Brief Introduction

The Seventh International Colloquium on Bluff Body Aerodynamics and Applications (BBAA7) is held in Shanghai, China, on September 2-6, 2012. BBAA7 is co-organized by Tongji University, China Academy of Building Research, Hunan University, Southwest Jiaotong University, State Key Laboratory of Disaster Reduction in Civil Engineering and CCCC Highway Consultants Co., Ltd., and in cooperation with International Association for Wind Engineering, Natural Science Foundation of China, Shijiazhuang Tiedao University, Chang'An University, Key Laboratory of Wind Resistance Technology of Bridges of Ministry of Transport and Tianjin Research Institute for Water Transport Engineering of Ministry of Transport. It follows the sprits set in the previous 6 BBAA Colloquia held in Japan in 1988, Australia in 1992, United States in 1996, Germany in 2000, Canada in 2004 and Italy in 2008. It provides a stimulating and constructive forum to facilitate the exchange of the latest scientific and technical information in the field of flow around fixed and vibrating bluff bodies both in terms of fundamentals as well as applications, particularly to Wind Engineering. The major topics for BBAA7 include experimental, computational and analytical studies of vortex shedding and wakes, fluid-structure interaction and aerodynamics of bridges, cables, buildings and vehicles and so on. A total of 200 papers are collected in the colloquium proceedings, including 5 keynote session papers and 195 parallel session papers.

Preface

August 15, 2012

The Seventh International Colloquium on Bluff Body Aerodynamics and Applications (BBAA7) is to be held in Shanghai, China, on September 2-6, 2012. It is co-organized by Tongji University, China Academy of Building Research, Hunan University, Southwest Jiaotong University, State Key Laboratory of Disaster Reduction in Civil Engineering and CCCC Highway Consultants Co., Ltd., and in cooperation with International Association for Wind Engineering, Natural Science Foundation of China, Shijiazhuang Tiedao University,Chang'An University, Key Laboratory of Wind Resistance Technology of Bridges of Ministry of Transport and Tianjin Research Institute for Water Transport Engineering of Ministry of Transport.

BBAA7 follows the spirits set in the previous BBAA Colloquia held in Japan in 1988, Australia in 1992, United States in 1996, Germany in 2000, Canada in 2004 and Italy in 2008. It provides a stimulating and constructive forum to facilitate the exchange of the latest scientific and technical information in the field of flow around fixed and vibrating bluff bodies both in terms of fundamentals as well as applications, particularly to Wind Engineering. The major topics for BBAA7 include experimental, computational and analytical studies of vortex shedding and wakes, fluid-structure interaction and aerodynamics of bridges, cables, buildings and vehicles and so on.

A total of 200 papers are collected in the colloquium proceedings, including 5 keynote papers, 20 organized session papers and 175 general papers. The three organized sessions are NSFC-JST Project of New Strategies for Wind Disaster Risk Reduction of Wind Sensitive Infrastructures - focusing on Typhoon simulation and Universal ESWL, Bluff Body Aerodynamics: Application to Dispersion of Pollutants, and New Technology for CFD Wind-resistant Design of Buildings. The specific topics of general papers cover Wind Environment; Wind Characteristics; Prism Aerodynamics including Rectangular, Circular and Square; Bridge Aerodynamics including General, Modeling, Buffeting, Vortex Excitation, Flutter and CFD; Building Aerodynamics including CFD, Interference, High-rise, and Low-rise; Vehicular Aerodynamics; Cable Aerodynamics; Aerodynamics of Other Structures; Tree/Vegetation; PIV Application; and Wind Energy. All the papers included in this proceedings have received peer reviews under the coordination of the International Scientific Committee of BBAA7.

The editors would like to express sincere gratitude to all contributors for their submissions with high academic quality and to the organizers of three organized sessions for their organization with interesting topics as well as to reviewers for their useful opinions and comments to make this 2000-page proceedings extraordinarily outstanding. We hope this special issue will serve as a milestone in BBAA and provide indications for further research and development in the wind engineering field.

ABSTRACT: Although vorticity is an essential characteristic of bluff body wakes, its origin, transport and conservation is not always explored or understood. Prior to discussing the evolution of wakes from cylinders, a generalised formulation of vorticity generation at boundaries is presented, ranging from free to no-slip boundary conditions and including fluids ranging from the limits of solid to vacuum. Vorticity is found to be generated by tangential pressure gradients or relative acceleration of fluid at interfaces. Examples of vorticity generation, diffusion and storage are given, including that for a rotating cylinder. The enigma of apparent vorticity disappearance for a submerged cylinder is explained. Alternative descriptions in terms of vorticity and momentum are contrasted; vorticity is shown to be conserved in each case. The wake transitions from two-dimensional vortex sheets to three-dimensional modes for the circular cylinder are shown to change dramatically under the influence of oscillation and geometrical modification.

KEYWORDS: Vorticity, Bluff Bodies, Wakes, Stability

1 INTRODUCTION

Fundamental to some of the major problems - such as vortex induced vibrations - that arise in the flow around stalled airfoils and bluff bodies in aeronautics and wind engineering are the dynamic wake structures and the transitions between different wake modes. In particular, as smaller structures such as micro-aircraft and surface modifications are considered, the question of wake structure and stability in the Reynolds number range of 10-10^3 becomes increasingly important.

Vorticity is one of the most important physical quantities in fluid mechanics. Boundary layers, wakes and turbulence in bluff body flows owe their presence to, and are essentially defined by, vorticity and vortices, whose motions are "the sinews and muscles of fluid motions" (Küchemann[1]) and are associated with fluctuating forces in a flow.

A dynamical formulation for the generation of vorticity has previously been sought (Morton[2]). Considering mainly the flow next to a solid wall, it was concluded:

1. Vorticity is generated at boundaries by the relative acceleration of fluid and wall produced instantaneously:
   i) from the fluid side by tangential pressure gradients;
   ii) from the wall side by acceleration of the boundary, where generation is again partially masked by viscous diffusion when there is continuing generation.
2. For an impulsive change, wall stress does not produce vorticity.
3. The only means of decay or loss of vorticity is by cross-diffusion and annihilation of vorticity of opposite signs.

The case of a free surface has also been studied, and it has been shown that vorticity is conserved (Lundgren and P. Koumoutsakos[3]). That is, vorticity (in terms of total circulation) is not

lost through the free surface but rather is "stored" in the line vortex representing the free surface. This is an important result that needs to be considered in our formulation.

The aims of this paper are:

i) to demonstrate how vorticity is generated at boundaries, redistributed into the flow, and interacts with other boundaries;
ii) to examine the 3D transitions that arise in the vorticity generated at, and shed from, bluff body surfaces.

A generalised description of the generation of vorticity at interfaces between fluids ranging from a vacuum to a solid, and for partial slip conditions at the interface ranging from free to no-slip, is presented. We extend important previous works (Morton[2], Lundgren and P. Koumoutsakos[3]) to cover vorticity generation at interfaces, both flat and curved, between fluids for a range of densities and viscosities, in addition to different degrees of slip. Furthermore, a number of examples are considered to demonstrate the power of this generalised formulation and to provide a physical insight into the generation, redistribution and conservation of vorticity. These include planar Couette flow, a cylinder translating horizontally below a free surface, and a rotating circular cylinder in a fluid with an outer radial boundary. The development of three-dimensional wakes modes from the initial two-dimensional vorticity shed from cylinders is then studied, with emphasis on the difference in the order of appearance and characteristics of the modes.

2 NUMERICAL METHODS

A spectral-element solver using a semi-implicit time-stepping scheme was used to solve the Navier-Stokes and continuity equations (Thompson et al.[4]). The Navier-Stokes equations were discretised with the use of a semi-implicit spectral-element scheme that uses time-splitting for the temporal discretisation. This code has previously been employed to obtain accurate solutions for the flow around cylinders (Thompson et al.[4,5]; Ryan et al[6]), spheres (Thompson et al.[7]; Thompson et al.[8]) and rings (Sheard et al.[9]). The implementation for the time-splitting or fractional step method is given in Karniadakis et al.[10], which is based on a method originally proposed by Chorin[11].

To examine the sensitivity of the flow around the bluff body to three-dimensional perturbations in the spanwise direction, a linear stability analysis is carried out. This involves solving the linearized Navier–Stokes equations based on a pre-computed two-dimensional base flow. The approach has been documented in, for example, Ryan et al.[6]

3 RESULTS

The formation of wakes behind two-dimensional bluff bodies consists initially of the generation of two-dimensional vorticity at the surface, then the shedding of the vorticity into the wake, and finally the development of three-dimensional wake modes. We first examine how vorticity is generated and behaves near interfaces between fluids of varying properties. Then, the results of some previous two-dimensional and axisymmetric studies are examined to understand the generation and apparent disappearance of vorticity. Finally, the appearance of three-dimensional vortex structures originating from unstable two-dimensional bluff body wakes is presented.

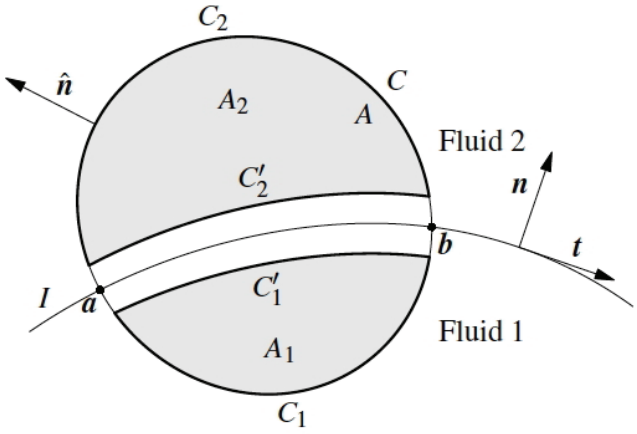

Figure 1. The interface I with normal vector **n** and tangential vector **t**. Shaded sub-regions A_1, A_2 of the region A in each fluid are bounded by the curves C_1,C_1' and C_2,C_2', respectively. The outward normal vector of a region is denoted by $\hat{n}$ and **n** is the outward normal vector to the interface.

3.1 *Vorticity in a two-fluid system*

A generalised formulation of vorticity generation is presented that includes the spectrum of fluids from solid to vacuum. The Helmholtz vorticity equation,

$$\partial\omega/\partial t + (\mathbf{v}.\nabla)\boldsymbol{\omega} = (\boldsymbol{\omega}.\nabla)\mathbf{v} + \nu\nabla^2\omega, \quad (1)$$

where ω is vorticity, **v** is velocity, and ν is the kinematic viscosity, gives little information on how vorticity is generated because it contains no true generation term (Morton[2]). The first term on right is a processing term describing the effects of local amplification (or concentration) of vorticity by stretching and/or local turning of vortex filaments. The second term on right represents viscous diffusion; that is, the spread of vorticity due to viscosity. Therefore, for a homogeneous fluid, vorticity is generated only at boundaries.

Consider a two-dimensional, viscous incompressible fluid in some domain in the plane (see Fig. 1). Let A be a material region in the domain, bounded by the simple curve C. From a standard application of the divergence theorem on the vorticity transport equation, one obtains for the rate of change of vorticity in A:

$$d/dt \int_A \omega \, dA = \oint_C \nu\nabla\boldsymbol{\omega}.\mathbf{n} \, ds, \quad (2)$$

where **n** is the outward unit normal. The equation states that the total vorticity in the region changes only because vorticity diffuses across the boundary. Thus, there are no sources of vorticity in the simple domain A. However, vorticity may arise at the interface, as will be shown.

Assume now that an interface between two fluids passes through A. We assume that all relevant physical quantities and all of their derivatives have limits as the interface is approached in each of the fluids. These limits when approached in fluid 1(2) are denoted by the subscript 1(2). Only if a quantity **q** is continuous across the interface is it well-defined at the interface. Otherwise, only the jump $[[\mathbf{q}]] = \mathbf{q}_2 - \mathbf{q}_1$ is single-valued at the interface.

Restricting attention to interfaces that do not change location in time (i.e., the normal velocity of the fluids at the interface is zero), then after some manipulation, one can show that the time rate of change in total circulation is related to the pressure (p) difference along the interface:

$$d/dt(\int_A \omega \, dA + \int_a^b \gamma \, ds) = \oint_C \nu \nabla \boldsymbol{\omega} . \mathbf{n} \, ds + [[p/\rho]]_a - [[p/\rho]]_b. \quad (3)$$

where ρ is the local density of the fluid and γ is the circulation. The first term on the right side of the equation is not a generation term – rather, it represents the flow of vorticity into or out of the region due to viscous diffusion. The second term on the right represents the generation of vorticity due to tangential pressure gradients along the interface boundary for each fluid. The quantity $\gamma = -[[\mathbf{u}.\mathbf{t}]]$ represents the tangential velocity jump across the interface.

For the case where the interface is infinitely long or the pressure is the same at each end (e.g., bluff body) and for regions where no vorticity is diffusing across the outer boundaries, we have no net source terms (although there may be local ones at the interface), and vorticity is conserved:

$$d/dt \, (\int_A \omega \, dA + \int_a^b \gamma \, ds) = 0. \quad (4)$$

Note that the results of the present section are independent of any boundary conditions on the outer boundary or the interface; only the Navier-Stokes equations and incompressibility constraint are assumed.

3.2 *Vorticity in a single-fluid system*

Many problems in fluid dynamics are formulated as a single fluid region with boundary conditions imposed instead of an interface with another fluid. We now derive the vorticity integrals for single fluid domains by reducing the interface between two fluids to boundary conditions for two common cases: the no-slip condition and the free-surface condition.

3.2.1 *No-slip boundary condition*

Let fluid 2 be replaced by a solid body with a no-slip boundary condition imposed at the interface *I* **(**see Fig. 1**).** If the velocity of the surface of the solid body is denoted by **U**, the vorticity balance now has the form:

$$d/dt \, (\int_{A_1} \boldsymbol{\omega} \, dA \,) = \oint_{C1} \nu \nabla \boldsymbol{\omega} . \mathbf{n} \, ds - d/dt \, (\int_a^b \mathbf{U}.\mathbf{t} \, ds) - (p_1/\rho_1|_b - p_1/\rho_1|_a). \quad (5)$$

Note that no vorticity is stored at the no-slip boundary but a vorticity generation term (second on right) appears as a result of acceleration of the boundary (in addition to the generation term due to fluid pressure gradient along the boundary: the third term on the right), as found by Morton[2]. The boundary condition $\mathbf{u} = \mathbf{U}$ does not produce a simple boundary condition in terms of vorticity $\boldsymbol{\omega}$.

