with non-Gaussian PDF.

2.1 *Scaling properties of turbulence*

There are two significant scaling quantities describing the multi-scale structure of turbulence: the energy dissipation rate ε and the velocity difference δv. In this study, the characteristics of δv are utilized. For a turbulence flow, within the inertial range, the p^{th} order moment of δv_l at scale l has a power-law dependence on l [3],

$$\left\langle \delta v_l^p \right\rangle \sim l^{\tau_p} \tag{2}$$

where ⟨ ⟩ denotes the expectation of the random variable; τ_p represents the exponent at the p^{th} order moment. Within the EC range, δv is related to the boundary condition and may exhibit nonstationary features as it reflects the external mechanism.

2.2 *Statistical property of the Log-Poisson random cascade model*

The universal scaling law can be realized via a Log-Poisson process, which is a random multiplicative cascade process[1]. Within the inertial range, for the case of p=1, the velocity difference δv_{l_1} at scale l_1 and the velocity difference δv_{l_2} at scale l_2 has the following relation [1,3]

$$\delta v_{l_1} = W_{l_1,l_2} \delta v_{l_2} = \left[\left(\frac{l_2}{l_1} \right)^{\gamma-1} \beta^{n_{l_1,l_2}} \right]^{\frac{1}{3}} \delta v_{l_2} \tag{3}$$

where W_{l_1,l_2} is the multiplicative factor between δv_{l_1} and δv_{l_2}; γ and β are the scale-related parameters and need to be estimated based on the real turbulence flow, however, refer-

ence [3] suggests that $\gamma = 2/3, \beta = 2/3$; n_{l_1,l_2} is the independent Poisson random variable with mean λ_{l_1,l_2}, satisfying the following relation[1,2,3]

$$\lambda_{l_1,l_2} = -\frac{\gamma}{\beta - 1} \ln \frac{l_2}{l_1} \tag{4}$$

It should be noted that the above relation from l_2 directly to l_1 is identical to l_2 via l_3 to l_1.

3 SIMULATION OF WIND PROCESS

The wavelet technique is utilized here to simulate the multi-scale structure of the turbulence flow. Suppose only δv_l in the EC range depends on the external mechanism, it is reasonable to attribute the nonstationary part in the turbulence flow to δv_l within this range. Therefore, it is necessary to determine the critical scale l_c, which pinpoints the EC range and the inertial range. Usually, l_c is assumed corresponding to the frequency f_c which makes $f\tilde{S}_{VV}(f)$ maximum, where $\tilde{S}_{VV}(f)$ is the power spectrum of the wind velocity $V(t)$ with zero mean value. The frequency f_c is a function of mean wind velocity an integral scale as Karman spectrum is utilized.

Haar wavelet function is chosen here since it represents a clear physical meaning of velocity difference. Correspondingly, the relation between the wavelet scale order j and the dominant frequency f_j of *j*th Haar wavelet function can be determined[Appendix A]. Particularly, the relation between j_c and f_c is shown as

$$j_c = n + \mathrm{int}\left\{\log_2\left(\frac{f_c}{0.742}\right)\right\} \tag{5}$$

where *n* is the highest wavelet scale order used in the simulation.

3.1 *Simulation of univariate wind process*

Use $m_V(b_k, a_j)$ to denote the wavelet coefficient at the a_j scale and b_k time position, associated with the normalized form $\zeta(b_k, a_j)$. With Haar wavelet transform, $m_V(b_k, a_j)$ is closely related to δv at l_j scale[Appendix B].

3.1.1 *Simulation scheme*

The simulation scheme of univariate wind process in wavelet domain is presented in Fig. 1, which is described as follows:

(1) Determine j_c using Eq. (5);

(2) Within the EC range, $\{\delta v_{l_{j,i}}\}$ $(j = 1,\cdots,j_c;\ i = 1,\cdots,2^{n-1})$ are produced from *i.i.d* standard Gaussian sequence and transformed to $\{\zeta(b_k, a_j)\}$ $(j = 1,\cdots,j_c;\ k = 1,\cdots,2^{j-1})$;

(3) Within the inertial range, $\{\delta v_{l_{j,i}}\}$ $(j = j_c + 1,\cdots,n;\ i = 1,\cdots,2^{n-1})$ are produced independently from $\{\delta v_{l_{j-1,i}}\}$ or $\{\delta v_{l_{j_c,i}}\}$ base on

$$\delta v_{l_{j,i}} = W_{j,j-1}\delta v_{l_{j-1,i}} \quad \text{or} \quad \delta v_{l_{j,i}} = W_{j,j_c}\delta v_{l_{j_c,i}} \tag{6}$$

where

$$W_{j,j-1} = \left(\frac{l_{j-1}}{l_j}\right)^{\gamma} \beta^{n_{j,j-1}},\quad W_{j,j_c} = \left(\frac{l_{j_c}}{l_j}\right)^{\gamma} \beta^{n_{j,j_c}} \tag{7}$$

and then transform the generated $\{\delta v_{l_{j,i}}\}$ to $\{\zeta(b_k, a_j)\}$ $(j = j_c + 1,\cdots,n;\ k = 1,\cdots,2^{j-1})$;

(4) $m_V\left(b_k,a_j\right)$ is adjusted from $\zeta\left(b_k,a_j\right)$ according to the wavelet coefficients correlation at the same scale, which shares the following relation with conventional spectral density for stationary process[Appendix C]

$$m_V\left(b_k,a_j\right)=\zeta\left(b_k,a_j\right)\times\sqrt{\left\langle\left|m_V\left(b_k,a_j\right)\right|^2\right\rangle}=\zeta\left(b_k,a_j\right)\times\sqrt{2^{a_j}\int_{-\infty}^{\infty}\left|\tilde{\psi}_{a_j,b}\left(f\right)\right|^2 S_{VV}\left(f\right)df} \tag{8}$$

where $\tilde{\psi}_{a_j,b}\left(f\right)$ is the Fourier spectrum of wavelet function $\psi_{a_j,b}\left(t\right)$ at scale a_j; $S_{VV}\left(f\right)$ is the conventional spectral density with mean velocity. For a non-stationary process, the above equation is only approximately satisfied, while the exact energy distribution of wavelet coefficients should refer to the technique as Eq.(1). In essence, the eddies could be treated as scale-dependent stationary within the inertial range as they depend mainly on the internal mechanism of the turbulence rather than the external condition;

(5) Sythesize the wind process v from the generated $m_V\left(b_k,a_j\right)$.

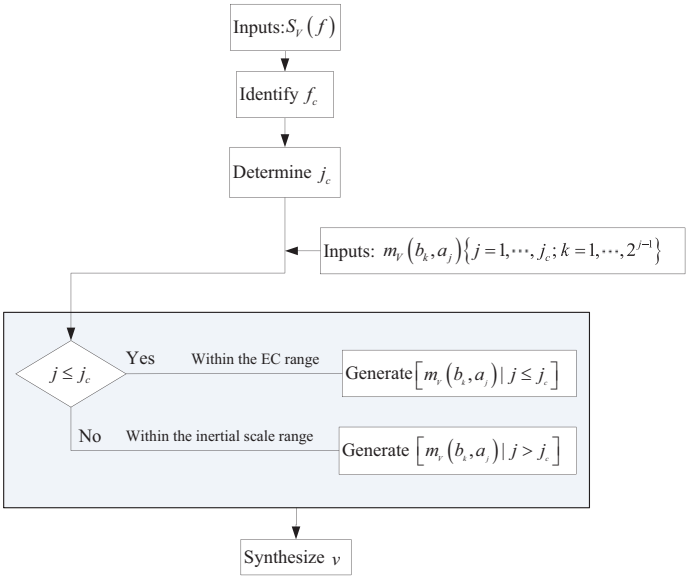

Figure 1 Simulation of univariate wind process.

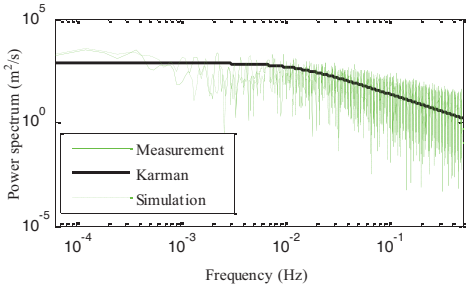

Figure 3 Power spectrum

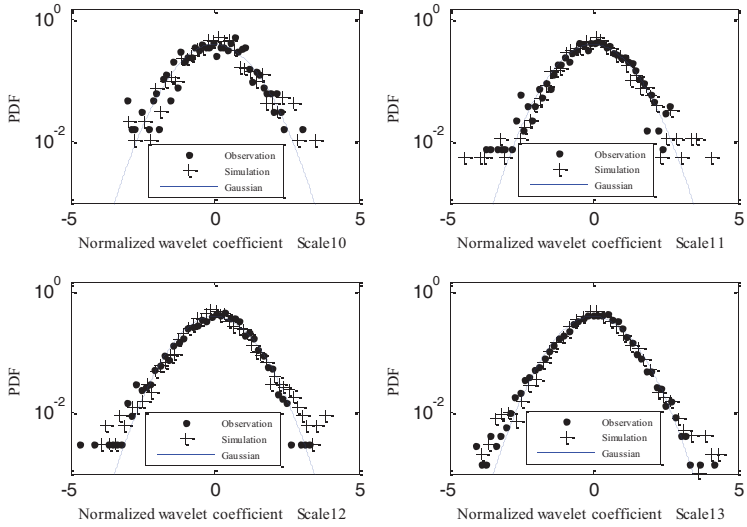

Figure 4 PDF of wavelet coefficients at some typical inertial scales.

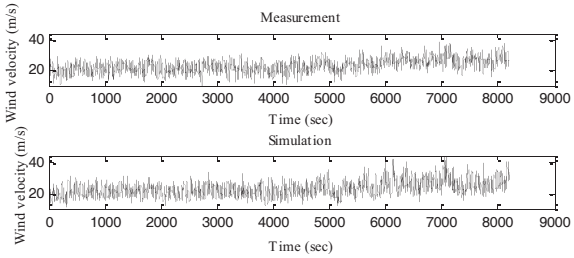

Figure 5 The measurement and simulation result of univariate nonstationary wind process.

3.1.2 *Case study*

Hurricane Katrina is utilized in this study to demonstrate the effectiveness of the proposed simulation framework. The measured data and the simulation result are shown in Fig. 2. ℓ_u is estimated as 247m and $j_c = 7$. The power spectra based on the measured and simulated data are presented in Fig. 3 together with Karman spectrum. PDFs of the wavelet coefficients at some typical inertial scales are given in Fig. 4. There is 4.59% error between the variances of the simulated process and of the measurement. A nonstationary case is shown as Fig. 5.

3.1.3 *Discussion*

It is interesting to notice that reference [1] has used a similar approach to simulate a univariate stationary wind process. This study offers a reasonable strategy for simulating nonstationary

wind. More importantly, there is a major distinction in the treatment of the Log-Poisson model between this study and reference [1]:

(1) Within the inertial range, it is known that the universal scaling law is obtained from the ergodicity assumption which implies stationarity, however, the algorithm for generating the wavelet coefficients in reference [1] distorts the ergodicity in three aspects. First, the odd wavelet coefficients are generated by involving an algebraic average of the wavelet coefficients at larger scale, while the even wavelet coefficients are not, which are given here[1],

$$\tilde{\zeta}\left(b_{k=2i+1},a_j\right)=s\times\left(2/3\right)^{m/3}2^{-1/9}\frac{\sqrt{2}\left[\tilde{\zeta}\left(b_{k=i},a_{j-1}\right)+\tilde{\zeta}\left(b_{k=i+1},a_{j-1}\right)\right]}{2} \tag{9}$$

$$\tilde{\zeta}\left(b_{k=2i},a_j\right)=s\times\left(2/3\right)^{m/3}2^{-1/9}\tilde{\zeta}\left(b_{k=i},a_{j-1}\right) \tag{10}$$

where s is a binomial random variable taking the value +1 or -1; m is equivalent to $n_{j,j-1}$ in this study. The ergodicity assumption indicates that $\zeta\left(b_k,a_j\right)$ should have identical property at each scale while reference [1] obtains the odd and even terms using different schemes; second, both $\tilde{\zeta}\left(b_{k=2i},a_j\right)$ and $\tilde{\zeta}\left(b_{k=2i+1},a_j\right)$ deviate from the actual random variables $\zeta\left(b_k,a_j\right)$ since another random variable s is involved in the expression. The case of $\tilde{\zeta}\left(b_{k=2i+1},a_j\right)$ is worse due to the average operation previously discussed; third, there should be 2^{j_n-1} basic *i.i.d* Gaussian random variables to generate the wavelet coefficients at each scale instead of 2^{j_c-1}.

(2) Reference [1] simply regards the wavelet coefficient $\tilde{\zeta}\left(b_k,a_j\right)$ equivalent to the velocity difference δv_{l_j} and supposes they have the same statistical property. Actually, inferred by the wavelet decomposition algorithm, $\tilde{\zeta}\left(b_k,a_j\right)$ should be determined based on the contribution from all the $\delta v_{l_{j,i}}$ s. The weighting of the contribution from each $\delta v_{l_{j,i}}$ depends on the selected wavelet function. For example, for Haar wavelet basis, which is utilized in this study, the relation between the velocity difference and the wavelet coefficients is presented in Appendix A.

(3) In reference [1], it is stated *"when the large fluctuations occurred at a certain scale j, the coefficient fluctuations become large around the same time at the other j: the local self-similarity was realized with the algorithm in this study."* Actually, this local strong fluctuation is a false appearance caused by the manipulation in the algorithm: all the samples of $\tilde{\zeta}\left(b_k,a_j\right)$ in the inertial range are generated from the same series of samples $\tilde{\zeta}\left(b_k,a_{j_c}\right)$. In this regard, the difference between the samples of $\tilde{\zeta}\left(b_k,a_{j_c}\right)$ will be passed down which causes similar corresponding difference between $\tilde{\zeta}\left(b_k,a_j\right)$ at all smaller scales. Actually, the universal scaling law holds true only in the statistical meaning rather than the sample meaning, therefore, the samples of $\tilde{\zeta}\left(b_k,a_j\right)$ should be generated independently from the samples of $\tilde{\zeta}\left(b_k,a_{j_c}\right)$, instead of reusing at each time.

3.2 *Simulation of multivariate wind processes*

The available information in simulating multivariate wind processes is the cross power spectrum $S_{XY}\left(f\right)$ and the trends represented by $\bar{m}_X\left(b_k,a_j\right)$ and $\bar{m}_Y\left(b_k,a_j\right)\left(j=1,\cdots,j_c;\ k=1,\cdots,2^{j-1}\right)$ at the target locations X and Y. The main object is to generate $\bar{m}_X\left(b_k,a_j\right)$ and $\bar{m}_Y\left(b_k,a_j\right)$ $\left(j=j_c+1,\cdots,n;\ k=1,\cdots 2^{j-1}\right)$ from the wavelet coefficient cross spectral density at the same scale between X and Y. The relation is shown as follows for stationary processes[Appendix C]

$$\tilde{C}_{m_Xm_Y}\left(f,a_j\right)=\int_{-\infty}^{\infty}C_{m_Xm_Y}\left(\tau,a_j\right)e^{-i\tau\omega}d\tau=2^a\left|\psi_{a_j,b}\left(f\right)\right|^2S_{XY}\left(f\right)e^{i\tau f} \tag{11}$$

where $\tilde{C}_{m_Xm_Y}\left(\omega,a_j\right)$ is the wavelet coefficient cross spectral density (CPD) at the same scale. Similar to the univariate case, for non-stationary processes, the above equations are approximately satisfied.