3.2.2 *Free-slip boundary condition*

Now consider the case where the interface has free slip, such as for a free surface of fluid 1. That is, we assume that the shear stress at the interface in fluid 1 is zero. For the mathematical formulation of the flow in fluid 1, no description of fluid 2 is needed. The vorticity balance for the flow region A_1 is:

$$d/dt \, (\int_{A_1} \omega \, dA + \int_a^b \mathbf{u_1}.\mathbf{t} \, ds) = \oint_{C1} \nu \nabla \boldsymbol{\omega} . \mathbf{n} \, ds - (p_1/\rho_1|_b - p_1/\rho_1|_a). \quad (6)$$

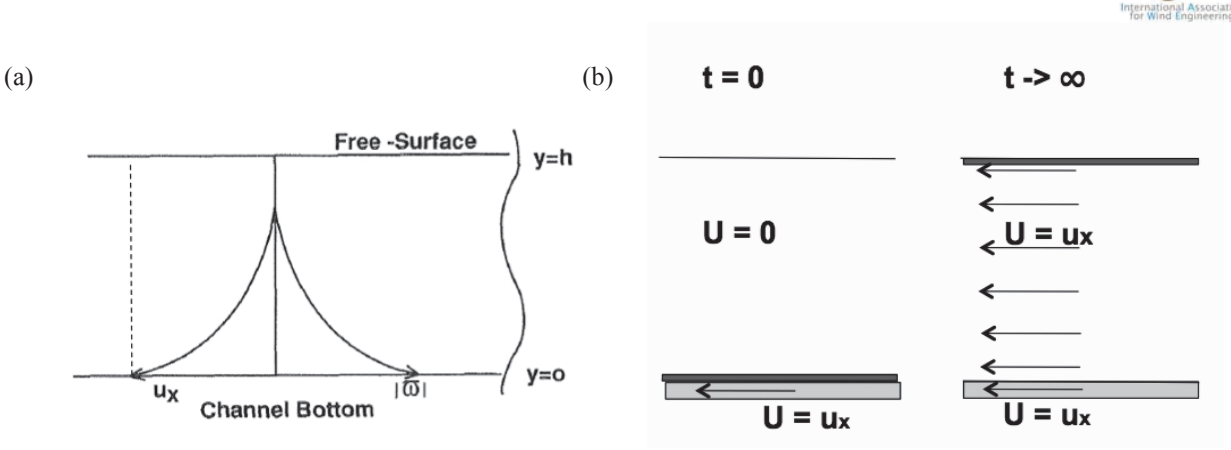

Figure 2. (a) Schematic after Rood[12]. Bottom plate is accelerated impulsively from rest to velocity u_x at $t = 0$. (b) As time approaches infinity, the initially quiescent fluid layer uniformly co-moves with the plate. The thicker dark lines on the bottom plate at $t = 0$ and at the upper free surface at $t \rightarrow \infty$ denote vorticity originally generated by the impuslively accelerated plate and vorticity stored at the interface in a vortex sheet, respectively.

That is, vorticity is generated in this case for a free or slip surface by a pressure gradient in the fluid along the surface, with vorticity being stored at the boundary (second term in brackets on the left). The boundary condition on vorticity (for zero normal velocity) is given by

$$\omega_1 = 2\,\mathbf{u_1}.\mathbf{t}\,\kappa = \kappa V_1. \tag{7}$$

Here, V_1 is the tangential fluid velocity at the interface and κ is the fixed surface curvature. Thus, vorticity can appear at the boundary due to curvature of the interface and tangential velocities induced by pressure gradients. However, this "additional" vorticity is balanced by the amount stored at the interface in the case; where there is no diffusion of vorticity into/out of the system, the total vorticity is conserved.

3.3 *Examples of vorticity generation and diffusion*

3.3.1 *Planar Couette flow with a free surface*

When the plate at the bottom of a finite, initially quiescent, fluid layer is impulsively accelerated, the final flow as time approaches infinity is a horizontal, uniform fluid flow of velocity equal to the plate velocity (see Fig 2). There appears to be no vorticity remaining as no velocity gradients exist in the fluid. Rood[12] concluded: "Vorticity is neither conserved nor is it angular momentum. Therefore it is physically acceptable that vorticity entirely disappears from a flow. The disappearance of the vorticity is unsettling if vorticity is erroneously ascribed the same conservation principle that applies to momentum". Contrary to this, we find that vorticity conservation is common, even for systems where momentum is continually changing.

According to (5), vorticity is generated at $t = 0$ due to the impulsive acceleration of the solid plate, i.e., through the d/dt ($\int_a^b \gamma\, ds$) term with γ (the velocity jump across the interface) = u_x (the plate velocity). Vorticity then diffuses away from the plate towards the free surface above. In the final state, there are no velocity gradients or vorticity diffusion in the flow (uniform horizontal flow) but the velocity at the free surface interface has increased from zero to u_x. If we consider the velocity in the vacuum above to have remained zero then this means that the velocity jump

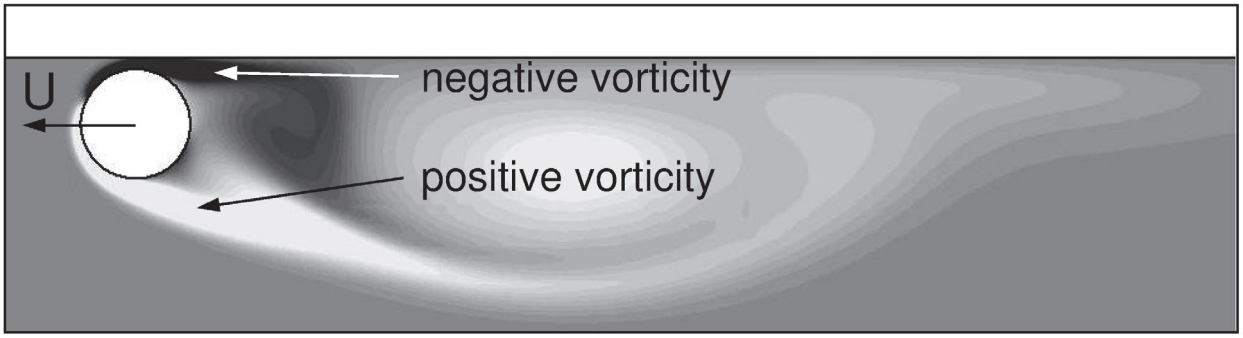

Figure 3. Cylinder translating horizontally, right to left, very close to a free surface. Vorticity layers shed from the upper and lower surfaces of the cylinder are of opposite sign. The net circulation within the fluid and within the vortex sheet at the free surface remains constant.

initially at the bottom interface is now at the top surface. Therefore, vorticity is impulsively introduced and is conserved here; accounting for its balance is simple. Interestingly, to keep the plate moving at constant velocity to overcome frictional resistance, momentum is required to be continuously introduced into the fluid and is therefore more complicated to track.

3.3.2 *Submerged cylinder*

Second, as a cylinder, relatively translating horizontally in a fluid layer, is moved closer towards a free surface, an intriguing phenomenon is observed (Sheridan et al.[13], Reichl et al.[14]). The vorticity shed from the upper cylinder surface rapidly disappears as it advects downstream and a net circulation seems to manifest in the flow (see Fig 3). No net vorticity is shed from the cylinder because its boundary is a closed curve and therefore no net pressure gradient can result (and there is no tangential acceleration of the solid surface). However, a closer examination shows that the deficit in vorticity present in the flow from the disappearing upper shear layer shedding is balanced precisely by the increase in the circulation of the line vortex (or velocity jump) at the free surface. Again, total vorticity in the flow is conserved even though the magnitude of the momentum of the flow is continuously increasing.

3.3.3 *Rotating cylinder*

Third, the case of a spinning cylinder in a flow is considered. When a circular cylinder is impulsively spun-up to angular velocity Ω in an initially quiescent flow, vorticity of sign opposite to that in the solid cylinder ($\omega = -2\Omega$) is generated at the surface of the fluid in contact with the cylinder. That is, instantaneously, a circular vortex sheet is generated in the fluid. This vortex sheet diffuses radially outwards in the fluid and distributes to a larger and larger area such that at any given point, $\omega \to 0$ for $t \to \infty$. At a given point, $|\omega|$ first increases and then tends to zero but never reaches that value. The flow tends to the potential flow around a line vortex having circulation equal that of the cylinder. The total vorticity of the system (cylinder plus fluid) remains zero.

When an outer free slip boundary is placed at a finite radius (see Fig. 4), one may expect the final solution to be analogous to that of example 1, where no vorticity remains in the main body of the fluid but resides in the vortex sheet at the surface. However, for a curved boundary, the boundary condition on vorticity is $\omega = 2\mathbf{u}_1.\mathbf{t} = \kappa V_1$, where V_1 is the tangential fluid velocity at the interface and κ is the fixed surface curvature. In the plane free-surface case, the curvature of the surface is zero and the vorticity is therefore identically zero there. In the curved surface case, non-zero and varying vorticity can be present at the free surface.

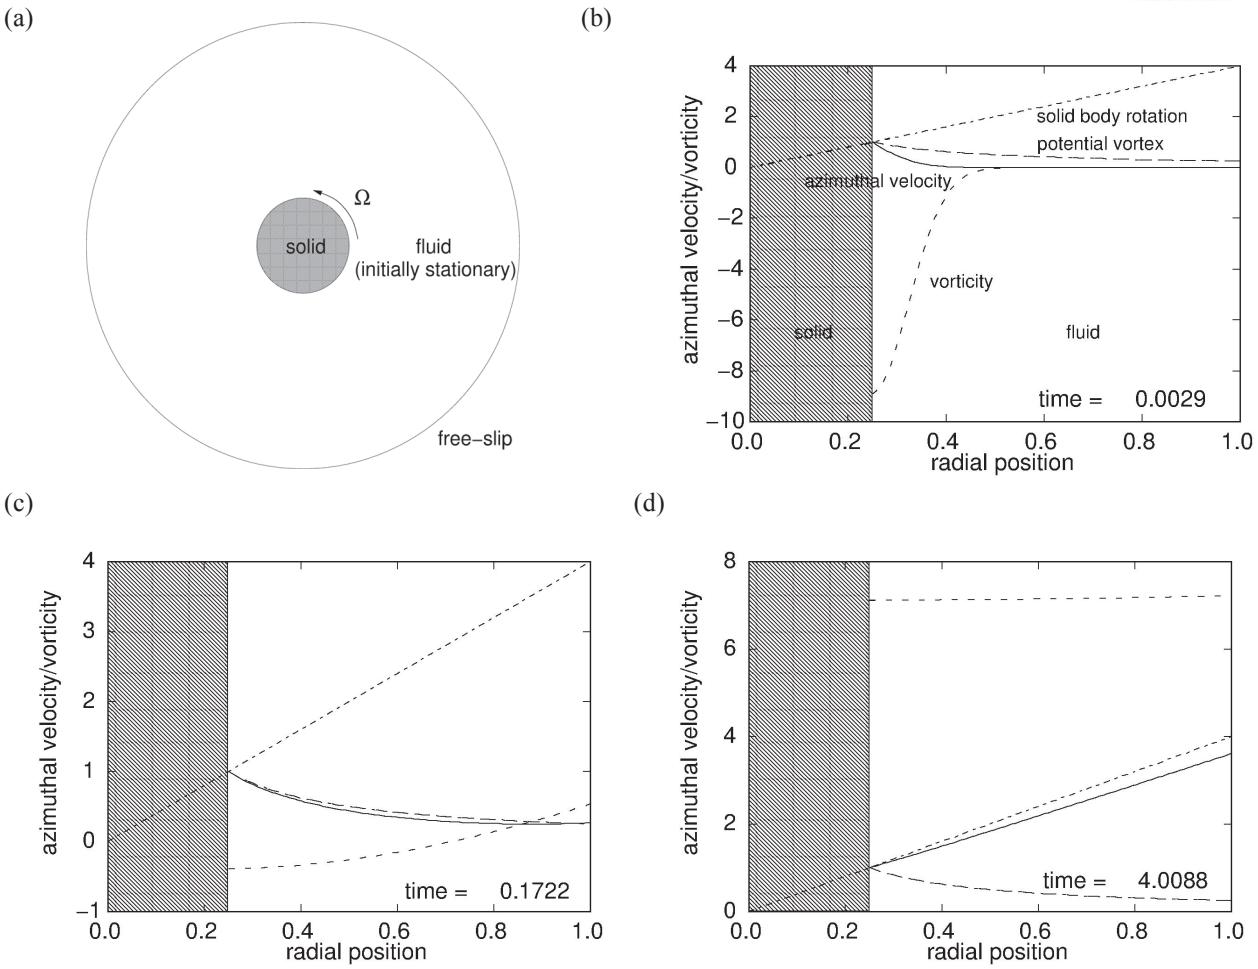

Figure 4 (a) Schematic of rotating cylinder with outer free boundary. (b), (c), (d): solutions for the velocity (solid line) and vorticity (medium dashed line) profiles in fluid at successive normalized times. Also shown for reference are the velocity distributions for the potential flow around a line vortex (long dashed lines) and for solid body rotation (short dashed lines).

When the cylinder is impulsively spun-up, the vorticity generated at the fluid inner boundary diffuses radially outwards, with a velocity profile initially tending to potential flow around a line vortex, as in the unbounded cylinder case. However, this potential flow solution is incompatible with the vorticity boundary condition at the free surface, and vorticity is fed back radially from the interface, leading ultimately to solid body rotation in the fluid. Nonetheless, vorticity is conserved in this problem, with the balance of vorticity stored in the circular vortex sheet at the outer boundary. Note again that no net vorticity is added after the initial spin-up but that angular momentum needs to be continually transferred to the system to keep the cylinder rotating at constant angular velocity.

3.4 *Transition of wakes to three-dimensionality*

Above, we have considered the generation and transport of vorticity in two dimensions or axisymmetry. For many bluff body flows, when the Reynolds number exceeds a threshold, the two-

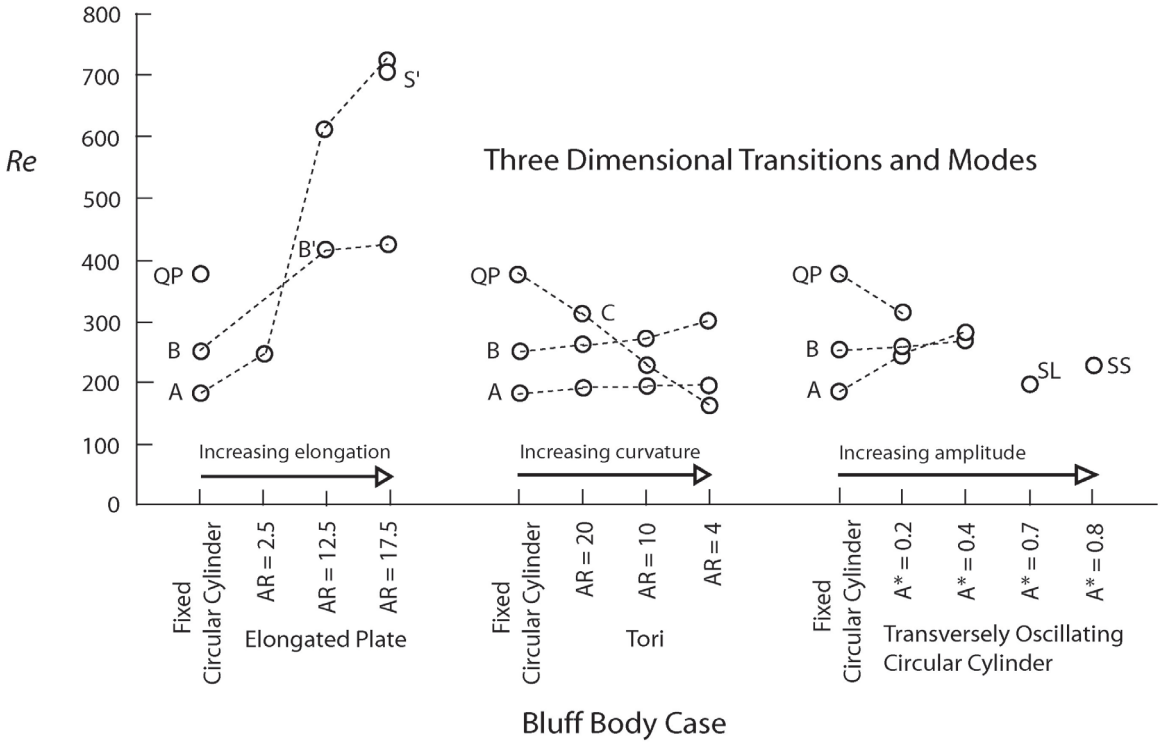

Figure 5. Three-dimensional transitions of different modes for variations of the fixed cylinder flow: elongation in direction of flow; increasing curvature to limit of sphere; increasing oscillation at the natural Strouhal frequency.

dimensional wakes, formed by vorticity shed from the bluff body surface, are found to transition to three-dimensionality. The canonical geometries for bluff bodies are the circular cylinder and the sphere, for which a considerable number of experimental and computational studies have been undertaken. Here, we will consider the basic geometry of a cylinder and examine the change in wake transition as the cylinder geometry is varied, or if the cylinder is oscillated as occurs in vortex-induced vibration.

For the circular cylinder, stability analysis indicates that the two-dimensional periodic wake becomes linearly unstable to mode A at Re ≈ 190, and the base flow undergoes a further bifurcation to mode B at Re ≈ 260. Experiments and direct numerical simulations (DNS) show that mode B becomes unstable at a significantly lower Reynolds number (Re = 230-240). At slightly higher Reynolds numbers, there is a strong nonlinear interaction between the modes and the wake undergoes a rapid transition to spatio-temporal chaos, so that it is effectively turbulent for a Reynolds number of just a few hundred.

In the case of the sphere, the wake undergoes a regular (i.e., time-steady) transition at Re = 212 to the two-threaded wake. This wake then becomes unstable at Re ≈ 270 through a Hopf (steady to periodic) bifurcation. At Re ≈ 350, the vortical wake structures no longer maintain the same strict alignment from one shedding cycle to the next. The overall wake structure is similar at considerably higher Reynolds numbers, although much more chaotic.

Although the wakes of the circular cylinder and the sphere have been well studied, the question is whether they really are generic or universal with respect to wake transitions. Shown in the Figure 5 are the wake transitions to three-dimensionality for a cylinder that is (i) increasingly elongated in the streamwise direction, (ii) increasingly curved and contracted into a torus (and eventually a sphere), and (iii) oscillated with increasing amplitude at the natural Strouhal fre-

quency. As can be observed, the transitions are not universal: not only does the Reynolds number at which transitions occurs change significantly, but the order of appearance of the modes varies, and in fact new modes can appear. For example, with increasing curvature of a torus, mode C appears before both modes A and B. Likewise, as the amplitude of transverse oscillation of a cylinder increases, mode B can appear at a lower Reynolds number than mode A and eventually other modes (SL, SS) appear. This has implications for the route to turbulence in the wakes of different bluff bodies and the difficulty of defining a "canonical" bluff body.

4 CONCLUSIONS

A formulation is presented of vorticity generation and behavior at fluid-fluid interfaces, where the fluid properties are generalised to include the limits of a solid and free surface, and the *fluids* can range in properties from a solid to a vacuum. The two-fluid model can also be reduced to the traditional one-fluid model with boundary conditions. As proposed by Morton[2], vorticity is generated at boundaries due to pressure gradients in the fluid or relative acceleration of the contiguous fluids. Consistent with Lundgren and Koumoutsakos[3], vorticity can be stored as a vortex sheet at a free surface, leading to conservation of vorticity in the system. Examples showing the generation, transport and conservation of vorticity are discussed to demonstrate the power of the formulation. In the second part of the article, the transition to three-dimensionality of initially two-dimensional wakes shed by bluff bodies is examined. In particular, the flow around the circular cylinder, which is considered the generic case for two-dimensional bluff bodies, is examined. It is found that the modes and order of transition can differ dramatically from those of a fixed circular cylinder when the cylinder shape is varied or the cylinder is oscillated.

5 ACKNOWLEDGEMENTS

Flutter and Its Application - Flutter mode and Ship Navigation

Masaru Matsumoto

Professor Emeritus,Kyoto University, Kyoto, Japan
Visiting Professor,Osaka Electro and Tele-Communication University, Osaka, Japan

1 INTRODUCTION

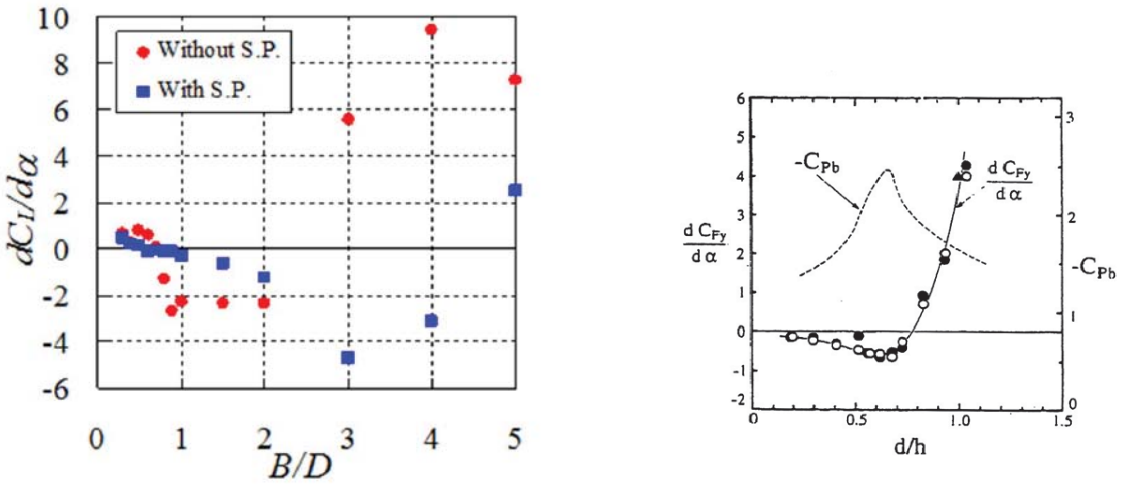
Galloping, Torsional flutter and coupled flutter, all of these are here classified as flutter, have been widely studied by numerous researchers. Their generation mechanisms have been clarified, through previous studies. These flutter phenomena are summarized from author' view-points. Galloping is classified into unsteady and quasi-steady galloping, and into flow reattachment type galloping and flow non-reattachment type galloping.(Matsumoto and Laneville[2011], Matsumoto[2011])) In these, it is described that inner circulatory flow and separation bubble plays essentially important role for satisfactory of den Hartog Criteria[1956], $dCF/d\alpha<0$. Furthermore, inclined cable aerodynamics, those are rain-wind induced vibration and dry galloping, which have become greatly concerns to cable-stay bridge design0, are briefly explained from their generation point of view. On torsional flutter, pointing out important role of separation bubble, it is explained that the change of flutter of rectangular cylinder with different side ratio, B/D, from torsional flutter to coupled flutter occurs continuously with B/D, bounded approximately with B/D=10.(Matsumoto[1997]) Analogy of aerodynamic derivatives between H-shaped cylinders and rectangular cylinders is introduced (Matsumoto[2004]). Related to Tacoma Narrows Bridge failure, on sudden change of oscillation mode, from 5th symmetrical heaving mode to 1st asymmetrical torsional mode, another possible cause of increasing wind velocity is shown through wind tunnel test (Matsumoto[2004]). On coupled flutter, step-by-step (SBS) flutter analysis is introduced in contrast to conventional complex eigen value flutter analysis(Matsumoto[2010]). Classification of flutter branch and fundamental flutter mode is explained. Furthermore, on similar Selberg formula[1961] to estimate coupled flutter critical velocity for thin plate, is driven basing on simple assumption(Matsumoto[2010]. As application of knowledge of flutter, fundamental flutter mode, that is H-90 mode, definitely important role to produce propulsion force. A primary ship navigation test has been carried out and generation mechanism of propulsion force by flapping plate has been discussed. Navigation system by flapping plate might have significantly advantage of saving power because of intelligent utilization of flutter power generation system in flapping plate(Matsumoto and Ishizaki[2010]).

2 GALLOPING –1DOF HEAVING FLUTTER

2.1 *Non-flow Reattachment Type Galloping*

Galloping can be classified into "Quasi-steady Galloping" and "Unsteady Galloping" (Nakamura and Hirata[1996] and Matsumoto[2008]). "Quasi-steady Galloping" which is 1DOF heaving flutter, has been known to be catastrophic fluid-induced vibration, and negative slope associated with pitching angle of lift force coefficient, that is $dCF/d\alpha<0$, is definite condition for its excitation, as den Hartog Criteria[1956]. A numerous studies on quasi-steady galloping have been carried out to verify its generation mechanism from the point of flow fields

around bluff bodies. As summary, the characteristic flow fields related to appearance of negative lift slope, dCF/dα<0, are classified into two different one, that is inner-circulatory flow appearance on side surface of bluff body, which is originally proposed by Bearman[1972], and separation bubble formation on side surface of body. On former flow field, Nakamura[1981] lately pointed out “flow reattachment type pressure distribution flow”. For 2D rectangular cylinders with pitching angle of 0°, quasi-unsteady galloping caused by this flow field can be observed at the range of side-ratio, B/D (B: along-wind length, D: cross-wind length) between 0.75 and 2.8 in smooth flow (see Fig.1)



Matsumoto[2006] Nakamura[1996]

Fig.1. dCL/dα-B/D Diagrams of Rectangular Cylinders

2.2 *Flow Reattachment Type Galloping*

On the later flow field, stalling phenomena of airfoil at stalling pitching angle has been well known. McAlister and Carr[1978] has shown clear visualized separated vortex and vortex patch during forced torsional motion of airfoil at stalling angle and Shimizu, Nishihara and Ishihara[2006], and Matsumiya, Nishihara and Shimizu[2010] studied on galloping on transmission line with snow, and indicated that flow reattachment and formation of separation bubble should excite galloping instability at critical pitching angle, as shown in Fig.2.

(c) Flow Reattachment and Formation of Separation Bubble at $\alpha=20^0$ and $\alpha=154^0$ corresponding Galloping Appearance(Matsumiya, and Shimizu[2010])

Fig 2. Quasi-Steady Galloping of Transmission Line caused by Flow Reattachment and Formation of Separation Bubble (from Shimizu, Oka, Ishihara[2006] and Matsumiya, Nishihara and Shimizu[2010])

2.3 *Unsteady Galloping*

As far as “unsteady Galloping”, Nakamura and Hirata[1994] reported “Low Speed Galloping (LSG)” for bluffer rectangular cylinders with less than B/D=0.75, which appeared at lower reduced velocity range than Vr=1/St. These bluffer cylinders do not show $dC_L/d\alpha<0$, but $dC_L/d\alpha>0$ as shown in Fig.1. Hirata[1993] precisely measured the unsteady presure on side surface during LSG, and found the appearance of “reattachment type pressure” on side surface. Therefore, LSG must be unsteady galloping, which cannot be excited by den Hartog criteria. Appearance reduced Ranges of conventional quasi-steady galloping(Nakamura[1994] named it as High Speed Galloping(HSG) for contrast to LSG, and LSG of rectangular cylinders are illustrated as show in Fig.3(by Nakamura[1994]).

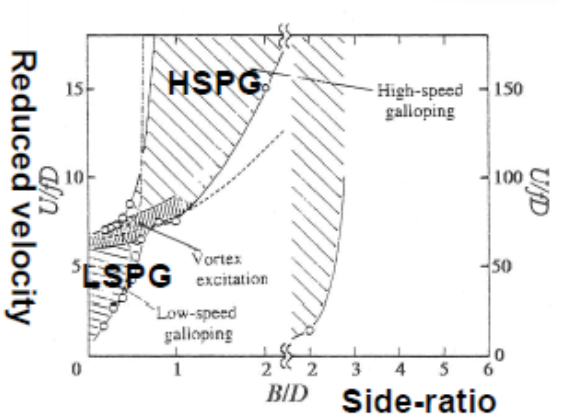

Fig 3. HSG and LSG of Rectangular Cylinders(Nakamura[1994])

As another exmaple of unsteady galloping, yawed circular cylinder with yawing angle of 45°, significant cross-flow response appears when Karman vortex(KV) shedding becomes weak as shown in Fig.4. On Generation of quas-isteady galloping in relation to mitigation/damaged Karman vortex(KV), further investigation might be needed.

(d) Band-Passed Amplitude of Cross Flow Response and Standard Deviation of Fluctuating Velocity in a Wake
Fig.4 Unsteady Cross-Flow Response of Yawed Circular Cylinder with Yawing Angle of 45°(Matsumoto[2007])

Furthermore, bluff rectangular cylinders , thoseside ratios are B/D=0.3, 0.4,0.5,0.6,0.7, with fixed splitter plate in a wake show unsteady galloping. An example of C_L, C_D, C_L', and Strouhal number v.s. pitching angle, , diagrams as shown in Fig.5 and its H_1*, which is related to aerodynamic damping, defined by Scanlan[1971],shows large positive magnitude. Basing on den Hartog Criteria, galloping is never excited, but violent galloping is observed in free bibration test for this case. (see Fig.5 and Fig.6) This galloping should be caused by "fluid-memory", corresponding the undulation of seaprared flow in near wake generated by body motion,. In another expression the lift force has significant phase lag from body motion. That means typical unsteady effect of lift force. Circular cylinder with a fixed splitter plate would show unsteady galloping.