3.2.1 *Simulation scheme*

The simulation scheme of multivariate wind processes in wavelet domain is presented in Fig. 6, which is described as follows:

(1) Generate respectively the initial wavelet coefficients $m_X^0\left(b_k,a_j\right)$ and $m_Y^0\left(b_k,a_j\right)$ using the univariate simulation strategy described in section 3.1;

(2) Within the EC range, produce the final wavelet coefficients $m_X\left(b_k,a_j\right)$ and $m_Y\left(b_k,a_j\right)$ using conventional multivariate Gaussian simulation strategy at each scale;

(3) Within the inertial range, estimate the first four moments $d_{X,i,j}^T$ and $d_{Y,i,j}^T$ $\left(j=j_c+1,\cdots,n;\ i=1,\cdots,4\right)$ at each scale from the produced $m_X^0\left(b_k,a_j\right)$ and $m_Y^0\left(b_k,a_j\right)$. Calculate the target $\tilde{C}_{m_Xm_Y}^T\left(f\right)$ from $S_{XY}\left(f\right)$ and set the initial coherence value $\gamma_{m_Xm_Y}^D=\gamma_{m_Xm_Y}^T$, the iteration number *it*=1, where

$$\gamma_{m_Xm_Y}^2\left(f\right)=\frac{\left|\tilde{C}_{m_Xm_Y}\left(f\right)\right|^2}{\tilde{C}_{m_Xm_X}\left(f\right)\tilde{C}_{m_Ym_Y}\left(f\right)} \tag{12}$$

(4) A set of Gaussian correlated processes $m_X^G\left(b_k,a_j\right)$ and $m_Y^G\left(b_k,a_j\right)\left(j=j_c+1,\cdots,n\right)$ are generated using a standard multivariate Gaussian simulation algorithm[8];

(5) Transform respectively the obtained m_X^G and m_Y^G through forward Modified Hermite Transformation and spectral correction[9,10] to the non-Gaussian m_X^{NG} and m_Y^{NG} which matches their target $\tilde{C}_{m_Xm_X}^T\left(f\right),\tilde{C}_{m_Ym_Y}^T\left(f\right)$ and target moments $d_{X,i,j}^T$, $d_{Y,i,j}^T$;

(6) Measure the coherence $\gamma_{m_Xm_Y}^{NG}$ from the generated m_X^{NG} and m_Y^{NG} and compare it with the target coherence $\gamma_{m_Xm_Y}^T$ to determine the error as

$$err=\left\|\gamma_{m_Xm_Y}^{NG}-\gamma_{m_Xm_Y}^T\right\| \tag{13}$$

(7) If the error is below the acceptance level, the iteration ends. If not, update $\tilde{C}_{m_Xm_Y}^D$ by

$$\tilde{C}_{m_Xm_Y}^D\left(it+1\right)=\tilde{C}_{m_Xm_Y}^D\left(it\right)+\tilde{C}_{m_Xm_Y}^D\left(it\right)\left(\tilde{C}_{m_Xm_Y}^T-\tilde{C}_{m_Xm_Y}^{NG}\right) \tag{14}$$

until the error is accepted;

(8) Generate the wind processes v_X and v_Y from $m_X\left(b_k,a_j\right)$ $\left(j=1,\cdots,j_c\right)$, m_X^{NG} and $m_Y\left(b_k,a_j\right)$ $\left(j=1,\cdots,j_c\right)$, m_Y^{NG} respectively .

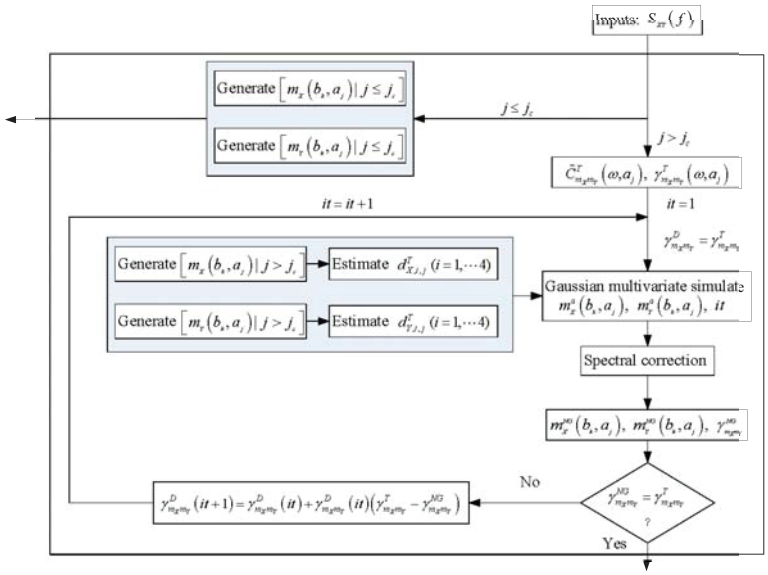

Figure 6 Simulation of multivariate wind processes.

3.2.2 *Case study*

Two measurements drawn from different passages of Hurricane Katrina are employed to simulate the multivariate wind processes. The generated time histories are show in Fig. 7. The cross correlation coefficients of the measurement and simulation exhibit good agreement (Fig. 8).

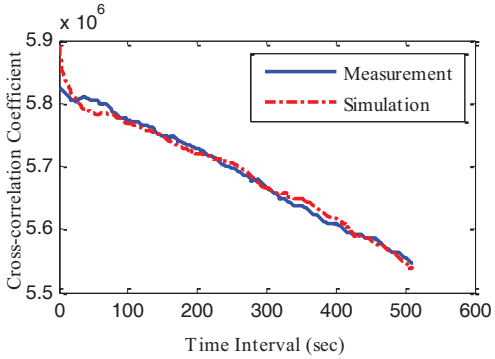

Figure 8 Coefficients of cross-correlation function.

4 CONCLUSION

A methodology of simulating univariate and multivariate turbulence flows in wavelet domain is proposed. This method, utilizing the Log-Poisson random cascade model, emphasizes the internal intermittency effect of the turbulence fluctuations in this simulation. The simulation results agree with both the power spectrum and the statistical information presented by the scaling law, thus present a better representation of the natural wind process than the conventional methods which only considers the second-order moments. Furthermore, in the simulation of the multivariate processes, the wavelet coefficients are iteratively updated to match the wavelet coefficients coherence at the same scale, thereby guaranteeing the consistence of the cross correlation function between the measurement and the simulation results.

5 ACKNOWLEDGEMENTS

The support for this project provided by the NSF Grant # CMMI 09-28282 which is gratefully acknowledged. We also thank Dr. Kurtis R. Gurley for the assistance in programming the multi-variate non-Gaussian simulation and providing the data set.

6 APPENDIX

A. When time interval is 1sec, the Fourier spectrum of Haar wavelet function is shown as

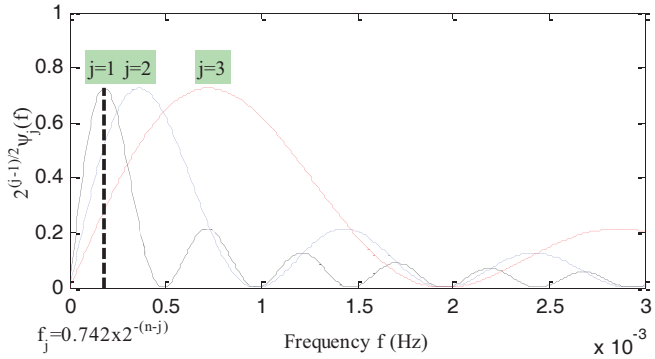

Figure 9 Absolute Fourier spectrum of Haar wavelet

B. The Discrete Haar wavelet reconstruction algorithm is shown as follows:

$$m_V\left(b_k,a_j\right)\sim\frac{1}{2^{n-j}}\sum_{i=2^{n-j}\times(k-1)+1}^{2^{n-j}\times k}\delta v_{l_{j,i}},\ \left(k=1,\cdots,2^{j-1}\right) \tag{15}$$

In order to explain clearly the relation between velocity difference δv_{l_j} and wavelet coefficient $m_V\left(b_k,a_j\right)$, the above algorithm is expressed in unnormalized form. Specifically, suppose a wind process $v(t)$ including 8 discrete points, there are

$$\begin{aligned}
&m_V\left(b_1,a_3\right)\sim\delta v_{l_{3,1}}=v_1-v_2,\ m_V\left(b_2,a_3\right)\sim\delta v_{l_{3,2}}=v_3-v_4,\cdots,m_V\left(b_4,a_3\right)\sim\delta v_{l_{3,4}}=v_7-v_8\\
&m_V\left(b_1,a_2\right)\sim\frac{1}{2}\sum_{i=1}^{2}\delta v_{l_{2,i}}=\frac{1}{2}\left[\left(v_1-v_3\right)+\left(v_2-v_4\right)\right],\ m_V\left(b_2,a_2\right)\sim\frac{1}{2}\sum_{i=3}^{4}\delta v_{l_{2,i}}=\frac{1}{2}\left[\left(v_5-v_7\right)+\left(v_6-v_8\right)\right]\\
&m_V\left(b_1,a_1\right)\sim\frac{1}{4}\sum_{i=1}^{4}\delta v_{l_{1,i}}=\frac{1}{4}\left[\left(v_1-v_5\right)+\left(v_2-v_6\right)+\left(v_3-v_7\right)+\left(v_4-v_8\right)\right]
\end{aligned} \tag{16}$$

When applied in the reconstruction like the simulation in this study, $\left\{\delta v_{l_{j,i}}\right\}$ represent a *i.i.d* sequence. Therefore, $m\left(b_k,a_j\right)$ is another random variable different from δv_{l_j}, furthermore, indicated by Central Limit Theorem, $m\left(b_k,a_j\right)$ approaches Gaussian distribution closer than δv_{l_j}.

C. The relation between the wavelet coefficients cross-correlation at the same scale and the conventional cross-correlation is shown as[11]

$$\begin{aligned}
C_{m_X m_Y}\left(b_1,b_2,a_1,a_2\right)&=\left\langle\int_{-\infty}^{\infty}m\left(b_1,a_1\right)m^*\left(b_2,a_2\right)\right\rangle\\
&=\left\langle\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\psi\left(t_1-b_1,a_1\right)\psi^*\left(t_2-b_2,a_2\right)x\left(t_1\right)y^*\left(t_2\right)dt_1dt_2\right\rangle\\
&=\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\psi\left(t_1-b_1,a_1\right)\psi^*\left(t_2-b_2,a_2\right)\left\langle x\left(t_1\right)y^*\left(t_2\right)\right\rangle dt_1dt_2\\
&=\sqrt{2^{a_1+a_2}}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\psi\left(2^{a_1}t_1-b_1\right)e^{-it_1f}\psi^*\left(2^{a_2}t_2-b_2\right)e^{it_2f}R_{XY}\left(t_1,t_2\right)e^{i(t_2-t_1)f}dt_1dt_2
\end{aligned} \tag{17}$$

If X and Y are both stationary, the above equation can be written further as

$$C_{m_X m_Y}(b_1,b_2,a_1,a_2)=\sqrt{2^{a_1+a_2}}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\psi\left(2^{a_1}t_1-b_1\right)e^{-it_1 f}\psi^*\left(2^{a_2}t_2-b_2\right)e^{it_2 f}\int_{-\infty}^{\infty}S_{XY}(f)\,df\,dt_1 dt_2$$
$$=\sqrt{2^{a_1+a_2}}\int_{-\infty}^{\infty}\tilde{\psi}_{a_1,b_1}(f)\tilde{\psi}^*_{a_2,b_2}(f)S_{XY}(f)\,df \tag{18}$$

Then it can derive the following expressions

$$C_{m_X m_Y}(\tau,a_j)=2^{a_j}\int_{-\infty}^{\infty}\left|\tilde{\psi}_{a_j,b}(f)\right|^2 S_{XY}(f)\,df \tag{19}$$

$$\tilde{C}_{m_X m_Y}(f,a_j)=2^{a_j}\left|\tilde{\psi}_{a_j,b}(f)\right|^2 S_{XY}(f) \tag{20}$$

$$C_{m_V m_V}(\tau,a_j)=2^{a_j}\int_{-\infty}^{\infty}\left|\tilde{\psi}_{a_j,b}(f)\right|^2 S_{VV}(f)\,df \tag{21}$$

$$\tilde{C}_{m_V m_V}(f,a_j)=2^{a_j}\left|\tilde{\psi}_{a_j,b}(f)\right|^2 S_{VV}(f) \tag{22}$$

Obviously, a stationary process implies a scale-dependent stationary process.

Coupling method of WRF-LES and LES based on scale similarity model

Kojiro Nozawa [a], Tetsuro Tamura [b]

[a]*Institute of Technology, Shimizu Corporation, Tokyo, Japan*
[b]*Tokyo Institute of Technology, Yokohama, Japan*

ABSTRACT: The one-way coupling method is applied to connect meso-scale model WRF and micro-scale LES using the scale similarity model to get rid of numerical errors at the interface between coarse grid and fine grid. The coupling between coarse-grid WRF-LES and fine-grid LES is studied on a free convective boundary layer flow with no heat flux from the ground. We found that the connection between the coarse grid WRF-LES and the fine grid LES works well without large interpolation errors.

KEYWORDS: Large-Eddy-Simulation, WRF, scale similarity model, one-way coupling, immersed boundary method.

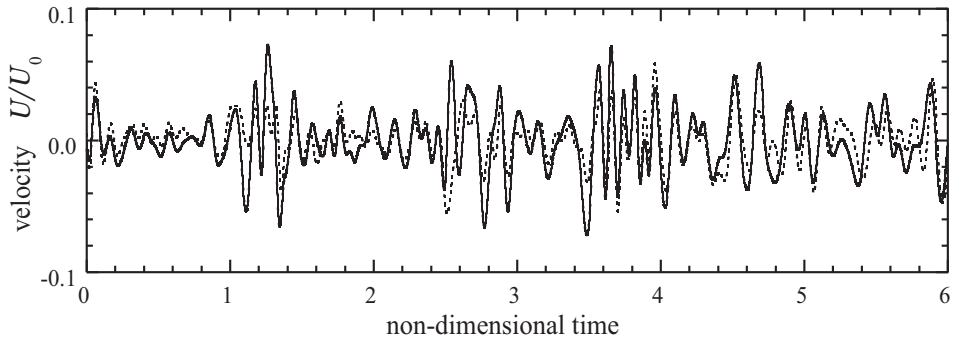
1 INTRODUCTION

The connection between a meso-scale model and a micro-scale LES is significant to simulate the micro-scale meteorological problem such as strong wind events due to the typhoon using LES. In these problems the mean velocity profiles and the mean wind directions change with time according to the movement of the typhoons. The inflow turbulence generating technique for LES which uses turbulent boundary layer driver can't support such mean velocity transition because this technique assumes that the simulating turbulent boundary layer flow is in equilibrium. Although, a fine grid micro-scale LES could not be connected to a coarse grid meso-scale WRF directly.