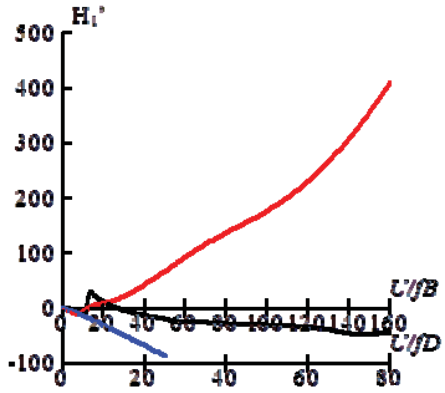

Fig 6. H_1* of rectangular cylinder without a splitter plate (black line) and with a fixed splitter plate (red-line) (blue line is obtained from Teodorsen function)

2.4 *Galloping of Inclined Stay Cables of Cable Stay Bridges*

Aerodynamic vibration of stay cable of cable stay bridge has frequently observed observed in dry state, that is without rain, or in wet state, that is in rainy state. Those are called as Rain Wind induced vibration(RWV) and dry galloping(DG). Recently author has summarized that three major factors play definitely important role for excitation of RWV and DG, independently and individually. Those are formation of water rivulet(WR) on upper cable surface originally pointed out by Hikami[1986], axial flow(AF) in a near wake originally pointed out by author[1989,2008,2010], and critical Reynolds number(Recr) which has originally pointed out by Macdonald[2005]. All of these factors generate particular flow field around cable surface, that is "separation bubble" by local flow-reattachment (Matsumoto[2011]). Taking into account of the appearance of "separation bubble" in "flow reattachment type galloping" in the process from non-flow reattacment state to flow reattachment state, on the other hand, the appearance of "inner circulatory flow" in "flow non-reattachment type galloping" in the process from flow separation state to flow reattachment state, DG at the range where Re number towards to Recr, corresponding to drag crisis, separeted flow tends to closely moves to cable surface, "inner circulatory flow" should be generated. At Recr separated flow reattaches on cable-surface, then "separation bubble" is generated on cable surface(Bass[1985]). Thus, generation mrchanism of inclined RIV and DG is summarized as indicated in Fig.7 and Fig.8.

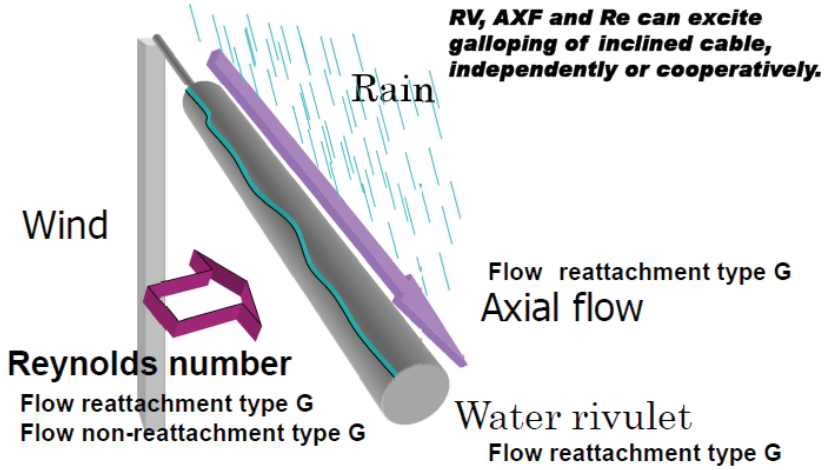

Fig 7. Illustration of Three Major Factors in Relation to RWV an DG of Inclined Stay Cable(Matsumoto[2011])

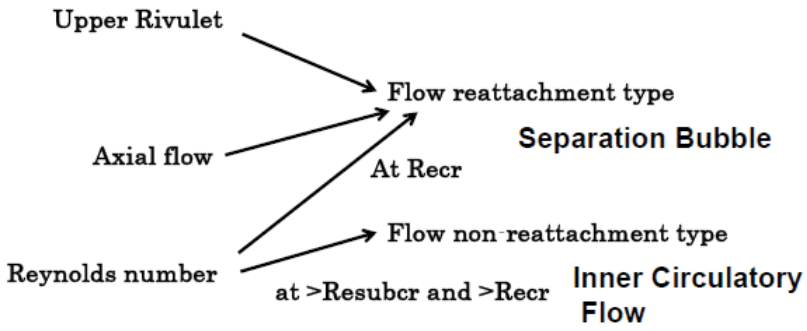

Fig 8. Characteristic Flows for excitation of RWV and DG of Inclined Stay Cable (Matsumoto[2011])

3 TORSIONAL FLUTTER

It has widely known that airfoil shows torsional flutter near stalling angle and its flow field can be characterized by flow separation, flow reattachment and formation separation bubble. Fig.9 is visualized flow pattern during torsional motion of airfoil by Mc-Alister and Carr[1978]. It has been verified that unsteady change of size of sepparation bubble during torsional oscillation should be generation mechanism.

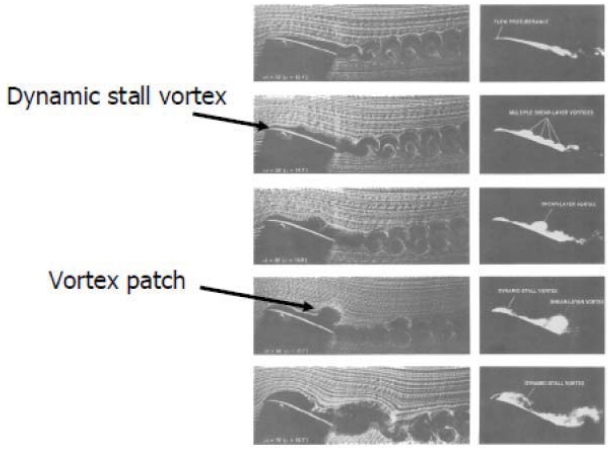

Fig 9. Visualized Flow Field of Airfoil, NACA0012, during Torsional Motion (by Mac-Alister and Carr[1978])

For rectangular cylinders with B/D from 5 to 20, unsteady pressure properties,those are amplitude of pressure coefficient, Cp, and phase, ψ, of negative pressure from the maximum angle of attack (for heaving motion: neutral position during downward motion and for torsional response nose up maximum) are shown in Fig. 6. It can be verified that flow separates from the leading edge of cylinder and flow reattaches on side surface for B/D=8,10,12.5, 15 and 20, and for B/D=5, flow tends to reattaches near at trailing edge. It should be noted that the maxmum peak of Cp appears at almost same positionon side surface for all cylinders and phase,ψ, is almost identical in various side ratios. Furthermore, it should be noted that if relative angle of attack in heaving and torsional motions is identical, Cp and ψ are almost same. Basing on these unsteady characteristics, it is verified that flow field around rectangular cylinders with B/D=5 to 20 might be less affected by the after body-length. Heaving and torsional 2DOF differential equations are expressed as follows:

$$m\ddot{\eta} + c_\eta\dot{\eta} + k_\eta\eta = \rho b^2\omega_F H_1^*\dot{\eta} + \rho b^2\omega_F^2 H_4^*\eta + \rho b^3\omega_F H_2^*\dot{\phi} + \rho b^3\omega_F^2 H_3^*\phi$$

$$I\ddot{\phi} + c_\phi\dot{\phi} + k_\phi\phi = \rho b^3\omega_F A_1^*\dot{\eta} + \rho b^3\omega_F^2 A_4^*\eta + \rho b^4\omega_F A_2^*\dot{\phi} + \rho b^4\omega_F^2 A_3^*\phi$$

where, m and I:mass and mass inertia per unit length, c_η and c_ϕ :heaving and torsional damping coefficient, k_η and k_ϕ :heaving and torsional stiffness, b:half chord length, ρ : air density, ω_F : flutter circular frequency, H_i^* and A_i^* (i=1-4) :aerodynamic derivatives.These 8 aerodynamic derivatives can be obtained from unsteady pressure properties(Scanlan[1971]), those are Cp and ψ , as follows:

$$H_1^* = \frac{-V^2}{2b\omega^2\eta_0}\int_{-1}^{1}\tilde{C}_p\cos\psi_H dx = \frac{V^2}{2b\omega^2\eta_0}\int_{-1}^{1}\tilde{C}_p H_1^* dx$$

$$H_4^* = \frac{-V^2}{2b\omega^2\eta_0}\int_{-1}^{1}\tilde{C}_p\sin\psi_H dx = \frac{V^2}{2b\omega^2\eta_0}\int_{-1}^{1}\tilde{C}_p H_4^* dx$$

$$A_1^* = \frac{-V^2}{2b\omega^2\eta_0}\int_{-1}^{1}\tilde{C}_p x\cos\psi_H dx = \frac{V^2}{2b\omega^2\eta_0}\int_{-1}^{1}\tilde{C}_p A_1^* dx$$

$$A_4^* = \frac{-V^2}{2b\omega^2\eta_0}\int_{-1}^{1}\tilde{C}_p x\sin\psi_H dx = \frac{V^2}{2b\omega^2\eta_0}\int_{-1}^{1}\tilde{C}_p A_4^* dx$$

$$H_2^* = \frac{V^2}{2b^2\omega^2\phi_0}\int_{-1}^{1}\tilde{C}_p \sin\psi_T dx = \frac{V^2}{2b^2\omega^2\phi_0}\int_{-1}^{1}\tilde{C}_p H_2^* dx$$

$$H_3^* = \frac{-V^2}{2b^2\omega^2\phi_0}\int_{-1}^{1}\tilde{C}_p \cos\psi_T dx = \frac{V^2}{2b^2\omega^2\phi_0}\int_{-1}^{1}\tilde{C}_p H_3^* dx$$

$$A_2^* = \frac{V^2}{2b^2\omega^2\phi_0}\int_{-1}^{1}\tilde{C}_p x\sin\psi_T dx = \frac{V^2}{2b^2\omega^2\phi_0}\int_{-1}^{1}\tilde{C}_p A_2^* dx$$

$$A_3^* = \frac{-V^2}{2b^2\omega^2\phi_0}\int_{-1}^{1}\tilde{C}_p x\cos\psi_T dx = \frac{V^2}{2b^2\omega^2\phi_0}\int_{-1}^{1}\tilde{C}_p A_3^* dx$$

In particular, torsional instability can be measured from A_2^*. If $A_2^*>0$, torsional flutter appears, on the contrary if $A_2^*<0$, aerodynamically stable against torsional flutter. Positive or negative of A_2^* can be determined by the position of diagram of $C_pH_2^*$, it means if it locates upstrem side or downstream one from mid-chord point, A_2^* shows negative or positive, respectively. (see Matsumoto[2005])

○:B/D=5
●:B/D=8
◇:B/D=10
◆:B/D=12.5
△:B/D=15
▲:B/D=20

Fig 10 .Unsteady Pressure Characteristics, C_p and ψ, of Rectangular Cylinders with Various Side-Ratios from B/D=5 to 20 under Forced Heaving(a) and Torsional vibrations (b)(Matsumoto[2005])

Aerodynamic derivative of A_2^* , in consequence, changes continuously from negative to positive with increase of B/D as shown in Fig.10. The rectangular cylinder with B/D=10 shows almost $A_2^*=0$, and more bluffer cylinders with less than B/D=10 up to B/D=4 studied here, $A_2^*>0$, that means appearance of torsional 1DOF flutter. Rectangular cylinders with more than B/D=10 show coupled flutter instability.

On the aerodynamic derivatives between rectangular cylinders and H-shaped cylinders, there exists similarity as shown in Fig. 10. From this diagram, H-shaped cylinder possesses aerodynamically more bluff than rectangular cylinder, even though their side ratio,B/D, are identical.

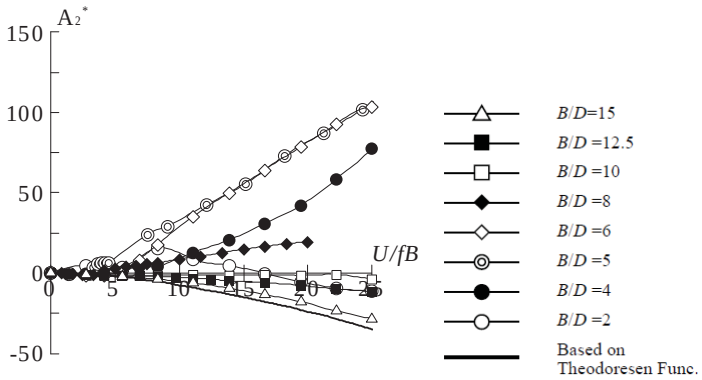

Fig 11. Aerodynamic Derivative of A_2^* of Rectangular Cylinders with Various Side Ratios (Matsumoto[2005])

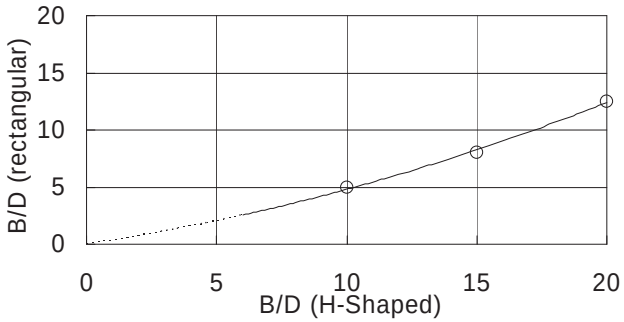
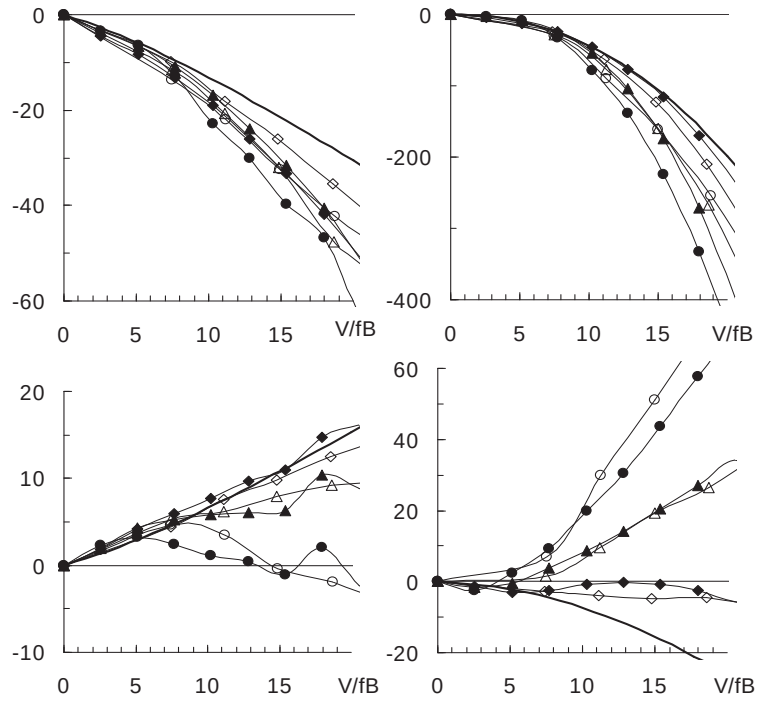


(a) Analogy of Flutter Derivatives of H-Shaped and Rectangular Cylinders



(b) Comparison of Aerodynamic Derivatives, A_1^*, A_2^*, H_1^* and H_3^*, of H-Shaped and Rectangular Cylinders

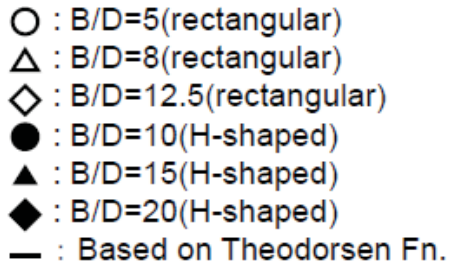


Fig.12 Analogy of Aerodynamic Characteristics between H-Shaped and Rectangular Cylinders (Matsumoto[2004])

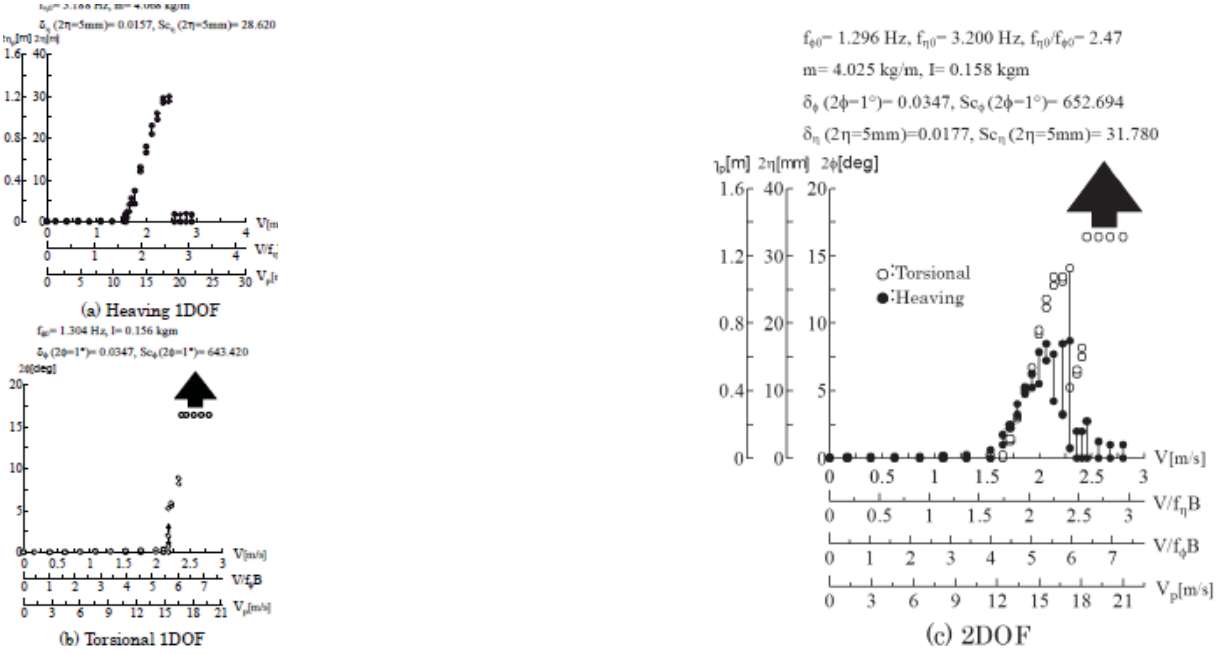
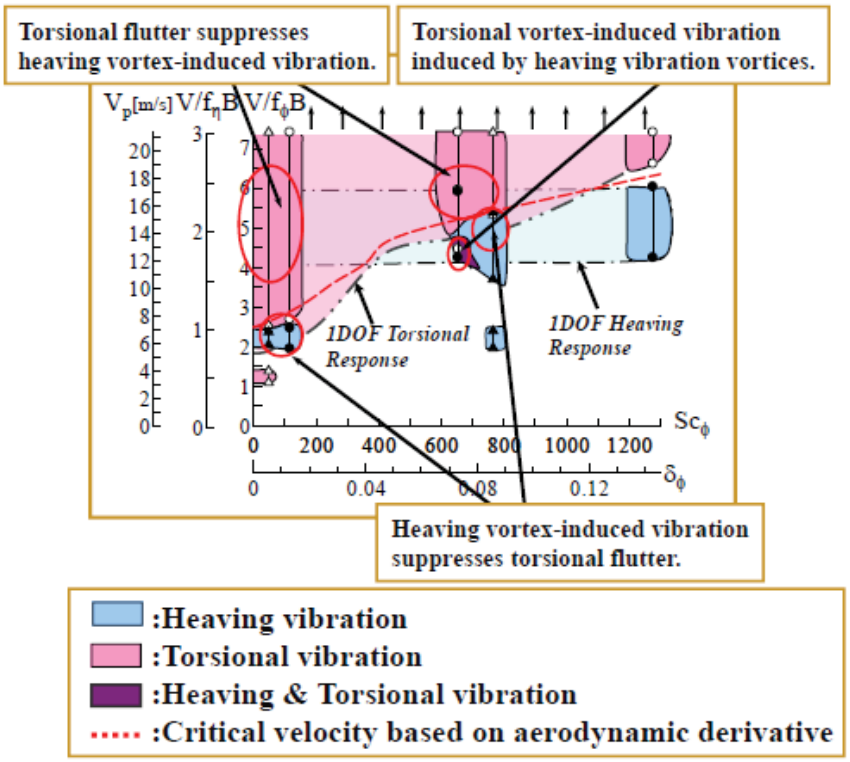
For bluff bodies which indicate torsional flutter, including rectangular cylinders, and H-shaped cylinders, aerodynamic interference between vortex-induced vibration(VIV) and torsional flutter becomes significant issues at particular frequency ratio in torsional frequency, $f_{\varphi 0}$, and heaving one, $f_{\eta 0}$. For example, original Tacoma Narrows Bridge had plate-girder with H-shape section with B/D=5. This bridge showed catastrophic torsional oscillation by 1st asymmetrical mode, after showing 5th heaving symmetrical mode under wind velocity less than 20m/s. Its frequency ratio, $f_{\varphi 0}/f_{\eta 0}$. , corresponding these modes, is 2.5.



(a) Response of Original Tacoma Narrows Bridge in 1DOF Heaving, 1DOF Torsional and 2DOF 2DOF Heaving and Torsional Vibration Systems



(b) Aerodynamically Unstable Range (Scruton Number-Velocity Diagram)
Fig.13 Response Characteristics of Original Tacoma Bridge (Matsumoto[2004])

The response characteristics investigated by wind tunnel test are shown in Fig.13. The Farquarhsen report [1949] pointed out sudden change of vibration mode, from 5th heaving to 1st torsional might be caused by broken of center diagonal stay cables by heaving VIV. However, the another explanation, basing on these wind tunnel test, might be possible. It might be caused by slight inrcease of wind velocity from 18m/s to 19m/s, which correspond to 16.3m/s to 17.2m/s as effective wind velocity crossing perpendicularly bridge girder, because of skewly crossing to the Tacoma Narrows Chanel by 25^0. Furthermore, Looking at 35mm film taken by Farqursen'group at the bridge site, during 5th mode torsional vibration of main span, vibration of side-span still maintained the frequency of 5th symmetrical heaving mode. Taking into account of velocity mitigation near land than the center part of channel. It should be natural in thinking that these different vibration modes should be caused by the difference of wind velocity. Also many cable strands of the main cable near at the cable band of center-diagonal stay cables had been severly damaged. Cable band does not move,in general, for heaving vibration, because of the role of center diagonal stay cable to prevent the torsional displacement of girder. The fact that many cable strands were severly damage near cable band, cater stay cables must be suvive after appearance of torsional vibration of girder.

4 COUPLED FLUTTER

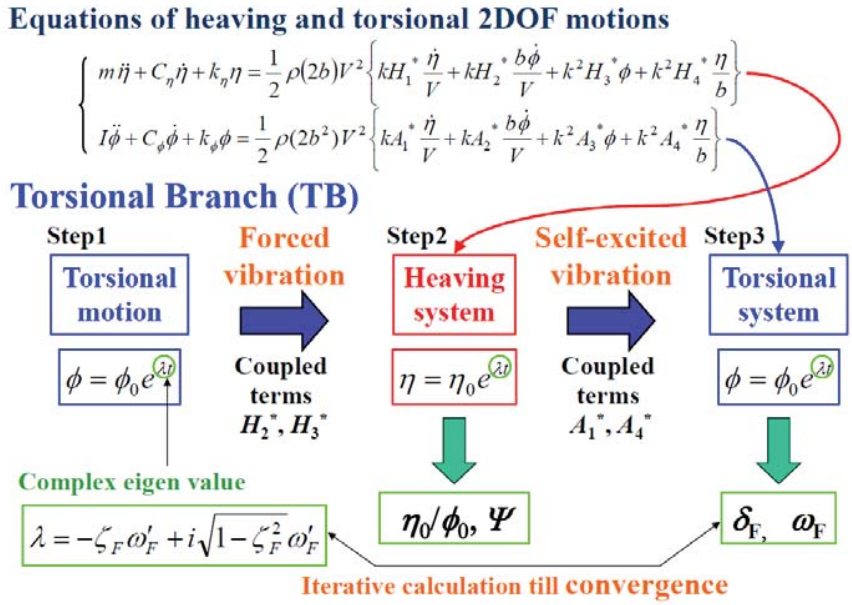
4.1 *SBS Flutter Analysis*

2DOF Heaving and torsional differential equations are expressed by equation (2.1) and (2.2). Aerodynamic derivatives of thin plate can be expressed by Theodorsen function as follows:

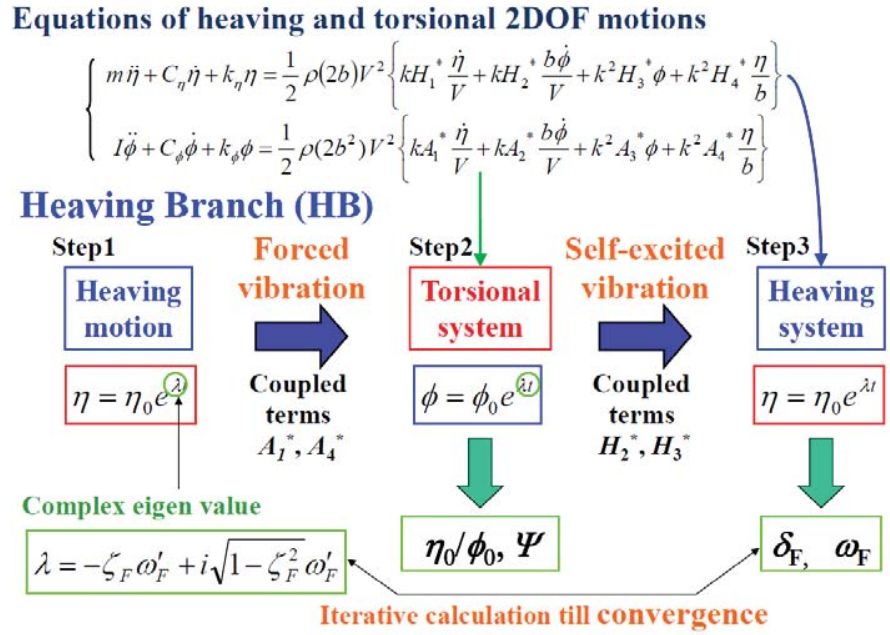
$$H_1^*(k) = -(2\pi / k)F(k)$$
$$A_1^*(k) = (\pi / k)F(k)$$
$$H_2^*(k) = -(2\pi / k)(-(1/2) + F(k)/2 - G(k)/k)$$
$$A_2^*(k) = (\pi / k)(-(1/2) + F(k)/2 - G(k)/k)$$
$$H_3^*(k) = -(2\pi / k)(F(k)/k + G(k)/2)$$
$$A_3^*(k) = (\pi / k)(F(k)/k + G(k)/2)$$
$$H_4^*(k) = -(2\pi / k)G(k)$$
$$A_4^*(k) = (\pi / k)G(k)$$

where C(k)=F(k)-iG(k) (4.1)

2DOF coupled flutter can be characterized by four properties, those are frequency v.s. velocity(ω-V) property, damping v.s. velocity (δ-V) property, amplitude ratio v.s. velocity(η_0/φ_0-V) property and phase difference v.s. velocity (ψ-V)property. These characteristic values are, in general, analyzed by complex eigen value analysis.
On the other hand, author has developed Step-by-Step analysis to get these values. (Matsumoto[2010])Branch switching in these values can be studied by use of SBS flutter analysis. Its procedure is briefly explained in Fig.10. Clarification of flutter branch is definitely important to understand of multi-mode flutter characteristics. Because coupled flutter should be coupled wind-induced vibration between heaving and torsional modes. Therefore, if flutter begins with HB or TB, then the other torsional modes or heaving modes, , except of fundamental pairing mode, must mainly contribute to change flutter onset velocity,V_{cr}, more or less, respectively. Moreover, through wind tunnel test, flutter onset in T0 mode might be milder than in H-90 mode. But on this flutter property, further studies should be needed.

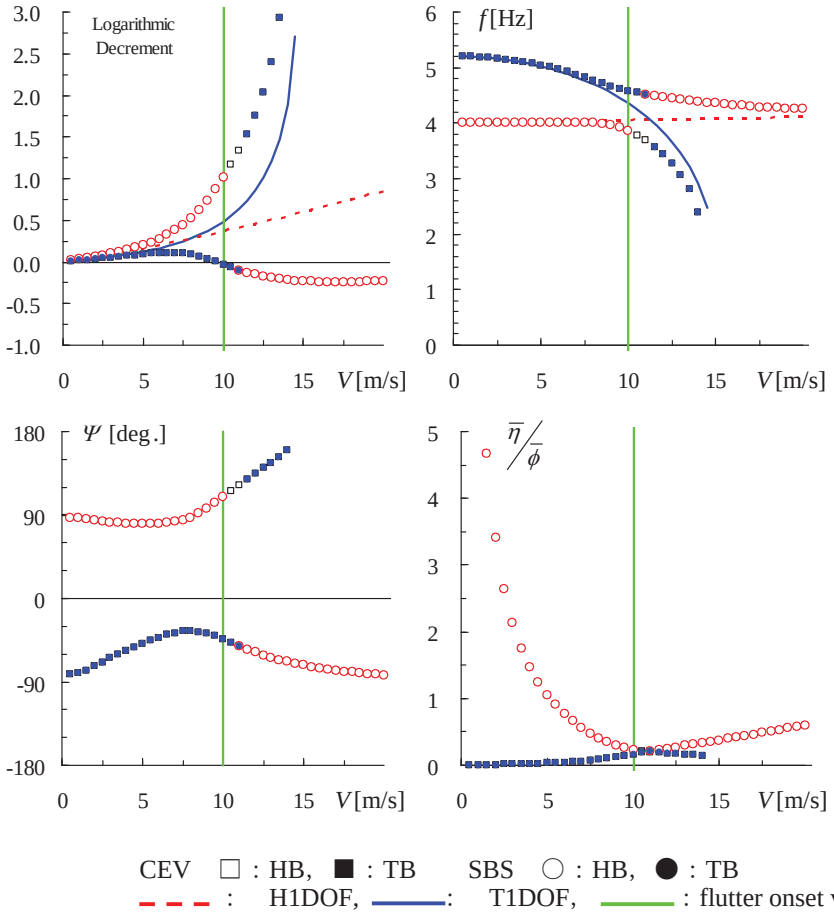


(a) Torsional Branch (TB)



(b) Heaving Branch (HB)
Fig .14. Illustration of SBS Flutter Analysis

Flutter properties analyzed by SBS and conventional Complex Eigen Value flutter analysis(CEV) for thin plate under certain structural dynamics are indicated in Fig.14 Theodorsen function are used for aerodynamic derivative as indicated above.