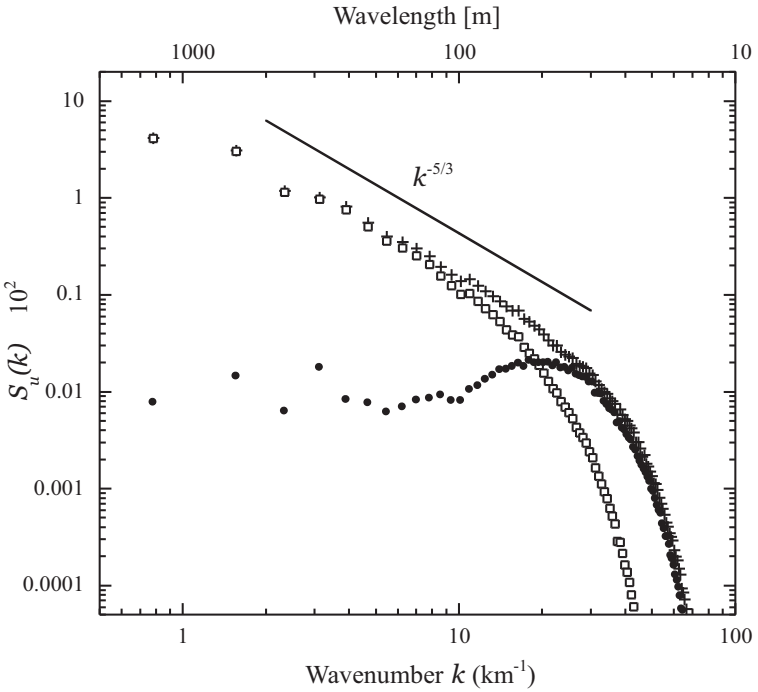
In LES when the grid is suddenly refined at the interface of nested grids which is normal to the mean advection the resolved shear stresses decrease due to the interpolation errors and the delay of the generation of smaller scale turbulence that can be resolved on the finer mesh [1]. The adjustment region is required to regenerate the high wavenumber part in the energy spectrum of the fluctuating velocity. In the grid nesting approach for LES the commutation errors are thought to be very significant near the nest inflow interfaces.

Nozawa and Tamura [2] proposed the method which could get rid of these numerical errors at the interface between coarse grid and fine grid by applying the one-way coupling method using the scale similarity model [3]. In the method the mean velocity component of the fine grid is equal to the velocity of the coarse grid and the averaged fluctuating velocity component of the fine grid is zero. Meanwhile the high wavenumber fluctuating velocity component of the fine grid which is implicitly estimated as subgrid-scale turbulence in the coarse grid is reproduced explicitly in the fine grid near the nest inflow interface. The fluctuating components of the fine grid velocity could be estimated solving the momentum equations which could be derived by subtracting coarse grid filtered Navier-Stokes equations from fine grid filtered Navier-Stokes equations. In order to validate the approach an apriori test was carried out. The LES of a turbulent boundary layer flow over rough surface was conducted using the fine grid and the fluctuating component of the fine grid velocity was reproduced introducing the low-pass filtered finely resolved velocity data into the momentum equations. The reproduced fluctuating velocity component agreed well with the true value which was derived by subtracting the generated low-pass

filtered velocity data from the finely resolved LES velocity data (Figure 1). The kinetic energy spectrum of total velocity by summing up the reproduced fluctuating velocity component and low-pass filtered velocity fitted well to the -5/3 power law for the inertial subrange (Figure 2).



Fgure 1. Time history of streamwise fluctuating velocity component for the apriori test conducted by Nozawa and Tamura [2], solid line: reproduced fluctuating component, dashed line: true value.



Fgure 2. Streamwise kinetic energy spectra for the apriori test conducted by Nozawa and Tamura [2], •: reproduced fluctuating component, □: low-pass filtered velocity, +: true value.

In this paper the method is introduced to nest meso-scale WRF [4] and micro-scale LES. The low-pass filtered velocity component of the micro-scale LES should be equal to the velocity of the meso-scale WRF and the averaged fluctuating velocity component of the micro-scale LES must be almost zero. Meanwhile the fluctuating velocity component of the micro-scale LES is implicitly estimated as subgrid-scale turbulence in the meso-scale WRF. So the grid-scale turbu-

lence in the micro-scale LES must be reproduced explicitly at the connection with the meso-scale WRF flow. This grid-scale turbulence in the micro-scale LES could be estimated using the scale similarity model when the filter width of the meso-scale WRF is in the range of inertial subrange of an energy spectrum. So in this study we carry out an idealized free convective boundary layer flow using WRF-LES mode [4-6]. The velocity data simulated in the WRF-LES is imposed to a fine-grid LES and the grid-scale fluctuating velocity of the fine-grid LES would be reproduced using the proposed one-way coupling method.

2 ONE-WAY COUPLING METHOD

The Navier-Stokes equations which are filtered with the LES grid filter width ($\overline{\Delta}$) are written as below:

$$\frac{\partial \overline{U}_i}{\partial t} + \frac{\partial \overline{U}_i \overline{U}_j}{\partial x_j} = -\frac{\partial \overline{P}}{\partial x_i} - \frac{\partial \overline{\tau}_{ij}}{\partial x_j} \tag{1}$$

where $\overline{U}_i$= velocity in *i*th-direction filtered with LES grid filter; $\overline{P}$=filtered pressure; and $\overline{\tau}_{ij}$=subgrid scale Reynolds stresses. In this filtered Navier-Stokes equations, the diffusion terms is neglected because of high Reynolds number. The filtered Navier-Stokes equations for coarser grid system which are filtered with filter width $\widetilde{\Delta}$ are written as below:

$$\frac{\partial \widetilde{U}_i}{\partial t} + \frac{\partial \widetilde{U}_i \widetilde{U}_j}{\partial x_j} = -\frac{\partial \widetilde{P}}{\partial x_i} - \frac{\partial \widetilde{\tau}_{ij}}{\partial x_j} \tag{2}$$

where $\widetilde{U}_i$=filtered velocity in *i*th-direction; $\widetilde{P}$=filtered pressure; and $\widetilde{\tau}_{ij}$=subgrid scale Reynolds stresses. We assume the filter width $\widetilde{\Delta}$ is much larger than that of the LES grid filter $\overline{\Delta}$. The filtered velocity $\overline{U}_i$ can be decomposed into $\overline{\widetilde{U}}_i$ and u_i as below:

$$\overline{U}_i = \overline{\widetilde{U}}_i + u_i . \tag{3}$$

The velocity $\overline{\widetilde{U}}$ is fluctuating very slowly due to the filter width, $\overline{\widetilde{\Delta}}\left(=\sqrt{\widetilde{\Delta}^2+\overline{\Delta}^2}\right)$. The velocity u_i is a fluctuation component which consists with subgrid scale turbulence of the coarser grid system. If the difference between the two filter widths is large enough we can obtain the equation:

$$u_i \approx \overline{U}_i - \widetilde{U}_i . \tag{4}$$

By using this relation, we can extract the equations of motion for fluctuation velocity components u_i by subtracting equation (2) from equation (1).

$$\frac{\partial u_i}{\partial t} + \frac{\partial}{\partial x_j}\left(\overline{U}_i \overline{U}_j - \widetilde{U}_i \widetilde{U}_j\right) = -\frac{\partial}{\partial x_i}\left(\overline{P} - \widetilde{P}\right) - \frac{\partial}{\partial x_j}\left(\overline{\tau}_{ij} - \widetilde{\tau}_{ij}\right) \tag{5}$$

Figure 3 indicates that we only have to obtain the difference between the finer grid grid-scale (GS) turbulence and the coarser grid GS turbulence to reproduce the fluctuation velocity components u_i of the equations (5). In the equations there two subgrid-scale stress terms, $\overline{\tau}_{ij}$ is for energy cascade from finer grid GS turbulence to SGS turbulence, and $\widetilde{\tau}_{ij}$ is the production term which cascade turbulence energy form coarser grid to finer grid.

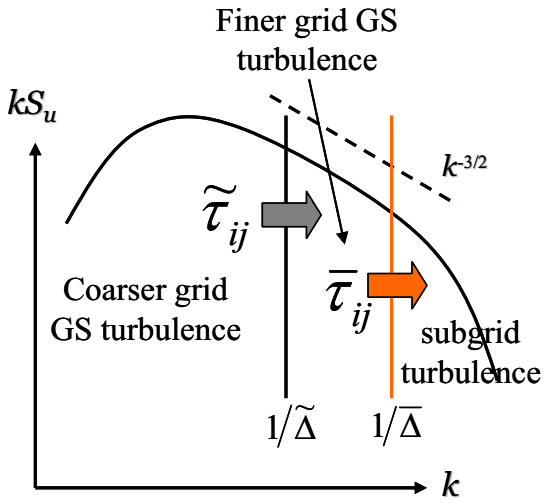


Figure 3. Schematic representation of the energy spectrum of turbulence.

These equations could be solved in the same manner to solve the Navier-Stokes equations by adding an equation of continuity for the fluctuation velocity. Additional restriction that time-space average of fluctuation velocity components u_i is zero will make averaged $\overline{U}_i$ follow the mean value of $\widetilde{U}_i$. The technique for the immersed boundary method proposed by Goldstein et al [7] is applied to force the averaged fluctuating velocity component to zero. Goldstein et al proposed the method to determine the velocity at particular point to the desired value in an unsteady viscous flow. The body force f_i which is controlled by the feedback system is imposed to the equation (5):

$$f_i(t,x_i) = \alpha \int_0^t err(\tau,x_i)d\tau + \beta \cdot err(t,x_i). \tag{6}$$

The quantities α and β are negative constants and $err(t, x_i)$ is a residual error between the simulated velocity and the determined velocity. The error being feed back is the velocity integral and the velocity itself. In this study we applied this feedback system to control u_i to zero. The quantities are α=-2000 and β=-30 in this study.

The subgrid scale Reynolds stresses implemented in coarser grid Navier-Stokes equation (2) is the production term in equation (5). In this method the scale similarity model [3] is applied to the subgrid scale stresses: $\widetilde{\tau}_{ij}$ and the Smagorinsky model is applied to the subgrid scale stresses: $\overline{\tau}_{ij}$. The filter width of the coarse grid has to be in the inertial subrange of energy spectrum to predict the production terms in equation (5) properly.

3 NUMERICAL METHOD

3.1 *WRF-LES*

The advanced research WRF[4] is widely used mesoscale meteorological model and in this study we carry out a single domain idealized free convective boundary layer flow using WRF-LES mode with the periodic boundary condition in horizontal plane. WRF-LES eddy viscosity is predicted using 1.5-order, level 2.5 Mellor-Yamada-Janjic (MYJ), TKE (turbulence kinetic energy) equation with local kinetic energy vertical mixing. The MYJ planet boundary layer scheme predicts the generation and redistribution of TKE in the boundary layer, uses the value of TKE to

compute a spatially varying eddy viscosity, and then diffuses simulated quantities vertically in the boundary layer. In this study the heat flux from the ground is zero. The geostropic wind speed is 10m/s in east-west direction. The Coriolis parameter is 10^{-4}/s.

In this study, the computational region of the WRF-LES is 13km in east-west direction, 6.5km in north-west direction and 2km in vertical direction. The horizontal grid space is 50m. The size of stretched vertical grid is from 40m to 60m (figure 4).

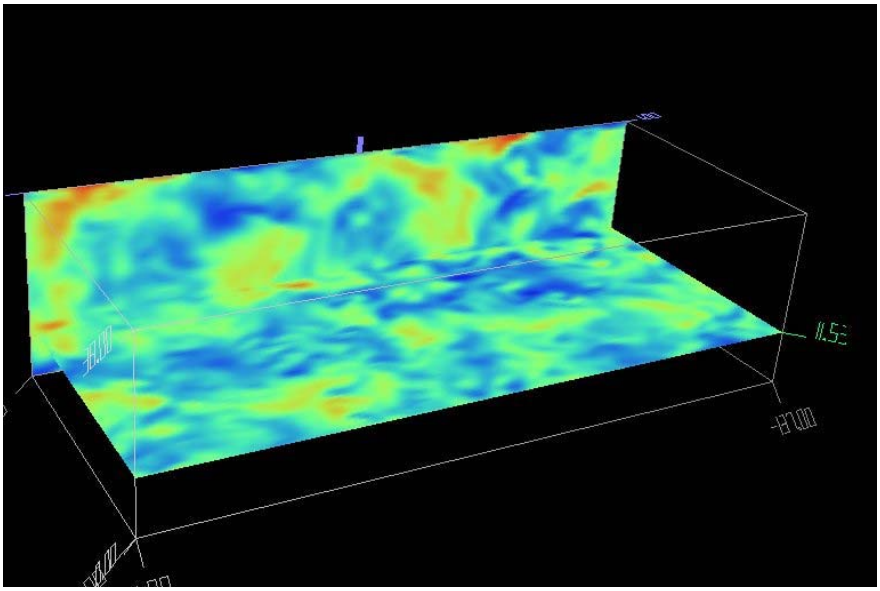

Figure 4. Distribution of east-west wind velocity using WRF-LES (red: high speed, blue: low speed).

3.2 *Micro scale LES*

The micro scale incompressible LES is simulated using the equation (5). Fourth-order central differencing scheme is used as spatial discretization and second-order time accurate explicit Adams-Bashforth differencing scheme is used for the convective terms and SGS turbulent diffusion terms. There is no thermal effect to the fine-grid LES. The WRF-LES velocity data is interpolated to the filtered ($\widetilde{\Delta}$) variables in equation (5).

The LES horizontal grid space is 25m. The LES computational region is 6.5km in east-west direction, 2.7km in north-west direction and 1km in vertical direction.

In this method the scale similarity model which parameterizes the subgrid-scale stress terms requires the grid scale filter ($\widetilde{\Delta}$) of the WRF-LES in the fine-grid LES. Although the grid size ratio ($\widetilde{\Delta}/\overline{\Delta}$) is 2 in this study, high wavenumber turbulence has decline due to the numerical filter (damping) in WRF-LES. The numerical filter width ($\widetilde{\Delta}^*$) is estimated about 8.5 times as large as the grid size ($\overline{\Delta}$) in fine-grid LES. So in this study the explicit filter width ($\widetilde{\Delta}^*$) of the scale similarity model is set to $8.5\overline{\Delta}$.

4 RESULTS

The WRF-LES was run for 10 hours and statistical data were estimated with averaging over the horizontal plain. Figure 5 shows the time history of east-west direction velocities at height 740m.

The mean velocity of the WRF-LES simulation is 10m/s and its standard deviation is 1.3m/s. While the time averaged velocity of the fine-grid LES is 0.005m/s and its standard deviation is 0.71m/s. This meant that technique for the immersed boundary method worked well to force the averaged fluctuating velocity component to zero. The high frequency oscillation still occured in the fluctuating component of the fine-grid LES while the WRF-LES velocity has only lower frequency oscillation compared to that in the fluctuating component of the fine-grid LES. The high frequency turbulence is reproduced rapidly as soon as the coupling method is applied. The streamwise velocity contours at the horizontal section at z=800m are shown in figure 6. We could find the large scale turbulence structures in the WRF-LES contour, while the large scale turbulence is not generated in the fluctuating component of the fine-grid LES contour.

Figure 7 shows the kinetic energy spectra for east-west velocity fluctuations at height 740m. The inertial subrange of the kinetic energy spectrum of the coarse grid WRF-LES is limited up to wavenumber $2km^{-1}$. We could find the fluctuating component of the fine-grid LES has extended the high wavenumber region of the inertial subrange. The results indicate that the coarse-grid WRF-LES and the fine-grid LES could be smoothly connected by using the proposed method.

5 CONCLUSIONS

The one-way coupling method is applied to connect meso-scale model WRF and micro-scale LES using the scale similarity model. The coupling between WRF and LES is studied on a free convective boundary layer flow with no heat flux from the ground nesting coarse grid WRF-LES and fine grid LES.

The time history and the instantaneous contours of the east-west direction velocity showed that the high frequency oscillation was generated in the fluctuating component of the fine-grid LES while the WRF-LES velocity had only lower frequency oscillation compared to that in the fluctuating component of the fine-grid LES. The kinetic energy spectra for the east-west velocity fluctuations of the fine-grid LES had power in the high wavenumber region where energy by WRF-LES turbulence decreased due to the artificial damping. The results indicate that the coarse mesh and the fine mesh could be smoothly connected by using the proposed method.

In this study the time series of WRF-LES velocity data were interpolated to a whole domain of the fine-grid LES and the time-averaged velocity distribution coincide with the distribution of coarse-grid WRF-LES velocity. So to connect WRF-LES and LES against the flow over complex terrain the coupling method should be modified that time-averaged velocity distribution near the surface is determined by the local effect of the terrain.

ABSTRACT: The purpose of this paper is to investigate turbulence effects on characteristics of local severe suction on side face of a three-dimensional square cylinder by LES. The behavior of conical vortices associated with local suctions at the angle of the attack $\theta=0^o$, and glancing angle are focused on. First, the computed results for distribution of the pressure coefficients are validated through comparison with the experimental data. Next, using the computed results, the effects of inflow turbulence on the high peak suctions and flow characteristics are examined. As a result, high peak suctions occur associated with wake characteristics and flow reattachment characteristics affected by the large scale fluctuation of oncoming turbulence.

KEYWORDS: *LES, local severe suction, conical vortex, three-dimensional square cylinder*

1 INTRODUCTION

Recent advancements of computational techniques have made it possible to easily simulate the flow around a bluff body, and many investigations have been reported regarding as applicability of computational models. Recently, in AIJ (Architectural Institute of Japan) CFD working group, around 10 members computes the flow around a three-dimensional square cylinder (breadth(B):depth(D):height(H)=1:1:3,1:1:4) in boundary-layer turbulence by use of LES codes, such as commercial software, open source software and self-development software, and discusses adequate computational conditions and numerical formulations through the comparison with experimental data for the aerodynamic forces and the pressure coefficients.

On the other hand, the flow around a square cylinder is sensitively changed depending on angle of the attack. It is well known that local severe suctions occur in the flow separation regions of a three-dimensional square cylinder. Okuda et al. [(1)] showed from the results of wind tunnel experiments (wind pressure measurements and flow visualization) that the local severe suctions near the leading edge were mainly caused by two types of conical vortices. One was an inverted conical vortex on the middle or lower side of the cylinder in the case where the wind perpendicularly attacked the front of the cylinder ($\theta=0^o$). This inverted conical vortex was nearly periodically formed associated with vortex shedding and causes a large fluctuation of the pressure near the bottom of the leading edge. The other was a standing conical vortex near the upper corner of the leading edge at the glancing angle ($\theta=13\sim15^o$) which leads to large level of the negative pressure. This vortex is hardly affected by vortex shedding in the wake. If the wind velocity did not change, the fluctuating suction was zero [(1)].

These experimental results by Okuda et al. [1] clarified the flow mechanism of local negative suctions on the surfaces of a three-dimensional square cylinder. However, the boundary-layer thickness is much lower than a cylinder height, so the oncoming flow is nearly smooth flow except the lower region of a square cylinder.

On the other hand, Surry et al. [2] investigated relationships of high peak suctions with the characteristics of oncoming turbulence using the wind tunnel experiments. The results of pressure measurements on the side of the cylinder at angle of the attack $\theta=0^o$ reveal distinct periodicity associated with vortex shedding, as reported by Okuda et al [1]. Furthermore, the occurrence of peak event always coincides with the fluctuation induced by vortex shedding, an increase in turbulence intensity obscures the periodicity of vortex shedding, but peak relationship with remaining randomized vortex shedding appears to be maintained.

Okuda et al. [3] investigate characteristics of local negative suctions from the results of the outdoor measurements. Above two types of the local severe suctions are also recognized even in natural wind condition. However, the peak of the negative pressure becomes a sharp and peak values are much larger in natural wind condition compared with those of the wind tunnel experiments [1].

Above studies [1], [2], [3] on characteristics of local suctions near the leading edge have been investigated by utilizing the wind tunnel experiment. So, the data of pressure are easily obtained, but the information of flow structure could not be easily obtained. Namely, the flow mechanism causing local suctions especially in boundary-layer turbulence has not reached completely understanding.

The authors of this paper computed the flow around of a low-rise structure (B: D: H=1:1:0.5) by utilizing the LES method [4]. We used an over set grid in curvilinear coordinate system in order to sufficient grid resolution near the leading edge of the roof of the cylinder, and then showed that the computed results showed very good agreement with the experimental data. Also, based on the computed results, the flow mechanism causing the local suctions on the roof in uniform and boundary-layer turbulence flows is clarified [5].

In this research, the LES method [4] using sufficient grid resolution is applied to the flow around a square cylinder (B: D: H=1:1:4) in boundary-layer turbulence at angles $\theta=0^o$, $15^o$of the attack, and unsteady characteristics of conical vortex are investigated. First the present LES model is validated for prediction of the pressure characteristics on a square cylinder through comparison with the experimental data [6]. Next, the relationships between high peak suctions and unsteady motions of two types of conical vortices such as an inverted conical vortex and a standing conical vortex in boundary layer turbulence are investigated by computed data.

2 PROBLEM FORMULATION

The governing equations are given by the incompressible Navier-Stokes and the continuity equations. To advance the solutions of velocities and pressure in time, a fractional step method is employed. The time integral of the momentum equation is hybrid, that is to say, the Crank-Nicolson scheme is applied to the viscous terms and the explicit third-order Runge-Kutta method is used for convective terms. Spatial derivatives of variables are treated as second-order central difference. Convective terms are approximated using the higher-order interpolation method. We use the dynamic-mixed model. To avoid the numerical instability, the very small numerical dissipation is added to the convective terms. The details of the present numerical formulation can be referred in (Ono&Tamura, 2002[4]).

3 COMPUTATIONAL MODEL

As a computational model, we deal with a three-dimensional square cylinder (Breadth: Depth: Height=1:1:4). An overset grid is used to get sufficient resolution near the cylinder. Figure 1 shows computational grid system which consists of three grids (Grid1; 155X160X80, Grid2; 201X66X100, Grid3; 40X40X65). Wind angles of the attack are set to 0 and 15ºas shown in Figure 2. The convective condition is imposed at downstream boundary. No-slip condition is used at the cylinder surface. Smallest grid size is 0.1/ $(Re)^{0.5}$ ($Re=U_H B/\nu$,:$U_{H:}$ is oncoming velocity at the height of the cylinder, ν is the kinematic viscosity).The Reynolds number (Re) is equal to 36,000.

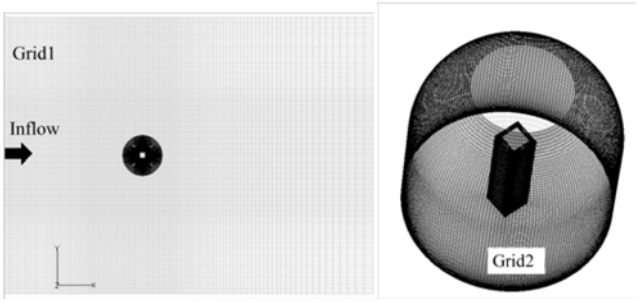

Figure 1 Computational grid system

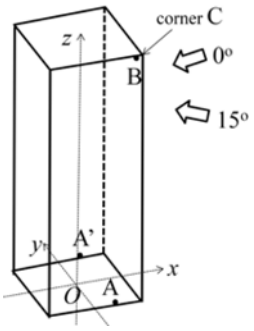

Figure 2 Angle of the attack

Inflow turbulence is generated using the simplified method of the quasi-periodic condition proposed by Kataoka et al. [7], and then developed over the upwind fetch with the surface roughness. Figure 2(a), (b) show the comparison of computed results for profiles of time-averaged velocity and turbulent intensity with the experimental data. The present computations show good agreement with the experimental results. The computed power spectrum distribution is also presented in Figure 2(c). It can be confirmed that the computed result agrees with the experimental data and the Karman-type spectrum. The computed turbulent scale by fitting to the Karman-type spectrum (Figure 3 (3)) is 4.5 B.

Figure 3 Comparison of computed inflow turbulence with experimental data

4 VALIDATION OF COMPUTATIONAL MODEL

Figure 4 (1), (2) show the comparison of the computed results with the experiments for the mean pressure distributions and the RMS value of the fluctuating pressure coefficients on a square cylinder. Concerning the mean pressure distributions, the present computations show good agreement with the experiments [6], though the computed stagnation points tend to be located upper than those in the experiments. This discrepancy must be due to the difference of vertical resolutions of the sampling points used for the visualization.

In the cases of $\theta=0^o$, large values of the fluctuating pressure coefficients are recognized near the bottom of the leading edges (A, A'). Furthermore, concerning the mean pressure distributions at the glancing angle, the local suction occurs near the upper corner of leading edge (B). Namely, local suctions at $\theta=0^o$ and the glancing angle which are observed in the experiments in smooth flow [1] are recognized even in boundary-layer turbulence.

5 STUDY OF RELATIONSHIP OF FLOW STRUCTURE AND LARGE SUCTION

5.1 *Large suction near the bottom of leading edge at angle of the attack $\theta=0^o$*

Figure 5 (1),(2) show experimental results[6] for time histories of pressure coefficients at the points A, A' (shown in Figure 2)near lower corner of the leading edge at $\theta=0^o$. In Figure 5(1), pulse-like peaks are randomly observed in the pressure fluctuations. On the other hand, looking at time histories in about 50 dimensionless time in details (Figure 5(2)), the levels of the negative pressures of A, A' change in turn periodically, though the peak values are randomly changed. These characteristics of peak suctions show the same tendencies as the experiments by Surry et al. [2].

Figure6 (1)-(4) show the iso-surface (p= -1.45) of pressure and the contours of the vorticities at the section of z/B=2, 0.01 before and after the high peak suction occurs at the point A. In (1) tU_H/B=326.3, the vortex begins to be formed in the wake region of the cylinder. After that, the separated shear layer approaches closely to the side surfaces of the cylinder and the negative pressure region is recognized in wide range near side face (2). In (3) where the high peak suction occurs, the shear layer reattaches to the side surface and the separatio bubble is formed near the bottom of the leading edge. In (4), wake vortex sheds downstream, the level of the negative pressure is recovered. Therefore, based on instantaneous flow characteristics, it can be presumed that the behavior of the wake vortices result in the reattachment of the separated shear layer near the bottom of the leading edge, and the strong curvature of the separation bubble leads to the high peak suction.

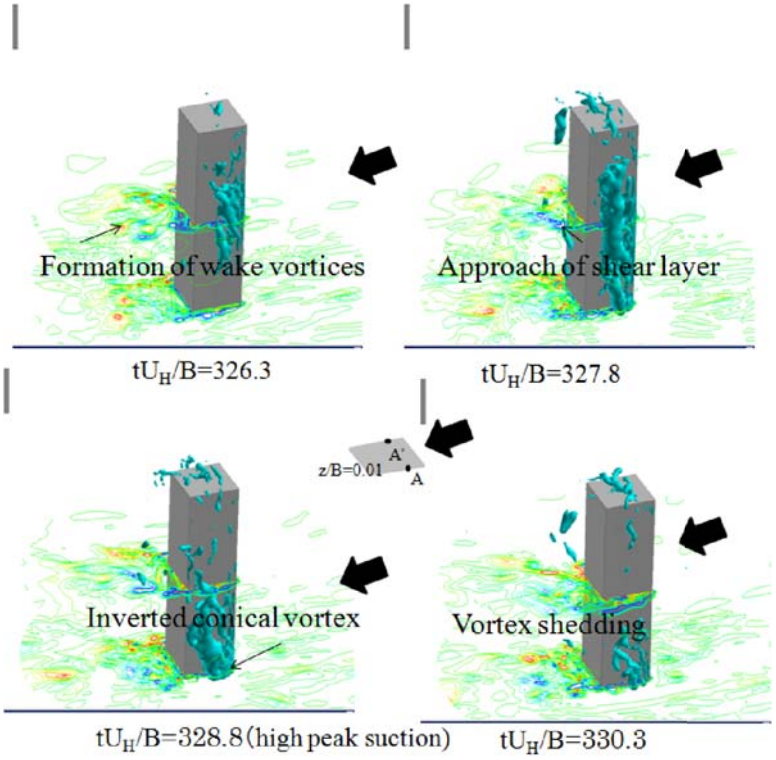

Figure 6 Iso-surface of instantaneous pressure and vorticities contours
(p=1.45, $\theta=0^{o}$)

Figure 7 (1),(2) show the iso-surface (p=-0.75) of the conditional pressure. Conditional sampling manner indicates two types of averaged data. One is the averaged data when the peak values (Cp_{peak}) of the pressure coefficients of point A are large than -1.5 and smaller than -1.0. The other is averaged data when Cp_{peak} are smaller than -2.3.

In the case (1) ($-1.5<Cp_{peak}<-1.0$), the iso-surface is depicted near the side of the cylinder. However, it is not recognized in wake region because the levels of the negative pressure are not so high. On the other hand, in case (2) ($Cp_{peak}<-2.3$), the iso-surface is depicted not only near the side surface but also near the base of the cylinder. Figure 8 (1), (2) show the contours of conditional vorticities at the section of z/B=0.01. The strong circulation of the separation bubble is recognized in the case (2)($Cp_{peak}<-2.3$).

Therefore, high peak suction occurs, when periodic vortices are strongly formed near the base of the cylinder and the early reattachment of the separated shear layer near the bottom of the leading edge is caused.

Figure 9 shows the time histories of the pressure coefficient at the point A and the fluctuating velocities at the three points (T0, T1, T2) in the upwind region. It can be seen that the velocities at all points largely increase and its state continues before the high peak suctions occur. It can be presumed that this process of change in velocities causes the wake vortices to be strongly formed, and then results in the large peak suction near the bottom corner of the leading edge of the cylinder.

Figure 9 Time histories of the pressure coefficients at A
and velocity at T0,T1,T2 (θ=0°)

5.2 *Large suction near the upper corner of leading edge at glancing angle*

Figure 10 (1), (2) show the time histories of the pressure coefficients at the point B (shown in Figure 2) near the upper corner of the leading edge at the glancing angle (θ=15^o). The pulse-like peaks are intermittently recognized in the temporally sequential data for both of the present computation and the experiments [6]. These kinds of peaks had not been observed in the experiments in smooth flow [1]. In the case of smooth flow [1], a standing vortex is formed near the upper corner of the leading edge and leads to stationary local suction.

In order to investigate relationship between the occurrence of high peak suctions and the behavior of a standing vortex in boundary-layer turbulence, the iso-surface (p=-1.2) of the pressure around the cylinder before and after the high peak suction occurs are shown in Figure 11 (1)-(4). In (1) tU_H/B=168.8, the flow separates from the leading edge of the cylinder and the regions of negative pressure are recognized near the side of the cylinder. On the other hand, in (2) tU_H/B =170.2, the conical vortex begins to be formed near the upper leading corner. In (3) tU_H/B 171.3 where high peak suction occurs, the conical vortex is clearly recognized. After that, negative pressure is recovered when the conical vortex becomes unclear.

This conical vortex is similar to a standing vortex in smooth flow [1]. However, this vortex does not always exist in boundary-layer turbulence. The conical vortex is intermittently recognized at the moment high peak suction occurs. Also, the level of peak suctions induced by the conical vortex is much larger than that by a standing vortex [1].

(1) tU_H/B= 169.2 (2) tU_H/B= 170.2 (3) tU_H/B= 171.3

Figure 13 Time series of velocity vectors and pressure distributions

Figure 12 shows the time histories of pressure coefficients at the point B and the fluctuating angle of the attack at the three points (T3, T4, T5) in the upwind region. It can be found that the angles of the attack of all points show a decrease (the angles of the attack changes in anticlockwise direction) before peak suctions occur. After that, peak suction is recognized when the angle of the attack gradually increases.