B=0.30 [m], m=2.42 [kg/m], I=0.0181 [kgm2/m], ρ=1.225 [kg/m3], $f_{\eta 0}$=4.0 [Hz] , $f_{\varphi 0}$=5.2 [Hz]
Fig 15. Coupled Flutter Properties of Thin Plate (frequency ratio: $f_{\varphi 0}/f_{\eta 0}$=1.30)

Flutter values characterizing property, ω,δ, (η_0/φ_0) and ψ, are completely identical in the both cases of CEV and SBS, as shown in Fig.1, but flutter branch at higher velocity after V_{cr}(=10m/s)are completely different in CEV analysis and SBS analysis. In SBS analysis, at a little bit higher velocity, 12.5m/s, than V_{cr}=10m/s、flutter branch suddenly changes from heaving branch(HB) to torsional branch (TB) or from TB to HB. At higher velocity range, HB flutter appears in SBS analysis, on the other hand, TB flutter appears in CEV analysis. Looking at ω-V diagram,ω is close to frequency of torsional 1DOF. This apparently indicates that at higher velocity range than flutter onset, this ω must correspond to TB not to HB. Therefore at near V_{cr} branch switching, from HB to TB, should occurs to satisfy this ω-property belonging to TB. Two flutter-values, ω and δ, from four-ones have been spot-lightened, because of determination of reduced velocity Vr=V/bω, which characterizes unsteady lift and pitching moment, and flutter onset velocity, Vcr. However, the another two flutter values, (η_0/φ_0) and ψ, have been less paid attention in discussion of flutter instability. It should be noted that these two flutter-values characterize flutter branches and flutter modes. These are significantly important to precisely verify the flutter coupling mechanism in multi-modes, that is multi-mode flutter, mechanism and generation mechanism of propulsion force during heaving and torsional coupling motion.

4.2 *Flutter Modes*

In coupled flutter, 6 fundamental modes can be defined as follows:

1. H mode: This is pure 1DOF heaving mode without torsional displacement, in another expression, is pure torsional mode around rotational axis fixed at the infinite point from mid-chord point of plate.

2. T mode: This is pure rotational mode around rotational axis fixed at mid-chord point of plate, without heaving displacement at this point.

3. T0 mode: This is pure rotational mode around leading edge. At heaving motion (the lowest is maximum)at mid-chord point has no phase difference against torsional motion(windward nose-up positive) at this point.

4. T180 mode: This is pure rotational mode around trailing edge. In this mode, torsional maximum delays from heaving maximum by -180 degree.

5. H90 mode: In this mode, the heaving maximum delays from the torsional maximum by 90 degree. This mode appears from quasi-steady point if $dC_L<0$.

6. H-90 mode: In this mode, the heaving maximum delays from the torsional maximum by -90 degree, it means the heaving maximum proceeds ahead to the torsional maximum by 90 degree. This mode appears from quasi-steady point if $dC_L>0$.

These four modes, T0, T180, H90 and H-90, are illustrated in Fig.2.

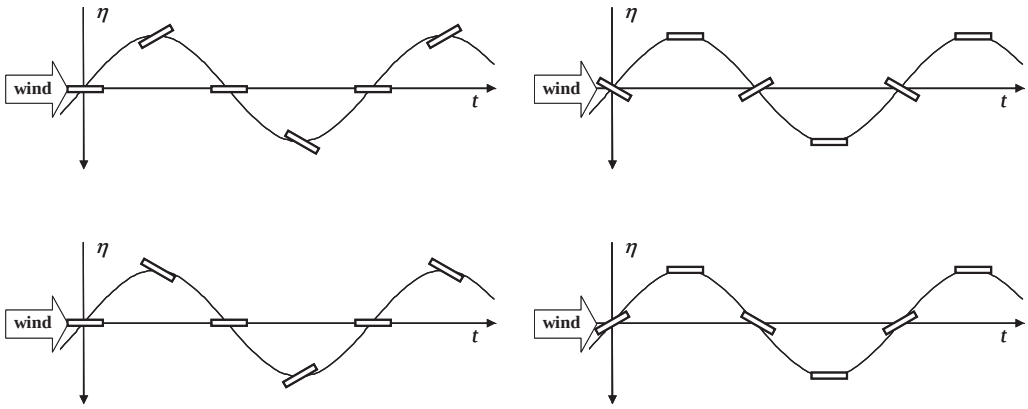


Fig.16 Fundamental flutter modes : T0, T180, H90 and H-90

4.3 *Flutter Branches*

Flutter branches can be defined from Amplitude ratio, η_0/φ_0, as shown in Fig.16. Around flutter onset, amplitude ratio, η_0/φ_0, shows the minimum. At lower velocity than Vcr,η_0/φ_0 for HB tends to infinite with decreasing velocity, it means heaving displacement dominates than torsional one .At V=0,torsional displacement becomes zero, $\varphi_0=0$, it means coupling motion is pure heaving motion or rotational axis at infinite point in upstream- or downstream-ward. On the other hand, for η_0/φ_0 of TB decreases together with decreasing velocity approaching zero at V=0. At V=0, heaving displacement is zero $\eta_0=0$. This means that flutter properties can be defined as TB at lower velocity range than around flutter onset. Similarly at higher velocity than

around flutter onset, HB and TB can be defined as HB and TB respectively basing upon flutter properties obtained by SBS flutter analysis.

At velocity range near V_{cr}, flutter branch would be defined from phase difference,ψ, as following procedure. Taking into account of flutter modes, H mode, T mode, T0 mode, T180 mode, H90 mode and H-90 mode, their torsional motion, φ(t), and heaving motion, η(t) are expressed respectively as follow:

$$H \bmod e : \eta(t) = \eta_0 \sin \omega t \qquad \varphi(t) = 0 \tag{4.2}$$

$$T \bmod e : \varphi(t) = \varphi_0 \sin \omega t \qquad \eta(t) = 0 \tag{4.3}$$

$$T0 \bmod e : \varphi(t) = \varphi_0 \sin \omega t \qquad \eta(t) = \eta_0 \sin \omega t \tag{4.4}$$

$$T180 \bmod e : \varphi(t) = \varphi_0 \sin \omega t \qquad \eta(t) = -\eta_0 \sin \omega t \tag{4.5}$$

$$H90 \bmod e : \varphi(t) = \varphi_0 \sin \omega t \qquad \eta(t) = -\eta_0 \cos \omega t \tag{4.6}$$

$$H-90 \bmod e : \varphi(t) = \varphi_0 \sin \omega t \qquad \eta(t) = \eta_0 \cos \omega t \tag{4.7}$$

When phase difference between torsion and heaving motion is ψ, coupling of heaving and torsional motions can be expressed as follow depending on ψ which varies between -90^0 and 180^0 in flutter property obtained by flutter analysis :

$$180^0 > \psi > 90^0 : \cos\psi < 0 \; and \; \sin\psi > 0 \tag{4.8}$$

$$90^0 > \psi > 0^0 : \cos\psi > 0 \; and \; \sin\psi > 0 \tag{4.9}$$

$$0^0 > \psi > -90^0 : \cos\psi > 0 \; and \; \sin\psi < 0 \tag{4.10}$$

Then,

$$\varphi(t) = \varphi_0 \sin \omega t \tag{4.11}$$

$$\eta(t) = \eta_0 \sin(\omega t - \psi) = \eta_0 \sin \omega t \cos\psi - \eta_0 \cos \omega t \sin\psi \tag{4.12}$$

For all terms on right hand of the upper equation, coupling motions can be resolved as follows:

$$180^0 > \psi > 90^0 : \varphi(t) = \varphi_0 \sin \omega t \qquad \eta(t) = -T180 \cos\psi - H90 \sin\psi \tag{4.13}$$

$$0^0 > \psi > -90^0 : \varphi(t) = \varphi_0 \sin \omega t \qquad \eta(t) = -T0 \cos\psi - H-90 \sin\psi \tag{4.14}$$

$$90^0 > \psi > 0^0 : \varphi(t) = \varphi_0 \sin \omega t$$
$$\eta(t) = T0 \cos\psi + H90 \sin\psi \qquad (4.15)$$

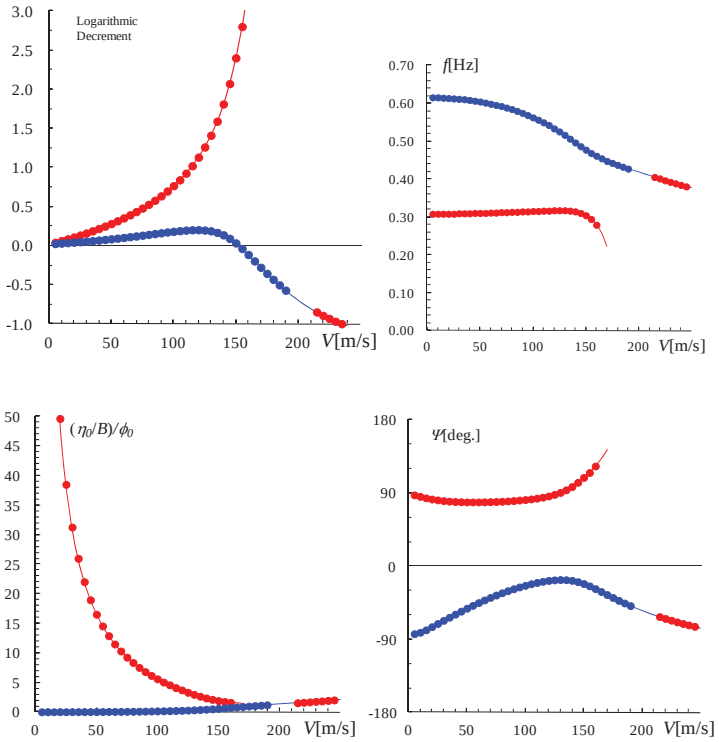
In HB and TB consist in two fundamental flutter modes depending on their amplitude ratio, η_0 / φ_0, and phase, ψ, as indicated in Fig.3. In detail,

for HB, at V=0 : H mode only,
at 0<V<Vcr : T0 mode and H90 mode,
at Vcr<V : T0 mode and H-90 mode,

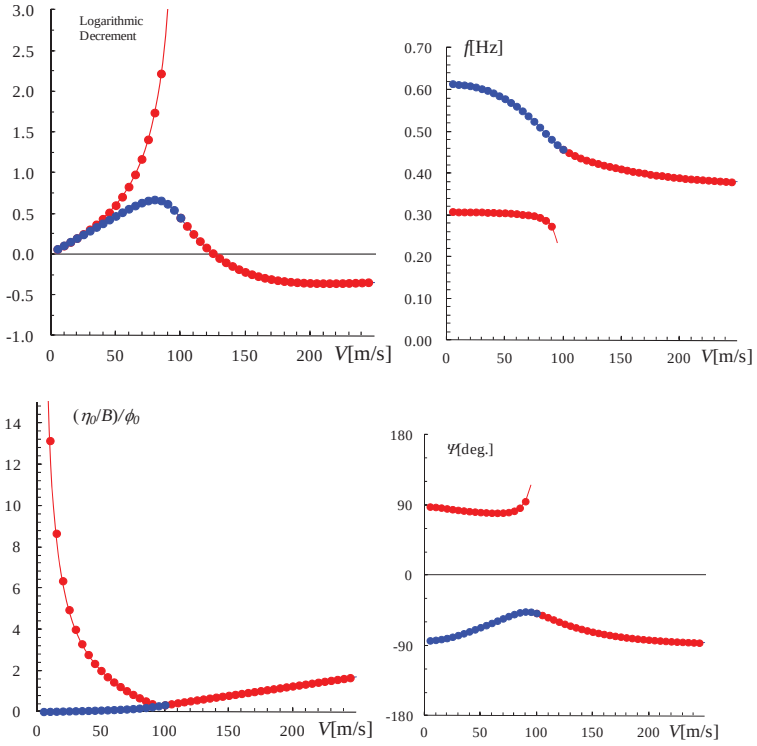
and for TB,

at V=0 : T mode only,
at 0<V<Vcr : T0 mode and H-90 mode,
Vcr<V : T0 mode and H-90 mode.

At near Vcr, flutter branch, HB or TB, which consists of T0 mode and H-90 mode for amplitude ratio- velocity diagram, can be classified by their magnitude of coefficients, those are sinψ and cosψ. If ψ=-45°, the contribution to flutter of TB and HB are identical. If ψ<-45°, HB plays more significantly for flutter onset than TB, and contrary if ψ>-45°, TB does than HB. Flutter branch when flutter occurs changes not only with different aerodynamic derivatives caused by change of geometrical shape of structures or with angle of attack of wind, but also with structural dynamics. Example of change of flutter branch is shown in Fig.17.



(a) Case1(B=27.8m, M=2.065e04Kb/m, I=1.90e06Kgm2/m, $f_{\eta 0}$=0.31sec-1, $f_{\varphi 0}$=0.62sec-1, $f_{\varphi 0}/f_{\eta 0}$=2.0, $\delta_{\varphi 0}/\delta_{\eta 0}$=0.02), where red plot for HB, blue plot for TB



(b) Case2(B=27.8m, M=2.065e04Kg/m, I=1.90e06Kgm2/m, $f_{\eta 0}$=0.31sec-1, $f_{\varphi 0}$=0.465sec-1, $f_{\varphi 0}/f_{\eta 0}$=1.50, $\delta_{\varphi 0}/\delta_{\eta 0}$=0.02)
Fig 17. Flutter Property of Thin Plate (red plot for HB, blue plot for TB)

Fig17 shows that flutter begins with TB(case1) or HB (case2), respectively. It should be noted that flutter branch at flutter onset changes by structural dynamics. On the other hand, Xu[2011] recently reported that flutter of full scale elastic model of the Sutong Bridge in China, the longest cable stayed bridge in the world, begins with To mode under the condition of horizontal wind, but it begins with H-90 mode under up-ward wind with the angle of attack of 3°. In this case, different aerodynamic derivatives change flutter branch at flutter onset.