Figure 13 shows the time series of the velocity vectors and the pressure distributions on the plane close to the side surface. A decrease of the angle of the attack causes the reattachment points to move downstream (the green domain showing a pressure recovery region moves downstream). On the other hand, reattachment points tend to approach closely to the upper corner (C) (the green domain approaches C), as angle of the attack begins to increase. The occurrence of the strong circulation of the conical vortex associated with this change in angle of the attack leads to high peak suction near the upper corner of the leading edge.

6 CONCLUSION

Unsteady characteristics of the conical vortices near the bottom of leading edge at $\theta=0^o$ and near the upper corner of the leading edge at the glancing angle are studied by LES analysis. It is made sure that the present LES model can simulate the pressure characteristics on the square cylinder through comparison with the experimental data. As a result of study of computed flow structure, it can be presumed that the large scale fluctuation of oncoming flow plays an essential role for vortex structures close to a square cylinder. It introduces a conical vortex generation and its concentration near the leading edge, and results in high peak suctions

ABSTRACT: Recent development of high-performance computers and techniques on computational fluid engineering has enabled us to simulate the complicated flow such as the wind in urban area. Large Eddy Simulation (LES) is expected to be adopted as an effective technique to evaluate wind load on buildings for wind-resistant design. In this research, the accuracy of LES to evaluate surface pressures on the 3D square cylinder model is examined. Especially, the availability of LES using unstructured grid system is studied to estimate fluctuating as well as mean component of pressures by comparison with experimental results. The computed results correlate highly with the experiments, including the case of a square cylinder with angle of attack for wind direction which introduces a local negative pressure on the side.

KEYWORDS: LES, Unstructured grid system, Fluctuating pressure, Square cylinder.

1 INTRODUCTION

As a result of wide spread of commercial or open source CFD software on the research as well as its practical usage, very large scale computations of complicated flow such as wind around a building and urban flows in cities have been often performed. Recent development of parallel computing technique based on the unstructured grid systems makes it possible to deal with the actual flow phenomena. While, it remains still important to investigate the accuracy of time variation of the physical quantities under the unsteady numerical simulation, such as Large Eddy Simulation (LES). So, using a fundamental object, many researchers have tried to predict the aerodynamic forces and pressures under the unsteady situations. Kataoka and Tamura [1] carried out the numerical prediction of the peak pressures on three-dimensional square cylinder by the overset structured grid system based on the generalized coordinate system. They suffered from the reproducibility of the minimum local negative peak pressure, because of the insufficient power of turbulence structures.

Unstructured grid systems are superior to conventional structured grid system in terms of not only the adaptability to configuration but also flexibility to element size density at each location in the computational region. Therefore the unstructured grid with local refinement can meet the sensitivity of aerodynamic forces on the square cylinder with a glancing angle [2]. This paper examines the accuracy of LES based on the unstructured grid system. Especially, focusing on the local pressure fluctuation, which is required to estimate the wind loads for claddings, the validity of LES is examined by comparison with experimental data.

2 BUILDING MODEL

A square cylinder model is chosen as an objective building and its width (B), depth (D) and height (H) are 30m,30m and 90m respectively. Namely, the aspect ratio H/B is equal to 3. The design wind speed is set as U_H=41.9m/s at the building's top.

3 WIND TUNNEL EXPERIMENT

The wind-tunnel experiment is carried out for obtaining reference data of fluctuating wind pressures. A 1/300 scaled model is used and wind pressures are measured at 308 points on the walls (figure 1 and 2). The experimental wind velocity is set as U_H=11.6m/s and the experimental Reynolds number is 77,000. The time- histories of wall surface pressures are recorded at 1kHz sampling frequency. Then they are converted into the time- histories of 1-second mean pressures with real scale by taking moving average over consecutive 12 data. The 4 parts of 10-minute (real scale) time- histories are taken and the pressure coefficients (mean value, fluctuating value, maximum value and minimum value) are determined by taking ensemble averaging over 4 values obtained from each 10-minute time- histories.

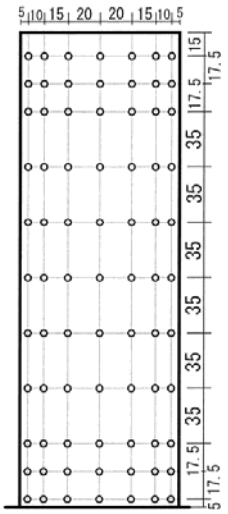

Figure 1. Measurement points

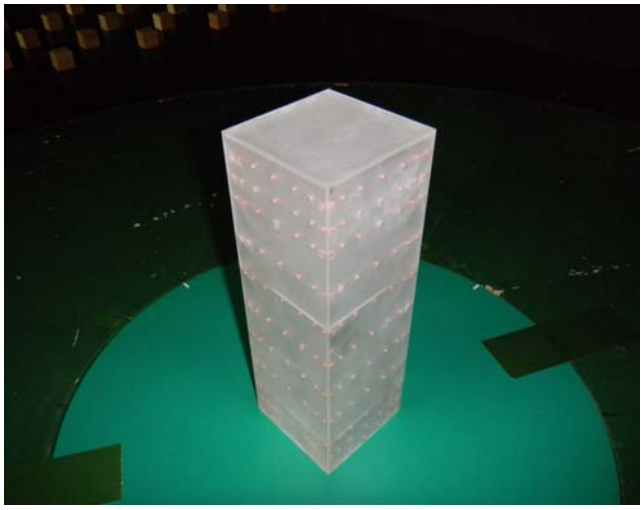

Figure 2. Experimental model

4 NUMERICAL METHOD

Three-dimensional incompressible Navier-Stokes equations are used as governing equations. The Reynolds number is set to 72,000. Equations are transformed into the discretized form by the finite volume method (FVM) and computational domain is divided using the tetrahedral and prismatic cells. As the flow velocities and the pressures are defined on the vertexes of cells, the configuration of control volume is polyhedral. The second-order central difference scheme is applied to the convective term and diffusion term. The time derivative term adopts the second-order implicit scheme. The physical time step is set as $\Delta t U_H/B$=0.03.

For subgrid scale model of LES, the standard Smagorinsky model is employed. The universal constant is equal to 0.15 and the filter size is automatically determined by a volume *V* of the con-

trol volume through $V^{1/3}$. Van Driest type of wall-damping function is applied for eddy viscosity of subgrid scale.

5 INFLOW TURBULENCE GENERATION

Inflow turbulence is numerically generated using the wind tunnel model shown in figure 3. Spires and roughness blocks are appropriately placed inside the wind tunnel model. Uniform flow is set on the inlet boundary and boundary-layer turbulence is developed in the model as is the case in the wind tunnel experiment. Time- histories of wind velocity are accumulated at each point on the section adjacent to the outlet boundary (shown in figure 3). The time- histories are saved in a file and applied to the inlet boundary of another model with a square cylinder described below as the inflow turbulence. Generated velocity profiles are shown in figure 4 with the reference wind tunnel data. The profiles of time averaged windward velocity <*u*> and turbulence intensity *I* are reproduced quite well. The power spectral density of windward velocity fluctuation is shown in figure 5 with the Karman-type spectrum. The computed spectrum power decreases rapidly at the non-dimensionalized frequencies nLx/U higher than 1.0.

6 GRID SYSTEM FOR 3D SQUARE CYLINDER

Figure 6 shows the unstructured grid system of whole domain for the 3D square cylinder model. The whole domain size is 20B×30B×15B. The distance between inlet boundary and the center of square cylinder is 8B. For the unstructured meshes the advancing front method is used to create the tetrahedral in the domain based on the volume mesh density at each location determined preliminarily. Then prismatic cells are inserted on the walls and the ground based on a triangular surface mesh. Figure 7 shows the grid systems near the square cylinder for wind directions of 0 and 15 degrees. These two grid systems are independently generated for the wind direction and possess the highest spatial resolution (approximately B/64) around the corner edges of the square cylinder. The number of cells is approximately 3,300,000 and the number of vertexes is approximately 660,000. The inflow turbulence, which is recorded as described in the last chapter, is imposed time-sequentially on the inlet boundary.

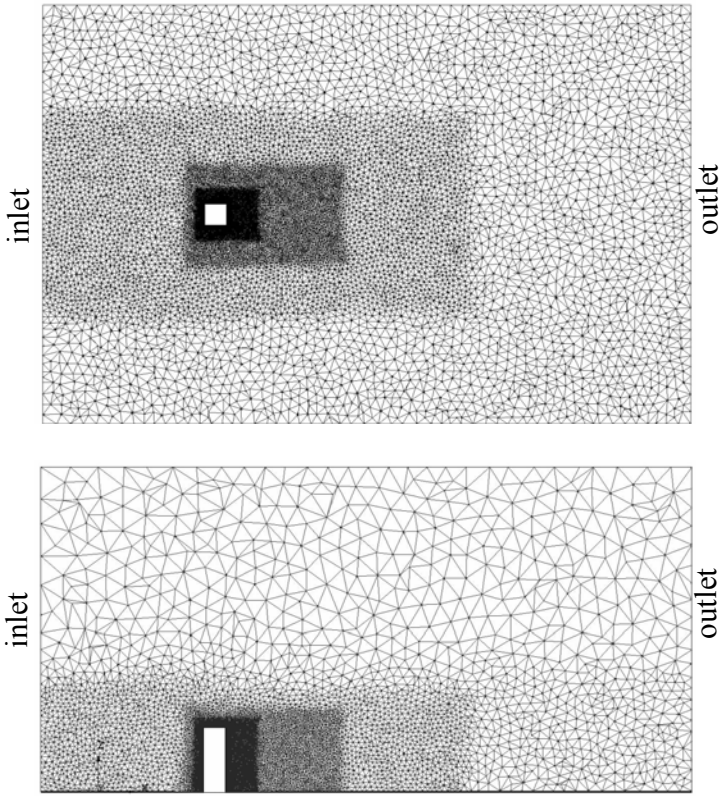

Figure 6. Unstructured grid system (whole domain)

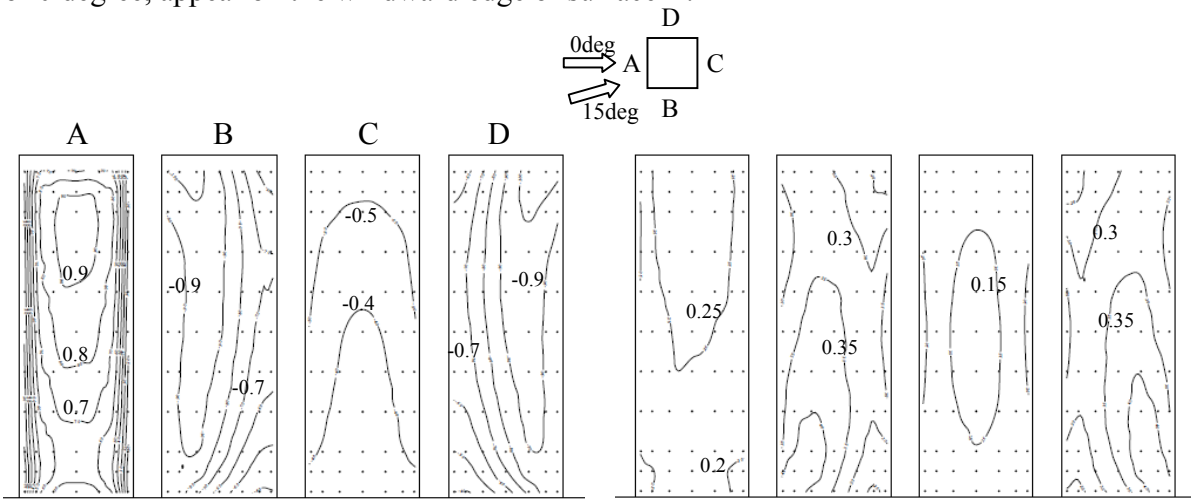
7 COMPUTED RESULTS

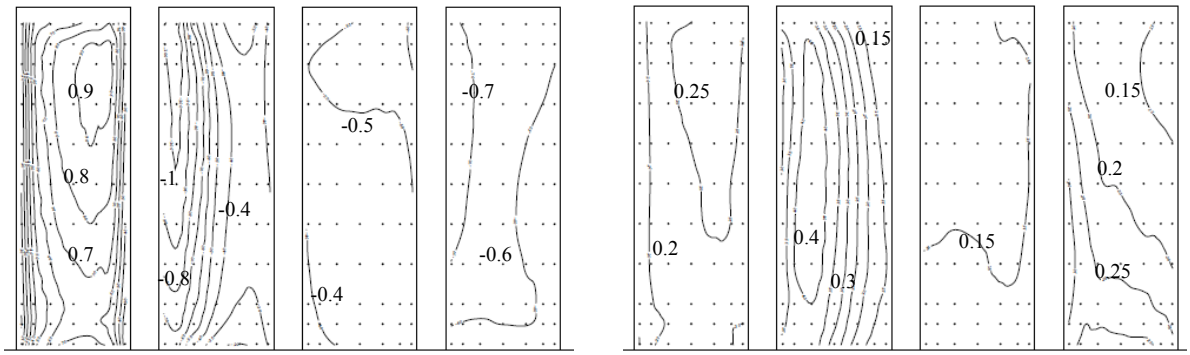
7.1 *Distributions of surface pressure coefficients*

Figure 8 and 9 show the distributions of surface pressure coefficients obtained by LES. The mean pressure coefficients Cpm and the fluctuating pressure coefficients Cps are shown for wind directions of 0 and 15 degrees. For the case of 15-degree wind direction, surface pressure coefficients show asymmetrical distributions. The position of maximum Cpm value moves toward windward side of surface A and local negative pressure value, which is definitely lower than that of 0 degree, appear on the windward edge of surface B.



Mean pressure coefficients Cpm Fluctuating pressure coefficients Cps

Figure 8. Distributions of surface pressure coefficients (wind direction 0 deg.)



Mean pressure coefficients Cpm Fluctuating pressure coefficients Cps

Figure 9. Distributions of surface pressure coefficients (wind direction 15 deg.)

7.2 *Correlations of surface pressure coefficients with experimental results*

Figure 10 and figure 11 show correlations of the computed surface pressure coefficients with the experimental results for wind directions of 0 and 15 degrees. The mean pressure coefficients Cpm, the fluctuating pressure coefficients Cps, the maximum peak pressure coefficients Cpmax, and the minimum peak pressure coefficients Cpmin are shown. Each symbol represents the com-

puted and the experimentally-measured values at a corresponding sampling point. The computed mean pressure coefficients Cpm quite coincide well with the experimental data, including the case of 15-degree wind direction. The fluctuating and peak pressure coefficients Cps,Cpmax and Cpmin also maintain high correlations although they show relatively disperse distributions compared with Cpm. The computed results slightly tend to overestimate the peak pressure coefficients. But we need to take care of an essentially-contained variability of experimental data and discuss the effects on the correlations.