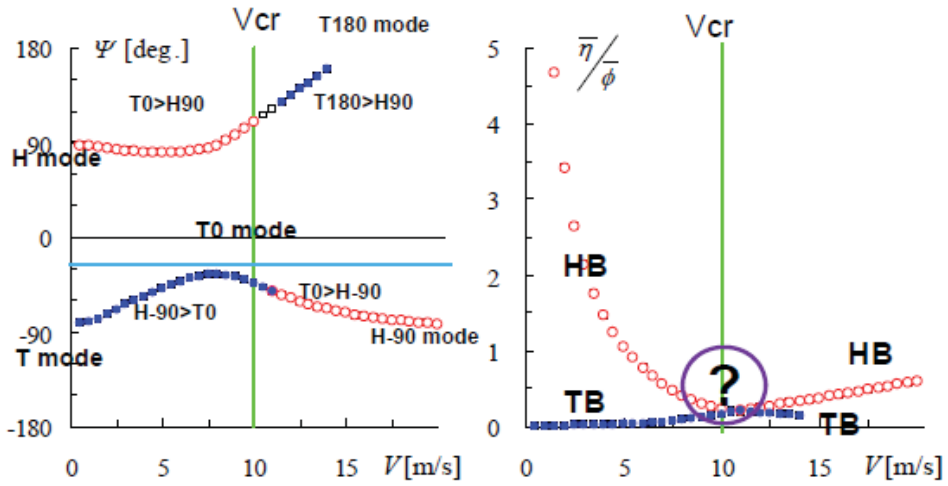


Fig.18 Illustration of Flutter Branch and Flutter Mode in Amplitude Ratio(η0/φ0)-Velocity(V) Diagram and Phase(ψ)–Velocity(V) Diagram (Thin Plate, B=0.3m,m=2.42Kg/m, I=0.081Kgm2/m, fφ=0.5.2sec-1, fη0=4.0sec-1, fφ0/fη=1.3, φ0=δη0=0)

Flutter branches and flutter modes of thin plate explained before are illustrated in ,velocity diagram and ψ -velocity diagram in Fig.18.

4.4 *Selberg Formula*

Selberg formula[1961] has been widely used for estimation of flutter critical velocity, in primary stage of design of long span bridge, as a desk work. Vcr obtained from Selberg Formula is for thin plate section, so the exact Vcr should be investigated by wind tunnel tests using scaled section-model or full scale elastic model, in indirect, measurement of aerodynamic derivatives or direct measurement of Vcr. However, how to be driven this useful Selberg Formula has been not clarified. Under following simple assumptions, significantly similar formula can be obtained (Matsumoto[2010]).

Assumptions:1. When torsional frequency,, decreasing with wind velocity, is identical to heaving frequency,, no-affected by wind velocity, that is , flutter appears.

2.fφis characterized by onlyA_3^*, and $A_3^*$is expressed by. $A_3^*=((\pi/k)(F(k)/k-G(k)/2))^{1/2}$

3.3.Using quasi-steady assumption,:F(k)=1 and G(k)=0, where k is reduced velocity=bω/V.

Then V_{cr} can be expressed similarly with Selberg Formula as follows:

$$V_{cr}=3.71 f_{\varphi_0}(2b)\left((mI)^{1/2}/\left(\rho(2b)^3\right)\left(1-\left(f_{\varphi_0}/f_{\eta_0}\right)^2\right)\right)^{1/2} \tag{4.16}$$

Selberg Formula

$$V_{cr}=3.81 f_{\varphi_0}(2b)\left((mI)^{1/2}/\left(\rho(2b)^3\right)\left(1-\left(f_{\varphi_0}/f_{\eta_0}\right)^2\right)\right)^{1/2} \tag{4.17}$$

obtained from upper assumptions for thin rectangular section

TheV_{cr}-values calculated two formula under some structural dynamics and exact ones analyzed by CEV analysis and SBS analysis are compared in Fig. 15.

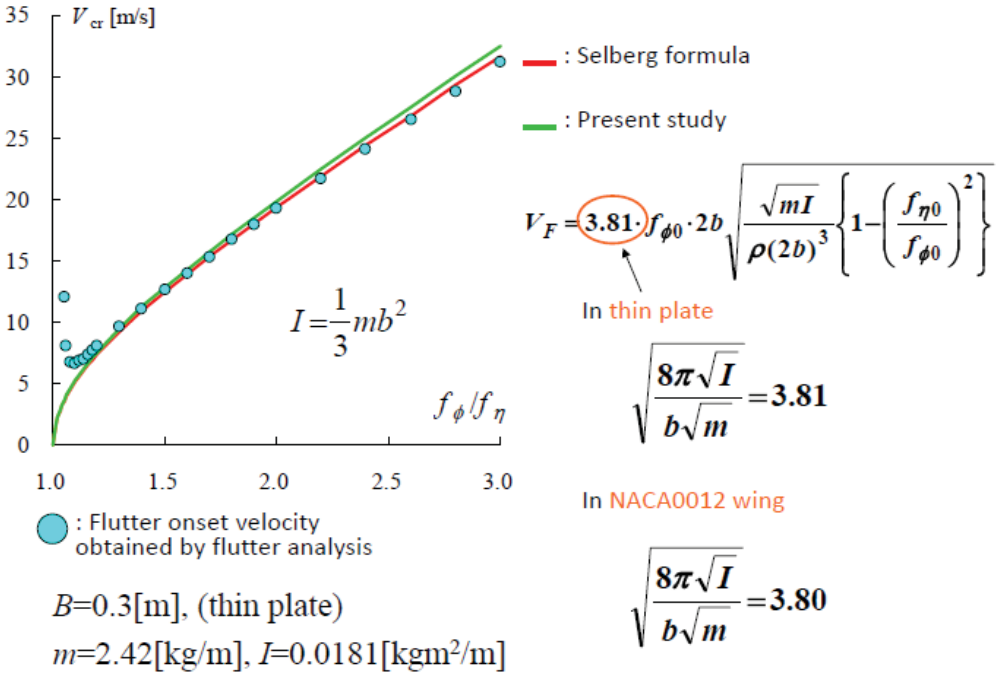

Fig.19 Comparison of Vcr obtained by Selberg Formula(equation(4.16)), Formula(equation (4.17)) and Flutter Analysis (Matsumoto[2010])

5 APPLICATION OF FLUTTER –GENERATION OF PROPULSION FORCE

5.1 *Generation of Propulsion Force*

According to former literatures, instantaneous propulsion force might be generated by coupling motion of heaving and pitching as term related to thin-airfoil theory,$F_{pair\text{-}foil}$, which consists in lift and drag force,$F_{PL\&D}$, and virtual mass effect,F_{pmass}, and jet disgorging term,F_{pjet} . Then, the propulsion force, F_P, can be expressed as follows:

Airfoil Theory term1 :

$$\begin{aligned} F_{P_{L\&D}} &= L(\alpha_{re})\sin\alpha^*_{re} - D(\alpha_{re})\cos\alpha^*_{re} \\ &= (1/2)\rho V_{re}^2 2blC_L(\alpha_{re})\sin\alpha_{re} - (1/2)\rho V_{re}^2 2blC_D(\alpha_{re})\cos\alpha^*_{re} \end{aligned} \tag{5.1}$$

where, L,D, C_L,C_D: unsteady force and coefficients

$$V_{re} = \left\{ V^2 + (d\eta/dt)^2 \right\}^{1/2} \tag{5.2}$$

$$\alpha^*_{re} = \arctan\left\{ (d\eta/dt)/V \right\} \tag{5.3}$$

$$\alpha_{re} = \alpha^*_{re\eta} + \phi \tag{5.4}$$

Airfoil Theory term 2(Karman&Sears[1938]) :(Virtual Mass Effect):

$$L_{mass} = \pi\rho b^2 I\left(d^2\eta/dt^2 + Vd\phi/dt\right)\text{: normal to plate, at } \eta(t)=0 \quad (5.5)$$

$$F_{P_{mass}} = L_{mass}\sin\phi\text{ : propulsive component, at } t=0 \quad (5.6)$$

Jet Disgorging term:

$$F_{P_{jet}} = \rho A_0(V+v)\{(V+v_p)-v\} = \rho A_0 v_p(V+v) \quad (5.7)$$

where, $v_p = v/2$ (5.8)

A_0 effective area at near trailing edge *where* jet passes into wake:,
v_p: disgorging jet velocity through A_0
v: jdisgorging jet velocity in a wake

Propulsion force in term of airfoil theory,$F_{PL\&D}$ and jet disgorging term,F_{pjet} show the maximum at having velocity maximum, that is pitching angle of zero in H-90 flutter mode, on the other hand F_{pmass} shows the maximum at zero heaving velocity, that is maximum pitching displacement.

Propulsion force, , is classified into 6 cases depending combination of torsional and heaving displacement, as follows (Matsumoto and Ishizaki([2010]):

I.Up-ward heaving motion(α_{re}^*<0)

I.1 Positive torsional angle(φ>0)

I.1.1 Absolute value of Torsional angle is larger than the one of relative angle of attack due to heaving velocity: $|\varphi|>|\alpha_{re}^*|$ (case1)

I.1.2 Absolute value of Torsional angle is smaller than the one of relative angle of attack due to heaving velocity: $|\varphi|<|\alpha_{re}^*|$(case2)

I.2 Negative torsional angle (case3)

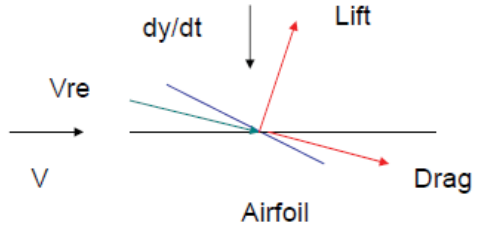
Ⅱ.Down-ward heaving motion

Ⅱ.1.Positive torsional angle (φ>0)

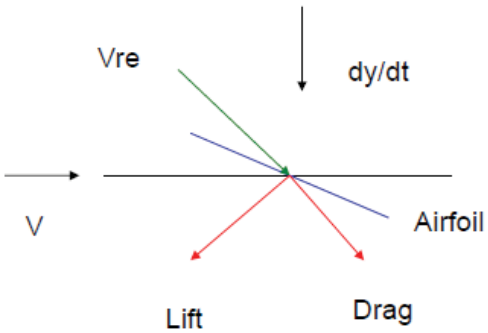
Ⅱ.2 Negative torsional angle (φ<0)

Ⅱ.2.1 Absolute value of Torsiona gle of attack

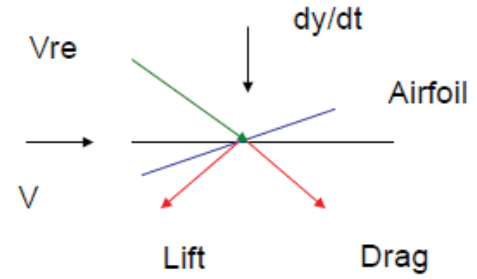
ve angle of



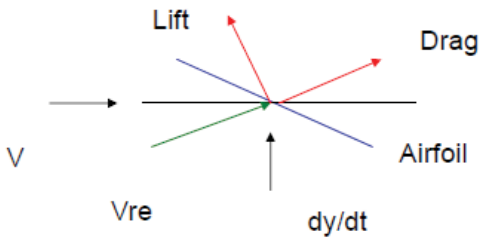
Case1



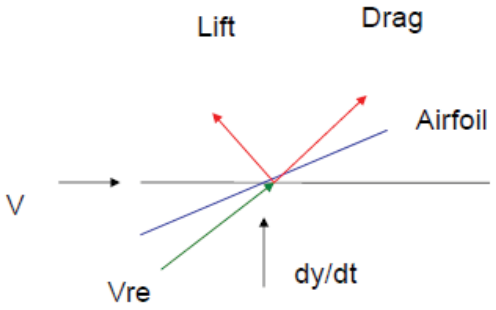
case2



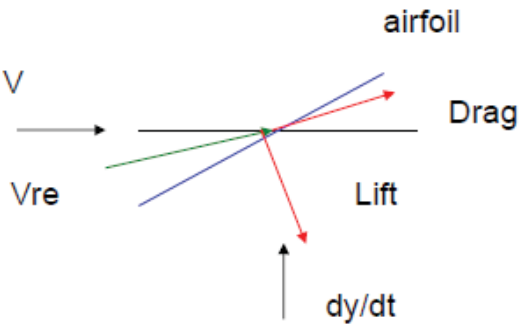
Case3



case4



Case5



case6

Fig.20 Lift and Drag Induced by Relative velocity Depending on Heaving and Torsional Displacement for 6 cases

From these generation mechanism of Lift and Drag depending torsional and heaving displacement, the following conditions to generate the positive propulsion force, , are definitely required:

For generation of lift force with the up-stream ward force component:

$$(\eta_0 / b)\varphi_0 > V_r = V / b\omega \tag{5.9}$$

For that the propulsive component of lift is larger than the one of drag:

$$\gamma(\alpha_{re})\tan\alpha_{re} - 1 > 0 \tag{5.10}$$

Where,

and : amplitude of heaving and torsional motion of flapping plate, respectively

V: propulsion velocity (or oncoming flow velocity)

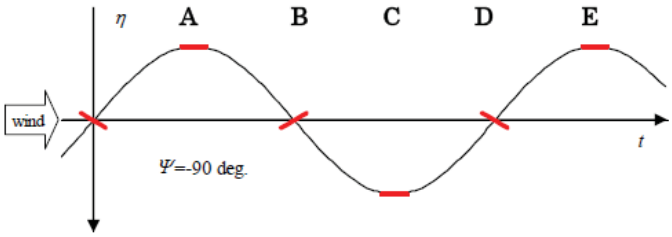
: circular frequency of flapping plate

: lift and drag ratio

α_{re}: relative angle of attack ($=\alpha_{re}^{*}+\varphi$)

α_{re}^{*}: angle of attack induced by heaving velocity ($=\arctan(d\eta.dt)/V$)

It is verified that positive propulsion force, $F_{PL\&D}$, can be always generated in H-90 flutter mode, if upper conditions are satisfied, as shown in Fig.17.



[A-B-C] case5(PF>0) and [C-D-E] case2 (PF>0)
Fig.21 Generation of Positive Propulsion Force during Coupling Motion of H-90 Flutter Mode

Previous studies on navigation mechanism of fish swimming(Tanaka and Nagai[1996]) and ship navigation by flapping plates(Terada, Yamamoto, Nagamatsu and Imaizumi[1998], Barannyk, Buckham and Oshkai[2010]) reported that the coupled motion on tail-fins of fish and flapping plate were controlled by H-90 flutter mode effectively generation of propulsion force. Tail-fin movement in fish swimming is shown in Fig.22 (Tanaka & Nagai[1996])

Fig.22 Tail-fin motion of Fish Swimming(Tanaka and Nagai[1996])

On propulsion force generated by jet disgorging, F_{pjet}, it has not been clarified at present as pointed by Barannyk[2010]. This jet disgorging might generate inverse Karman vortex in a wake, however, its detail mechanism and its effect on propulsion force should be studied more in a future.