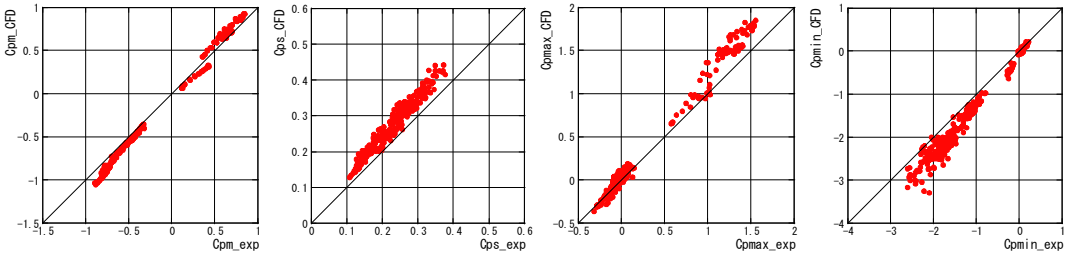


Figure 10. Correlations of pressure coefficients (0 deg)

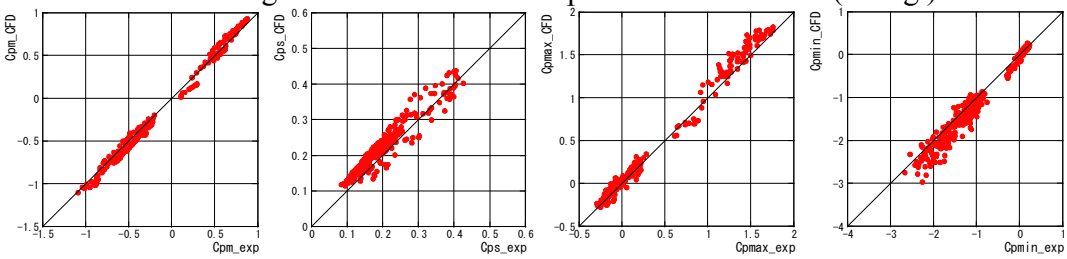

Figure 11. Correlations of pressure coefficients (15 deg)

8 CONCLUSIONS

The fluctuating as well as mean pressures on the square cylinder were computed by LES using unstructured grid system and compared with the wind tunnel experiments. On the whole, the computed results correlated highly with experiments though the computations slightly tended to overestimate the peak pressure coefficients. The reproducibility of inflow turbulence and appropriate spatial resolution at each location are required even in the case of unstructured grid system. It can be concluded that LES using unstructured grid system is effective to evaluate even the fluctuating component of the pressures on buildings for wind-resistant design.

ABSTRACT: We carried out LES of fluctuating wind pressure on a three-dimensional square cylinder for PIV-based inflow turbulence which is generated by using stereo PIV measurement data for inflow condition. PIV experiment was executed at low Reynolds number, so we try to produce the higher Reynolds number inflow turbulence using the low Reynolds number turbulence which was obtained on the basis of PIV measurement results. Also, using the obtained data at higher Reynolds number, we discuss the accuracy of prediction of wind loads on the cladding by comparison with wind tunnel experimental results.

KEYWORDS: LES, Wind Pressure, 3D Square Cylinder, Inflow Turbulence, PIV, Reynolds Number

1 INTRODUCTION

Wind loads acting on buildings immersed within a turbulent boundary layer are sensitively characterized by the approaching flow. In view of fluid dynamics, inflow wind fluctuations tend to affect the computed aerodynamic characteristics based on wake structures of an object, then their set-up should be concerned for CFD applications, since CFD has much flexibility for inflow generation. So, we proposed a new method for generating inflow turbulence where stereo PIV measurement results are directly used to impose the inflow boundary condition of LES (1). Namely we carried out LES of a turbulent boundary layer developed on a flat floor using stereo PIV measurement results at inflow and the generated PIV-based inflow turbulence was saved as the database after a full development. Also, this paper presents the computed results of the fluctuating wind pressure acting on rectangular cylinder obtained by LES under the condition of oncoming turbulence. But PIV experiment was executed at very low Reynolds number, so we try to make higher Reynolds number inflow turbulence modifying low-Reynolds-number turbulence provided by PIV measurement. It can be expected that this turbulent structures result in the accurate fluctuating components of physical quantities. Hence we aim at discussing the accuracy of prediction of wind loads on the cladding by comparison with wind tunnel experimental results.

2 LES FOR INFLOW GENERATION USING STEREO PIV MEASUREMENT DATA

PIV wind tunnel experiments were executed for a turbulent boundary layer developing on a flat plate using the wind tunnel of Building Research Institute. We measured the three-dimensional wind velocity of the turbulent boundary layer using a stereo PIV system assembled by SEIKA Corporation (Photo1 & Figure 1). The sampling frequency of the flow velocity images for the digital high-speed video camera was set to 1000Hz, and non-dimensionalized Nyquist frequency was equivalent to 3.57, and the Reynolds number Re_δ was equal to 8,400.
We used the image deformation correlation algorithm (sub-pixel image shifting) repeatedly five times for PIV images analysis to reduce noise elements in high frequency region. But a few noise

elements remain in high frequency region and sometimes very large spike-shaped peaks appear. So we corrected the PIV time histories by peak cutting and moving average. Figure 2 shows statistics of inflow velocity corrected PIV measurement data.

Figure 2 Statistics of inflow velocity based on PIV measurement data

LES computation using PIV-based inflow turbulence for inflow generation was carried out by OpenFOAM which has been widely circulated as an open-source code. The governing equations are given by the continuity and the incompressible Navier-Stokes (N-S) equations. This code uses the unstructured-grid based concept and the finite volume method for discretization of the governing equations. For the turbulence model of LES the standard Smagorinsky model is employed. The no-slip condition is used for the bottom boundary to this LES. This means the sufficiently fine mesh is required for near-wall region. The Reynolds number Re_δ (=U0δ/ν, U0: wind velocity above turbulent boundary layer, δ: turbulent boundary layer thickness, ν: kinematic viscosity) is 8,400 and Re_τ(=u_τ δ / ν, u_τ: friction velocity on floor) is about 360.

Fig.3 depicts the instantaneous velocity field as a result of LES computation. The wind velocity distribution has striped patterns with a long streamwise length near the floor. It can be thought that streak structures are surely formed immediately above the bottom surface. According to wind velocity contours in the vertical section, it is confirmed that velocity fluctuations given as inflow condition have convected smoothly downstream with drag effects by a bottom wall, and the turbulent boundary layer is appropriately developed with coherent structures such as bursting phenomena.

Fig.4 shows vertical profiles of mean wind velocity and turbulent intensity for *u*-component reduced by friction velocity u_τ. Both LES results correspond closely to experimental results by Degraaff and Eaton. Figure 5 shows the power spectral density of wind velocity of inflow data and the LES result with fully developed state near the wall (z+=11) and at the log-law region (z+=130). It is confirmed that turbulence structures near the wall are generated by appropriate

numerical method which can handle the grid size and the numerical dissipation. At the log-law region, spectral shapes of LES fit to the Karman type spectrum sufficiently.

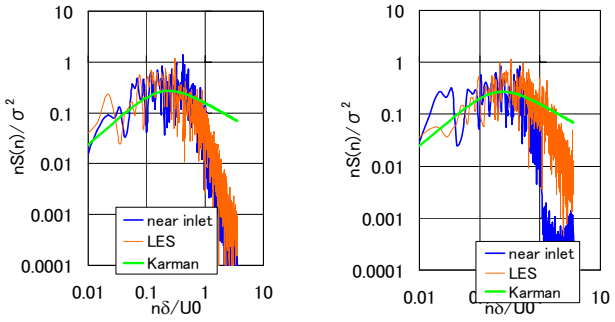
Figure4 Profiles of mean wind velocity and turbulent intensity reduced by friction velocity u_τ



(a) near wall (z^+=10.8) (b) log-law region (z^+=130)

Figure5 Power spectral density of LES result

Inflow data for turbulent boundary layer simulation provided by the stereo PIV measurement has low-frequency fluctuations but no high-frequency fluctuations, and the accuracy level of PIV data near the wall is low by reflection of laser beam. In LES low-frequency fluctuations given by

PIV measurement data are maintained in whole computational domain. While, high-frequency fluctuations are generated by the energy cascade. Turbulence structures near the wall can be reproduced by high resolution in near-wall region under the usage of no-slip condition. Accordingly, the present proposed models using LES, the turbulent boundary layer can be reproduced by relatively short fetch.

3 GENERATION METHOD OF HIGH-REYNOLDS INFLOW TURBULENCE

It is expected to acquire wind loads on structures by calculating flow field around bluff bodies with inflow turbulence which simulates the boundary-layer type of flow structures in wind engineering. We aim at creating the database of inflow turbulence for LES calculation based on the PIV measurement data. However, the Reynolds number and the boundary layer thickness obtained in PIV wind tunnel experiment are restrictive, so some problems occur in similarity to calculation for actual wind loads evaluation. Here, we propose a method generating inflow turbulence at higher Reynolds number. We have verified the validity of this method by LES using the inflow turbulence with the low Reynolds number developed on the flat plate shown in chapter 2, and discuss the enhanced applicability of inflow turbulence database based on PIV measurement results.

The Reynolds number Re_δ (defined by boundary layer thickness δ) of the PIV based inflow turbulence presented in the preceding chapter is about 8400, while the Reynolds number Re (defined by the width of 3D-cylinder) is about 2000. Here, in realizing the computation of the flow field around a three dimensional square cylinder at the same order of Re as the wind tunnel experiment, we try to set about 5 times Re as the order exceeding 10000. For this, the kinematic molecular viscosity is changed to 1/5 on calculation.

In the process of the rescaling by Lund et al.(2), a boundary layer is generally divided into two domains, one is an inner region where the law of the wall can be realized, the other is outer region where the velocity defect law can be realized. Basically using this concept, the conversion from low to higher Reynolds number flow for inflow turbulence is also enforced to each region.

In the inner region the law of the wall can be realized, and the mean velocity profile collapses the logarithmic distribution to z+ non-dimensionalized by the friction velocity u_τ and the kinematic viscosity ν shown in Fig.4. Since Re is converted into 5 times higher by 1/5 ν , also as a result of larger u_τ, the vertical size of the inner region estimated on the basis of z+ is reduced to less than 1/5 on dimensionalized scale (Fig. 6). In the outer region, the boundary layer thickness is the same for both the Reynolds number flows, inflow turbulence fluctuations are corresponding to each other at same height. However, since the wind velocity at the top of the inner region is specified, the velocity at upper location in outer region should be shifted following the inner value, so that this method assumes to have an average wind velocity profile according to the power law on the flat plate with α=0.15. The outline of the procedure of changing the Reynolds number of the inflow turbulence is shown in Fig. 6. The profile of mean wind velocity with z+ is shown in Fig. 7.

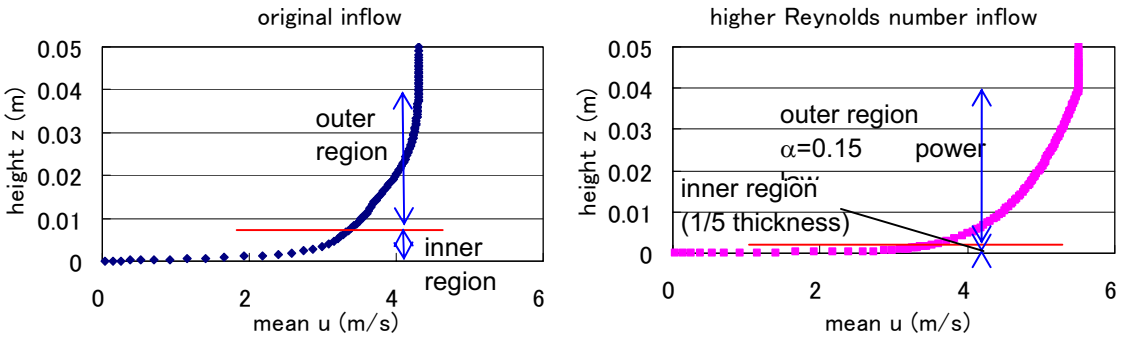


Figure 6 Outline of the procedure of changing the Reynolds number of the inflow turbulence

In order to confirm that this inflow turbulence generated for higher Reynolds number flow is adapted to the whole computational domain, we executed LES of turbulent boundary layer using this inflow turbulence for inflow condition. Computation outline is the same as that of the preceding chapter, the mesh resolution in the vertical direction is made for the first mesh point to be set to $z^+<1$ near the wall and the mesh resolution in the spanwise direction is twice finer than the former case.

Figure8 shows the profiles of mean wind velocity and the standard deviation reduced by friction velocity u_τ. In buffer layer, The computed wind velocity shows smaller values. It is considered that this phenomenon is caused by the discontinuity of fluctuation component of inflow at the connecting point between the inner and the outer regions, in spite of connecting mean component of inflow smoothly. Figure9 shows the instantaneous flow field of LES at the higher Reynolds number. In inner region, the distribution of 1/5 height of higher Reynolds number flow (fig.9 z=0.1mm) is similar to that of low Reynolds number flow (Fig.3 z=0.5mm). In outer region, the distribution of each flow at the same height (Fig.3 and Fig.9 z=20mm) is well alike. This means that it is rational to divide into two regions at inner and outer sides to generate the higher Reynolds number inflow turbulence.

Since it is mostly in agreement to inflow above log-law region, we carry out LES of flow field around a 3 dimensional square cylinder using this computed result as inflow turbulence.

4 LES AROUND 3D SQUARE CYLINDER FOR PIV-BASED INFLOW

LES of flow field around a 3-dimensional square cylinder is carried out using inflow turbulence generated in the preceding chapter. Figure10 shows the outline of mesh generation for this computation. The resolution around the square cylinder is raised using refinement mesh function equipped in OpenFOAM four times. Whenever it uses refinement function, the mesh resolution in the three directions becomes twice respectively. Therefore, the resolution of domain 5 is 16 times that of the outer domain 1. One side of the square cylinder is divided into 120 meshes.

Figure 11 shows the instantaneous flow field of the computed result. Figure 12 shows the mean and fluctuating pressure coefficients compared with the experimental result at several heights.

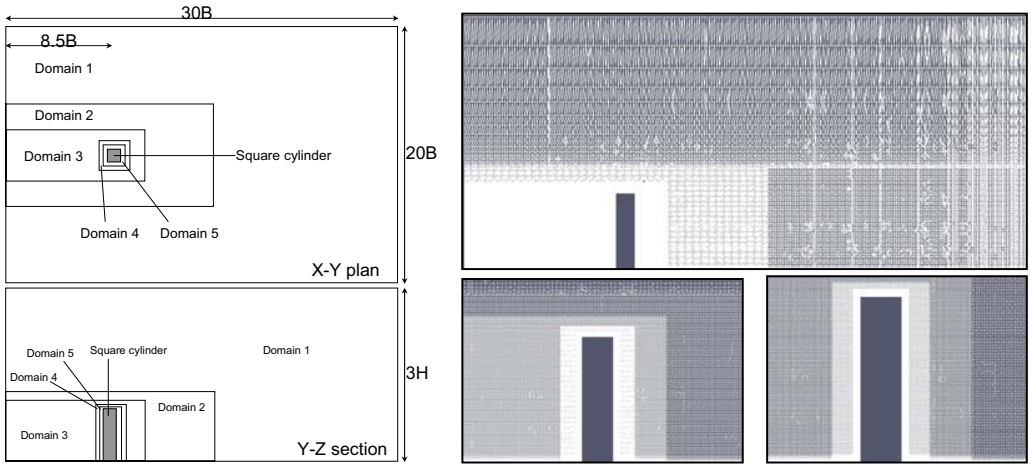

Figure 10 Outline of mesh generation by refinement function and meshes around a square cylinder

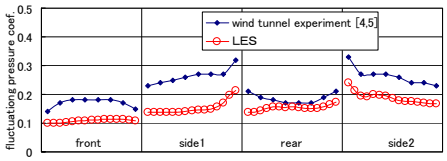
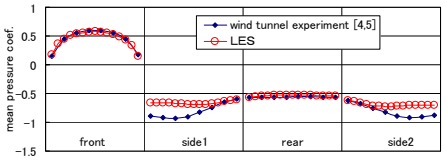
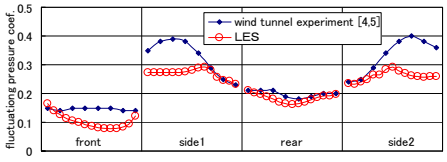
(a) mean pressure coefficient (z=3/4H)



(b) fluctuating pressure coefficient (z=3/4H)



(c) mean pressure coefficient (z=1/20H)



(d) fluctuating pressure coefficient (z=1/20H)

Figure 12 Pressure coefficients on a 3D square cylinder

Height at z=3/4H is located near the stagnation point, and height of z=1/20H is near the floor. Mean pressures of front and rear surfaces correspond with those of experiment. Mean pressure on side wall is different from that of experiment. Especially, it differs near the frontal location. Fluctuating pressure coefficient of front surface is different from the experimental result. At side surface, although fluctuating pressure coefficient value is different from the experimental result, it is qualitatively similar. At rear surface, fluctuating pressure coefficient is corresponding with experimental result. In this LES, since the height of the square cylinder to boundary layer thickness is higher as compared with the experiment, it can be considered that turbulent intensity in the upper part of a square cylinder is small. As a result, the fluctuating pressure coefficients are not in agreement with experimental data.

5 CONCLUSIONS

We executed LES of flow filed around a 3-dimentional square cylinder to estimate pressures on the surfaces using PIV based inflow turbulence for inflow condition. To compare LES results with experiment results, we tried to reproduce higher Reynolds number inflow turbulence modifying low-Reynolds-number turbulence provided by PIV measurement. In this paper, we proposed the method of generating inflow turbulence at higher Reynolds number, using the concept that the boundary-layer type of turbulent structures are divided into an inner and outer regions. In order to use this method, it is a future problem to maintain a continuity of turbulent structures at the connecting position. The LES results for wind pressure on the square cylinder using PIV based inflow turbulence was qualitatively in agreement with experimental data.

ABSTRACT: This paper discusses the availability of LES on the wind-resistant design of buildings in cities. In order to predict the wind pressures on actual complicated-shaped buildings with good accuracy, we introduce the unstructured-grid system which is formulated on the open source CFD code. Especially the hybrid method is employed consisting of the Cartesian grid for the accurate turbulence structures in the urban canopy, and the unstructured-grid for the accurate wake flows around the specified building inside the densely arrayed buildings in the center of cities. The obtained results of pressure distributions, focusing on the corner of buildings, are estimated in comparison with the previous experimental data.

KEYWORDS: LES, unstructured grid, wind pressure, city

1 INTRODUCTION

This paper discusses the higher-accurate LES (Large eddy simulation) for the wind loading estimation on a specified building in cities. Thus far Urban winds have been often simulated by RANS model from an environmental point of view, where the wind velocity prediction is essential. This case showed good performance of RANS model [1]. On the LES of the urban wind, the Cartesian grid system with equal increment was often used and its accuracy was generally enough for the wind velocity prediction [2], [3]. However with regard to the wind pressure and force predictions, we have encountered a different story. This paper introduces the overset grid with finer mesh for the near region of the specified building by employing the unstructured grid system and realizes the accurate aerodynamic prediction by LES. In order to simulate numerically the turbulent flows around buildings in cities, we have to take care of the following issues:

- The approaching flow is a turbulent boundary layer over a rough wall.
- The other buildings exist neighboring to the specified building
- A pack of buildings cover a region with a relatively large area which forms a canopy locally.

Accordingly for constructing the numerical model we have to set up unsteady turbulent flow field at the inflow condition and impose the bottom boundary condition representing directly the surface shape of buildings and trees. The authors showed, on the preceding paper [3], the numerical model for urban flows in Fig. 1. This model consists of two driver regions for the approaching turbulent flow. One is for generating the turbulent boundary layer over rough surface by the rescaling technique [4] and the other is for arranging the boundary layer to develop along the fetch under the boundary condition imposed to the urban area. Also, the model has the domain which is used for LES of the flow over an actual urban area. Using the uniform grids with 2.5m in the horizontal direction and the stretching grid upward with sufficiently fine grid near the ground, the building are represented by using several tens meshes for the building

breadth. It is not fine enough for mesh to represent the building shape but the previous LES examples showed the success of the LES prediction for the flow field. Accordingly the Cartesian-grid based method can simulate the gap flows among the buildings and transportation problems of mass and gas in cities. However the predictive accuracy of the above method is ambiguous for the estimation of the wind pressures and forces on the specified building which is focused on in the city.

This study examines advantages and disadvantages for the LES model applied to the wind-resistant design of buildings under high wind and proposes the higher-accurate predictive method appropriate to practical usage.

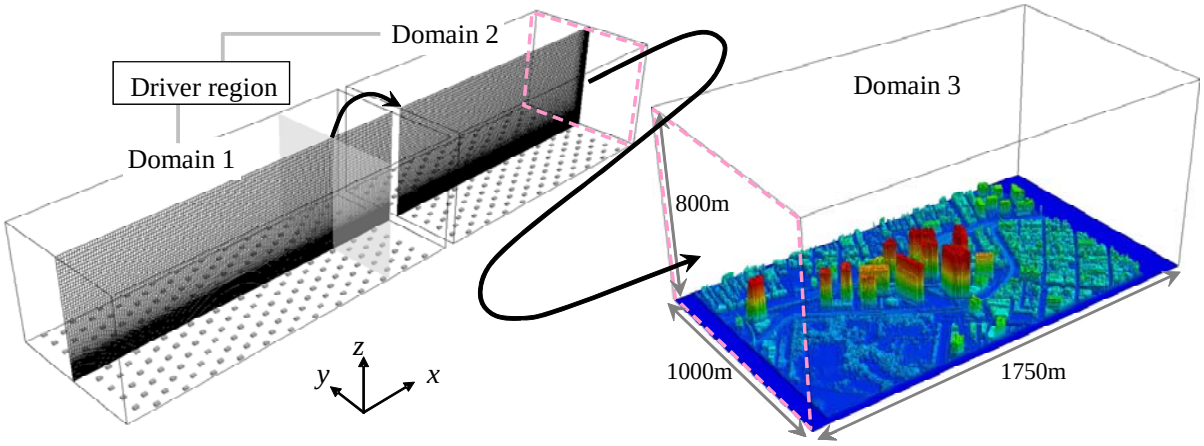

Figure 1. Numerical model of urban wind (Cartesian grid).

2 PROBLEM FORMULATIONS

2.1 *Hybrid method*

For the LES analysis for the specified building in the city center, it is important to set up how to resolve the flow around the building and its near region or the urban area consisting of many other buildings. As far as the prediction of wind velocity, it is not so significant to reproduce the shape of the building. The Cartesian grid method has been applied to this problem (see Figure 1). However in order to predict the wind pressures and forces, the overlaid method is sometimes employed, introducing the generalized coordinate system. When taking into consideration the building aspect in city, complexity level is very high due to the cladding, wall texture, window sash and balcony. Their representation requires multiple superposition of the overlaid area. These parts are so small that their influence on the wind pressure and force is weak, so they are possibly neglected. For checking it, this study introduces the numerical model which can estimate the effect of cladding, such as an unstructured grid system. Here we pick up OpenFOAM which is widely used as an open source code. Figure 2 illustrates the numerical model where the area including the specified building and its circumstances are clipped for the unstructured grid area obtained by the mesh generation software (SnappyHexa).

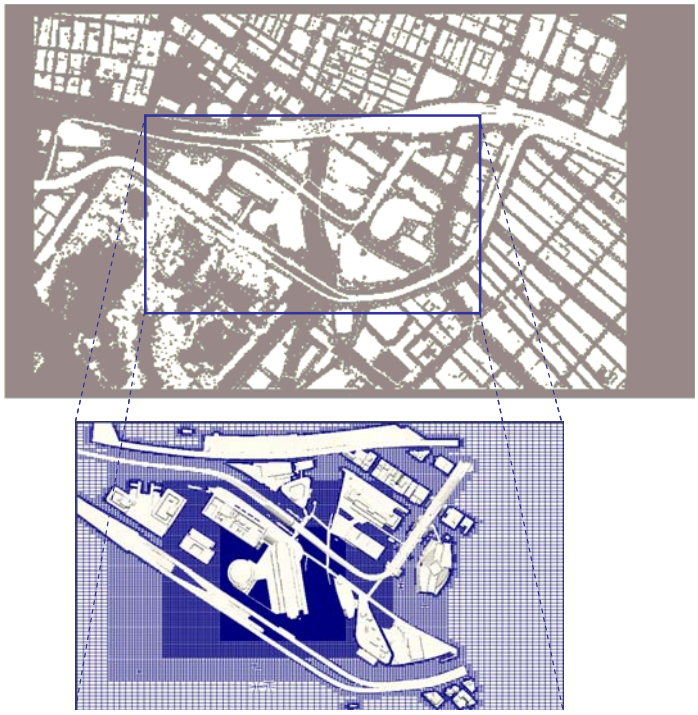

Figure 2. Unstructured grid for near-region of the building.

2.2 *Turbulent simulation*

The governing equations for LES are the filtered forms for the continuity and the incompressible Navier-Stokes equations as follows:

$$\frac{\partial \overline{u}_i}{\partial x_i} = 0 \tag{1}$$

$$\frac{\partial \overline{u}_i}{\partial t} + \overline{u}_j \frac{\partial \overline{u}_i}{\partial x_j} = -\frac{\partial \overline{p}}{\partial x_i} + \frac{\partial}{\partial x_j} \frac{1}{\mathrm{Re}} \left(\frac{\partial \overline{u}_i}{\partial x_j} + \frac{\partial \overline{u}_j}{\partial x_i} \right) - \frac{\partial}{\partial x_j} \tau_{ij} \tag{2}$$

where u_i, p, Re *and* τ_{ij} stand for velocity, pressure, the Reynolds number and the sub-grid scale (SGS) Reynolds stress ($\overline{u_i u_j} - \overline{u}_i \overline{u}_j$). Concerning the sub-grid scale modeling, the Smagorinsky type of dynamic procedure [5], [6] was employed for representing the eddy viscosity concept.

$$\tau_{ij} - \frac{1}{3}\delta_{ij}\tau_{kk} = -2\nu_e \overline{S}_{ij} = -2C\overline{\Delta}^2 \left|\overline{S}\right| \overline{S}_{ij} \tag{3}$$

where C denotes the model coefficient for SGS modeling of velocity, S_{ij} the strain rate tensor, and $\overline{\Delta} = \left(\overline{\Delta}_x \overline{\Delta}_y \overline{\Delta}_z\right)^{1/3}$ grid-filter width, respectively. The model coefficients C are evaluated dynamically using the Germano identity.

$$C = -\frac{\langle L_{ij} M_{ij} \rangle}{\langle M_{ij} M_{ij} \rangle}, \quad L_{ij} = \widetilde{\overline{u}_i \overline{u}_j} - \widetilde{\overline{u}}_i \widetilde{\overline{u}}_j, \quad M_{ij} = 2\left(\widetilde{\overline{\Delta}^2 \left| \overline{S} \right| \overline{S}_{ij}} - \overline{\Delta}^2 \widetilde{\left| \overline{S} \right| \overline{S}_{ij}} \right) \tag{4}$$

2.3 *Unstructured grid embedded in the near region of the specified building*

According to Figure 3, the curved surface of the building can be represented smoothly. On the inflow boundary of the unstructured grid area, turbulent flow is given by one-way method, which is obtained using LES on the Cartesian coordinate grid system. Appropriate resolution to the near region of the building, neighboring area and the surrounding buildings area is selected making use of the property of the unstructured grid such as the variability of the resolution on each area. Numerical method of OpenFOAM is summarized as follows [7]. This code uses the finite volume method to solve the systems of partial differential equations ascribed on any three dimensional unstructured grid of tetra, prism, hexa and polyhedral cells. The temporal term of the governing equations is treated by using the Crank-Nicolson scheme, which is the second-order difference in time. Other terms of the governing equations are discretized using the second-order limited central difference. The governing equations are solved sequentially using the resulting PISO (*P*ressure-*I*mplicit *S*plitting *O*peration) algorithm. The solution is performed implicitly by matrix inversion using the incomplete Cholesky conjugate gradient method. The code is parallelized using the message-passing interface (MPI).

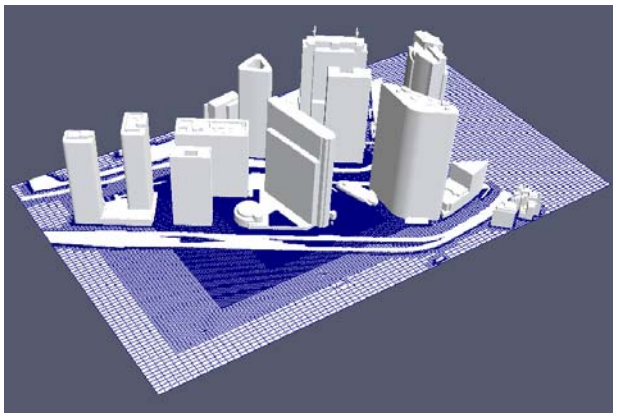

Figure 3. Unstructured grid system around buildings with smoothly curved surfaces.

3 LES RESULTS BY THE OPEN FOAM

This session shows the numerical results for turbulent flows around the buildings obtained by LES using Open FOAM as an open source code.

Figure 4 depicts the LES results for the wind velocity distributions among the densely arrayed tall buildings. It can be recognized that the flow with fully developed turbulence comes from the inflow boundary into the computational region. Also, the separated flow from a plate-shaped building at the center acts directly on the wing-type building behind and rolls into the wake formed between these two buildings. This rolling up is stronger at lower level. Also, it generates the high wind region in front of the wing-type building.

Figure 5 illustrates the turbulence structures developed behind a pack of the tall buildings. We can see that the wind velocity decreases in the wake, as increasing the fluctuation with small vortices generated there. These vortices exist in the higher altitude as well and influence widely the mechanism of unsteady flow patterns around the top edge of urban canopy.

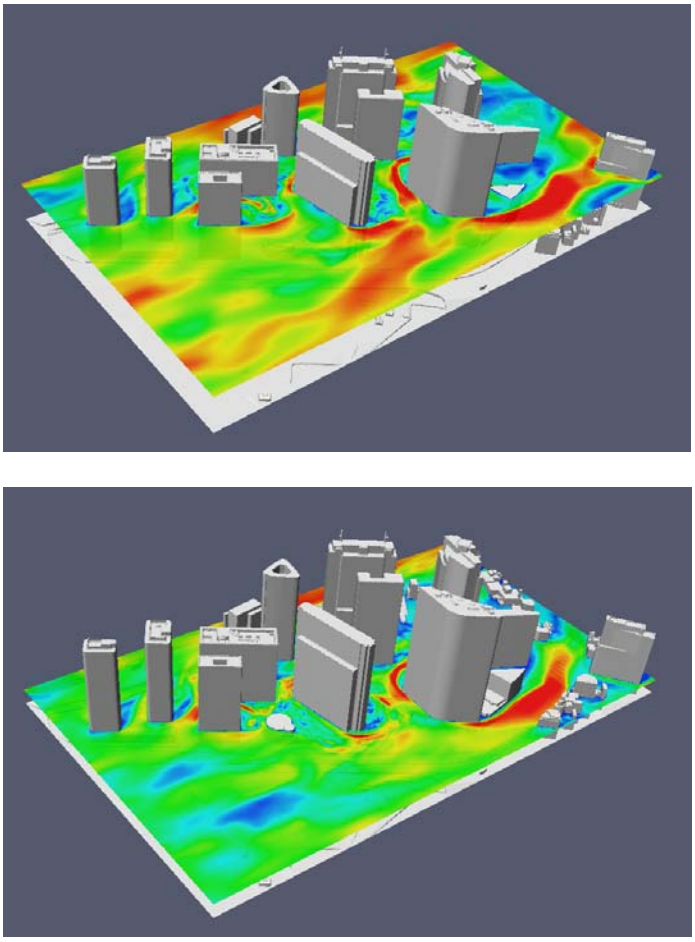

Figure 4. LES results of wind velocity around the densely arrayed buildings in cities (top: at 65m high, bottom: at 25m high).

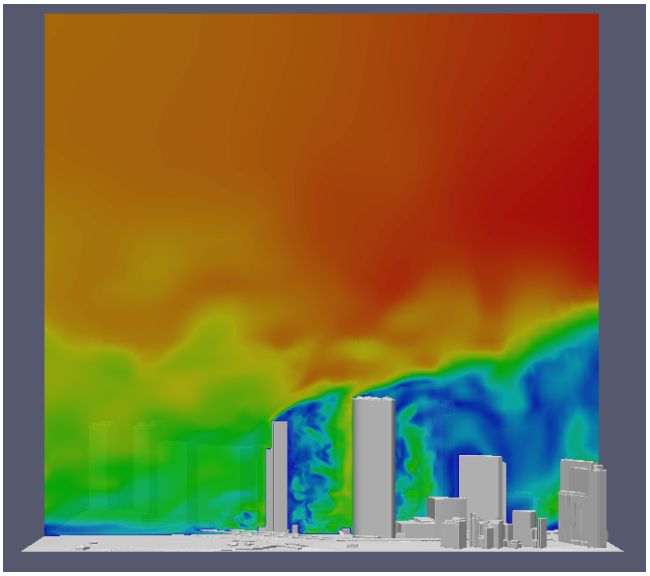

Figure 5. Computed wind velocity field on vertical section.

Figure 6 illustrates the pressure distributions on the surface of tall buildings existing densely in the triangular-shaped area. It is clearly recognized that there exist a positive pressure area at stagnation point in front of the plate-shaped tall building. Also, we can see partly high positive pressure zone at front surface of the wing-shaped building behind, where the shear flow separated from the frontal tall building acts straightly. On the tall building which locates further downstream inside a pack of tall buildings, the flow is rolling up behind the plate-shaped building and attacks with increasing its velocity. On the attacked area at the side of further downstream building, the high positive pressure occurs locally.

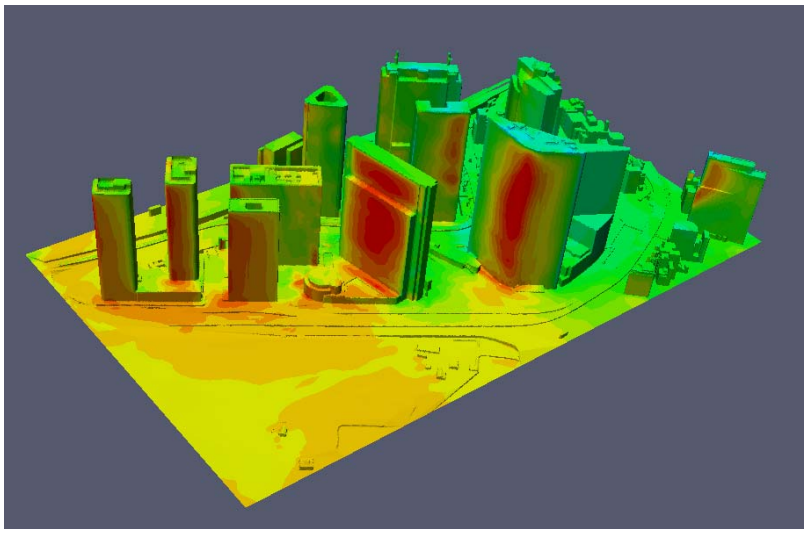

Figure 6. Computed instantaneous pressure contours on the tall buildings.

Figure 7 depicts the instantaneous streamlines added to the pressure distributions on various tall buildings in Fig.6. The flow, after attacking to the plate-shaped building, separated at its side. Subsequently the flow acted on the wing-shaped building at the rear. At the frontal stagnation of the wing building the flow is divided to right and left. One is going straight along the main street and the other is rolling inside between the plate- and the wind-shaped buildings and is followed by going into the closed-space area. Furthermore the flow attacks locally on the part of the frontal surface and forms the stagnation area biasedly. Accordingly in the packed area of tall buildings the flow is going inside with affected respectively by the surrounding building where the specific pressure distribution is attributed to each flow pattern formed.

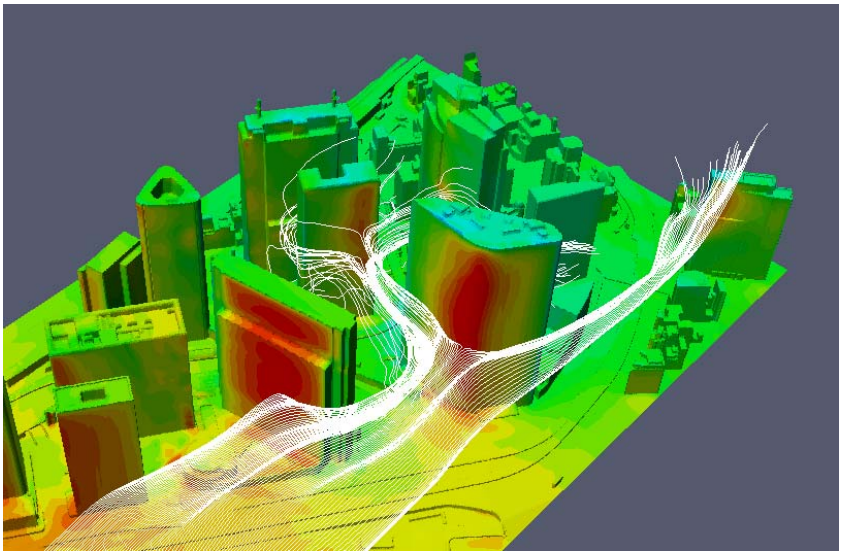

Figure 7. Computed instantaneous stream lines with pressure contours on the tall buildings.

4 PRESSURE DISTRIBUTIONS ON THE TALL BUILDING -COMPARISON WITH EXPERIMENTAL DATA

Figures 8 and 9 indicate details of the pressure distributions on the plate-shaped building. The pressures at higher level, since the section becomes smaller, are different from that of the lower level. The higher zone has another stagnation point separately and generates the very local negative pressures on both the upstream corners. Its magnitude is larger at the side of inside the pack where the separated shear layer is bending due to the surrounding buildings and approaching to the side of the plate-shape of building. Figure 9 shows the comparison of LES and experimental data for mean pressure coefficients at each height indicated by the dashed lines in Fig. 8. Correspondence of LES results (lines) and experimental data (symbols) is definitely good in quantitative sense at almost area, so guarantees the practical usage of LES technique. But the locality of the pressures on the upstream corner is so intensive that grid resolution at this area should be set with careful insight.

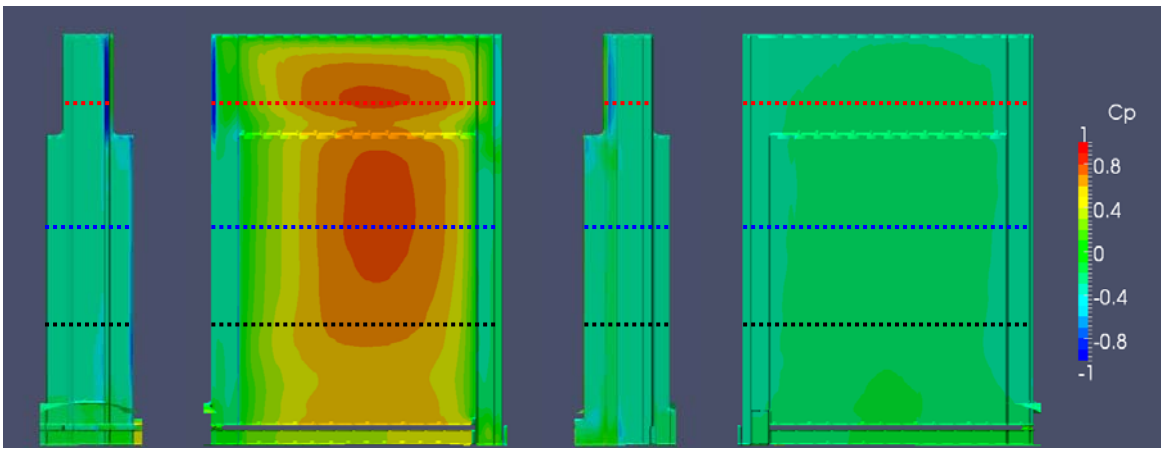

Figure 8. Computed time-averaged pressure contours on the tall building.

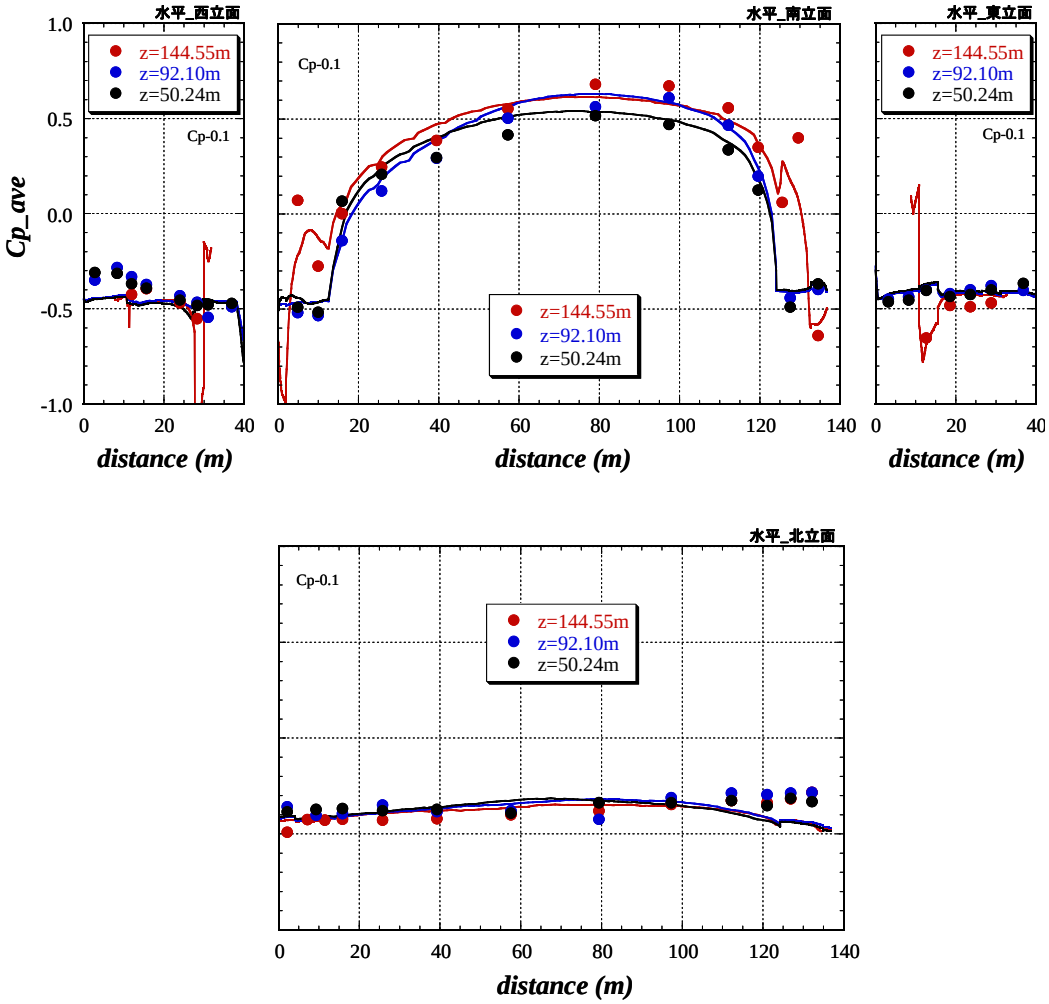

Figure 9. Computed and experimental time-averaged pressure contours at each height on the tall building(top: front and sides, bottom: back).

5 PRESSURE DISTRIBUTIONS ON THE TALL BUILDING -COMPARISON WITH EXPERIMENTAL DATA

Figure 10 shows comparison of the LES results obtained by using the conventional Cartesian grid and by using the unstructured grid system embedded in the near-region of the specified building. The unstructured grid used here is formulated at the Open FOAM and has a tendency to give solutions affected sensitively by the grid size. In the present case, very fine mesh is used near the plate-shaped building at center but the mesh behind it becomes rough rapidly. As a result, the solution there shows the vortex structures become smoother compared with the flow by the Cartesian grid and tend to lose their fine structures. But taking into consideration the same resolution at rear for Cartesian and unstructured grids, the numerical scheme of present unstructured grid has a tendency to generate the dissipative solution. This means it an expected issue that the high-accuracy of discretization for unstructured grid should be developed. However it can be considered that the finer mesh of unstructured grid in the limited area around the specified

building can generate the better results for the pressure distributions due to reproduction of the sufficiently fine turbulence structures comparable to the results by the Cartesian grid as well as the shape of the complicated building (refer to Session 4). The present overset grid method proposed is much expecting for the practical use since the unsteady structures of turbulence can be reproduced in almost area by the Cartesian grid and the higher compatibility to configuration of the object can be realized by the unstructured grid for the near area.

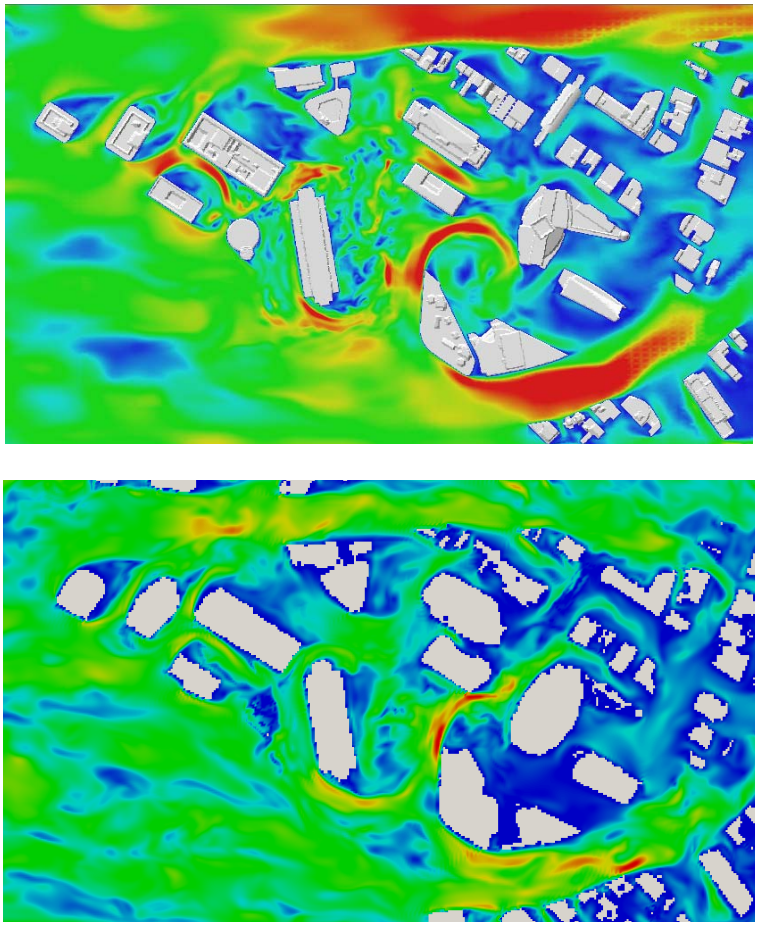

Figure 10. Comparison of wind velocity field (top: unstructured grid, bottom: Cartesian grid).

6 CONCLUSIONS

The conclusions of this study can be shown as follows:

- Using the LES model of the method overlaid by the unstructured grid system, the appropriate turbulence structures at inflow and among a pack of tall buildings can be simulated.
- The pressure distribution on the specified building obtained by the present LES is appropriate in order to realize the practical use of CFD technique for wind-resistant design of the buildings.