5.2 *Ship Navigation Test by Double Flapping Plates controlled Inverse Phase H-90 Modes*

The propulsion force measurement has been conducted by use of ship model with 2.5Kgf in weight, 0.72m in length, 0.33m in width and 0.01m in submerged depth, as shown in Fig. 19. Two rigid, flexible and half-flexible two flapping plates (see Fig.20) were installed at near trailing edge, and they were controlled in inverse phase in order to cancel the sway forces, mutually. Each flapping plate was controlled in H-90 mode, individually. The distance at each neutral position between two plates was 0.22 m. The size of flapping plates were, 0.04m(half chord length for rigid plate), 0.08m(half chord length for flexible plate), 0.06m(height for all plates). The thickness of plates were 1.5mm (for rigid and flexible plate) and 2.0mm(for elastic plate). The pitching axis was fixed at up-stream-ward quarter-point for flexible plate-2 and at mid-chord point for the others. The frequency of flapping plate was mainly 4Hz and flow velocity in water channel for measurement of resistance force was carried out in approximately

0.24m/s, 0.26m/s, 0.30m/s and 0.34m/s. The propulsion forces were measured in still water. The amplitude of heaving and pitching motion was fixed as 0.02m and $19.5^{0,}$ respectively. Besides, navigation velocity of ship model was measured in still water. The maximum navigation speed for flexible flapping plate was observed as over 0.55m/s in the case of f_0=4.35Hz, and the one for rigid plate 0.45m/s at f_0=4.35Hz as well.

An example of time history of propulsion force for rigid plate with f_0=4Hz at V=0m/s is shown in Fig.10. The propulsion force varies with time with showing many local peaks, but mainly fluctuates with the frequency of flapping plate. The maximum propulsive force is roughly evaluated as 170gf. It should be noted that this force fluctuating property, that is one peak appearance in one cycle motion of two flapping plates, This one peak appearance can be explained by effect of enhanced jet disgorging between two flapping plate controlled in inverse phase motion. The enhanced jet flow appears once in one cycle motion of flapping plate.

Ship navigation speed diagrams with various flapping plates and frequency are indicated in Fig.13.

Fig.23 Ship model

Distance for measurement : 400[cm]
Flapping frequency : 2.998[Hz], 3.968[Hz], 4.231[Hz], 4.347[Hz]
Flapping plate:W160[mm]×H60[mm]×t1.5[mm](flexible)
W80[mm]×H60[mm]×t2.0[mm]elastic wing)
W80[mm]×H60[mm]×t1.5[mm](rigid wing/plate)

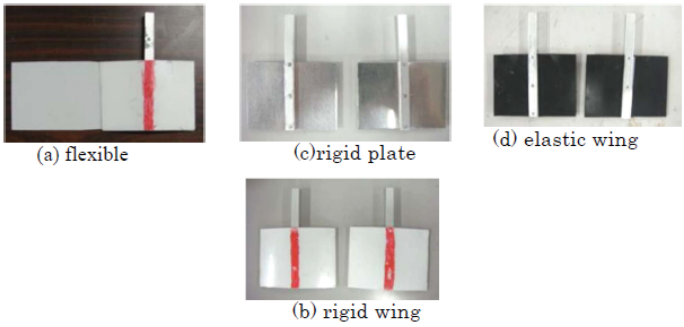


Fig24. Flapping Plates used in the Test

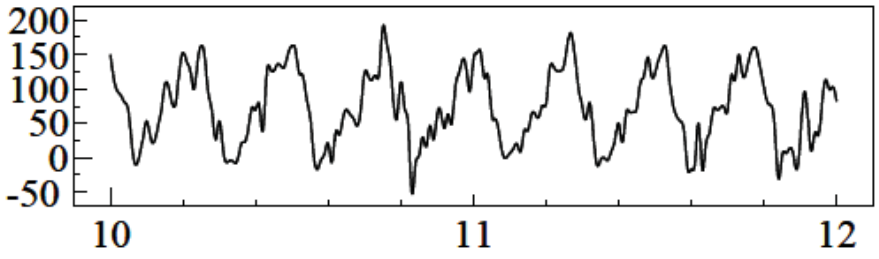

Fig.25 Time-History Propulsion Force (rigid plate, f0=4Hz)

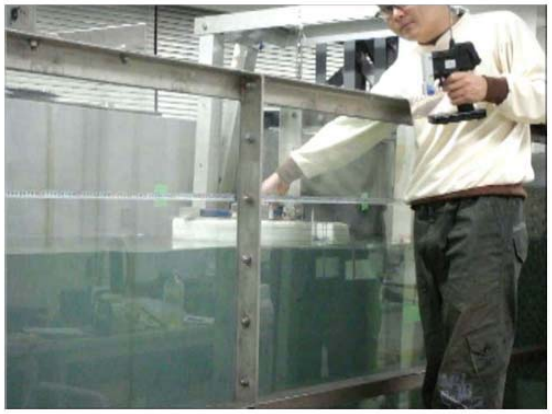

Fig.26 View of Ship Navigation Test

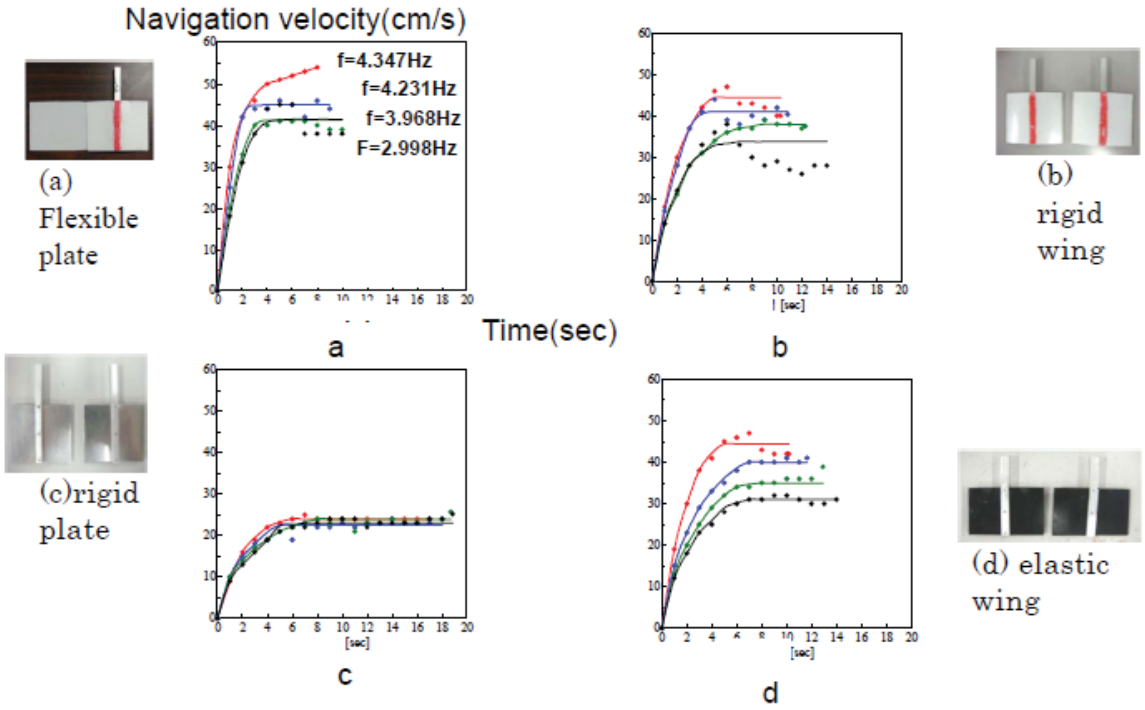

Fig.27 Time History of Navigation Velocity with Various Flapping Plates

As shown in this figure, navigation speed gradually increases after start (t=0). The maximum speed is over 55cm/s in the case of flexible flapping plates. For rigid plate, maximum speed is up to 45 cm/s as shown in Fig.27.Because of uncertainties on unsteady and non-linear force characteristics during coupling motion with large amplitude over stalling angle of attack and taking into account of appearance of quasi-steady behavior of H-90 flutter mode at high reduced velocity, it might be assumed to be quasi-steady force, F_{pquasi}, that is $F_{pairfoil} \cong F_{pquasi}$,at a primary study.

5.3 *Estimation of Propulsion Force induced Jet dDsgorging, Fpjet basing on CFD Analysis by Isogai[2006] for Dolphin Standing Swimming*

Described before on uncertainties on evaluation of propulsion force generated by jet disgorging, F_{pjet}, might be approximately estimated from CFD results for standing swimming of dolphin in still water analyzed by Isogai[2006], under assumption of quasi-steady lift and drag forces. CFD result showed dolphin can generate upward propulsion force to cancel dolphin weight(W=138Kgf) by flapping motion of tail fin (b=0.072m at center, l=0.432m, tail fin area =0.0377m^2, aspect ratio=4.96) with frequency of 4.07Hz. Amplitude of torsional and heaving motions are 58.9^0 and 0.36m, respectively. The tail-fin motion is controlled in almost H-90 flutter mode, where phase is not -90^0degree but -75.8^0. In this case, maximum propulsion force of 2750 N can be generated at the instant of heaving maximum velocity, 9.25m/s. The flow field around tail fin at the moment of $d\eta/dt|_{max}$ is shown in Fig.28.

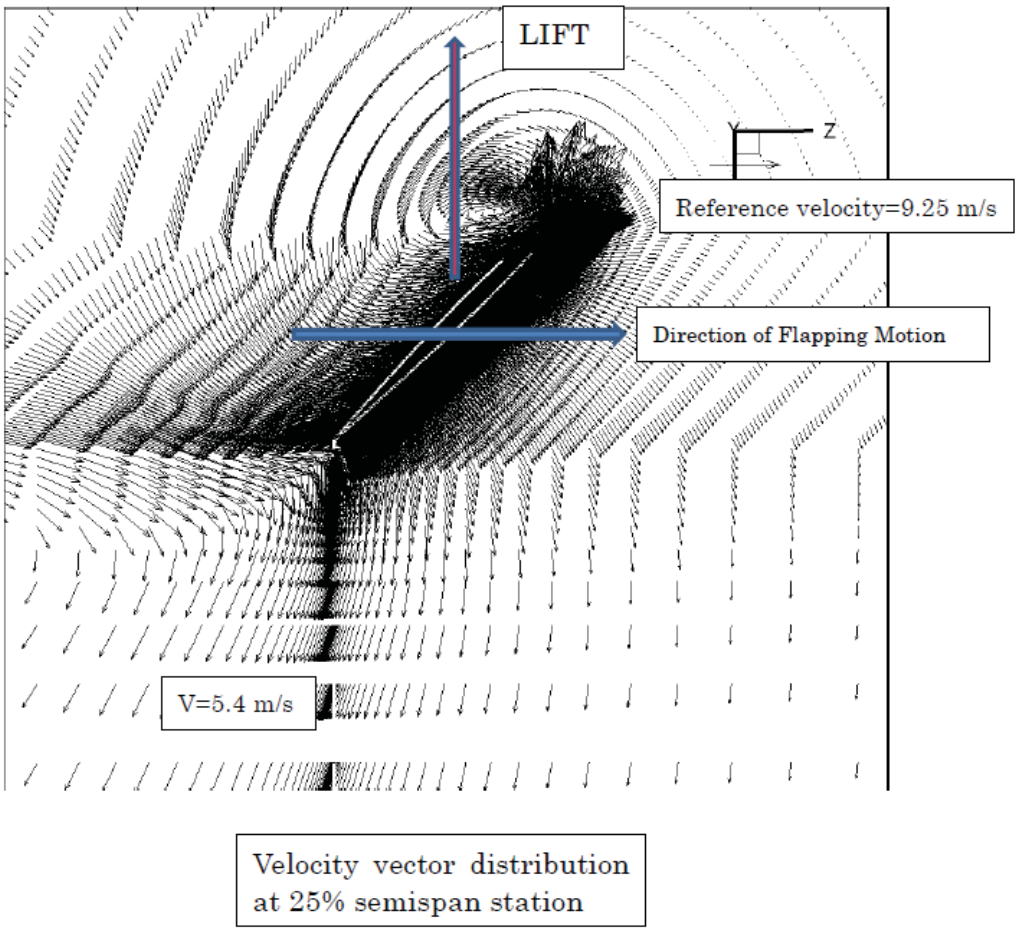

Fig. 28 Flow Field around Tail Fin of Dolphin during Standing Swimming (CFD by Isogai[2010])

It should be noted that jet disgorging velocity in a wake is v=5.4m/s in equation(5.7). Relative angle of attack, $\alpha_{re}=d\eta/dt/\ V+\varphi=90-58.9°=31.1°$, $C_L(\alpha_{re})=1.0$ and $C_D(\alpha_{re})=0.8$, of which values are for 3DOF delta wing measured by Okamoto[2008]. Then, basing on quasi steady lift

and drag forces, F_{Pquasi}, can be calculated as 1595.5N. Furthermore, if effective aera, Ao ,where jet ispassing, near trailing edge of tail-fin can be expressed by A_0=0.1555m2 (=$\eta_0 x_l$=0.36(m)×0.432m), besides jet disgorging up-ward velocity component is approximately 3.82m/s. Then from eq.(), maximum propulsion force at the moment of maximum heaving velocity, $d\eta/dt|_{max}$, generated by jet disgorging into wake, F_{pjet}, is obtained as F_{pjet}=1136N. Therefore, the total maximum propulsion force, $F_p|_{max}$, at the moment of maximum heaving velocity is obtained as 2730.5 N by summation of $F_{pquai}|_{max}$ and $Fp_{jet}|_{max}$ at heaving velocity maximum. This value is similar to the maximum propulsion force obtained by CFD (by Isogai[2006]). Of course, there are many simplified assumption in this calculation, so these agreement might be eventual one. However, contribution ratios of $Fp_{airfoil}|_{max}$ (=$Fp_{L\&D}|_{max}$) and $Fp_{jet}|_{max}$ to total maximum propulsion force, $Fp|_{max}$, in might be roughly evaluated from this result. That means $Fp_{jet}|_{max}$ and $Fp_{airfoil}|_{max}$ contribute to total maximum propulsion force, $Fp|_{max}$ by 42% and 58%, respectively.

5.4 *Flutter Power Generation*

The “concept of Flutter Power Generation(FPG)” has been proposed by Isogai [2003]. This is a practical application of coupled flutter. If forced torsional vibration to the plate or airfoil, then significantly intensive heaving vibration can be excited because of appearance of natural coupled flutter in flutter fundamental H-90 mode in this system. The point of this FPG is that enough small power for forced torsional motion can generate a big power by intensive heaving vibration of plate/airfoil. Isogai pointed that giving power for torsion is less 1% of obtaining power by heaving motion. At present, Abiru[2010]is demonstrating in the field (in small river), to show its efficiency.

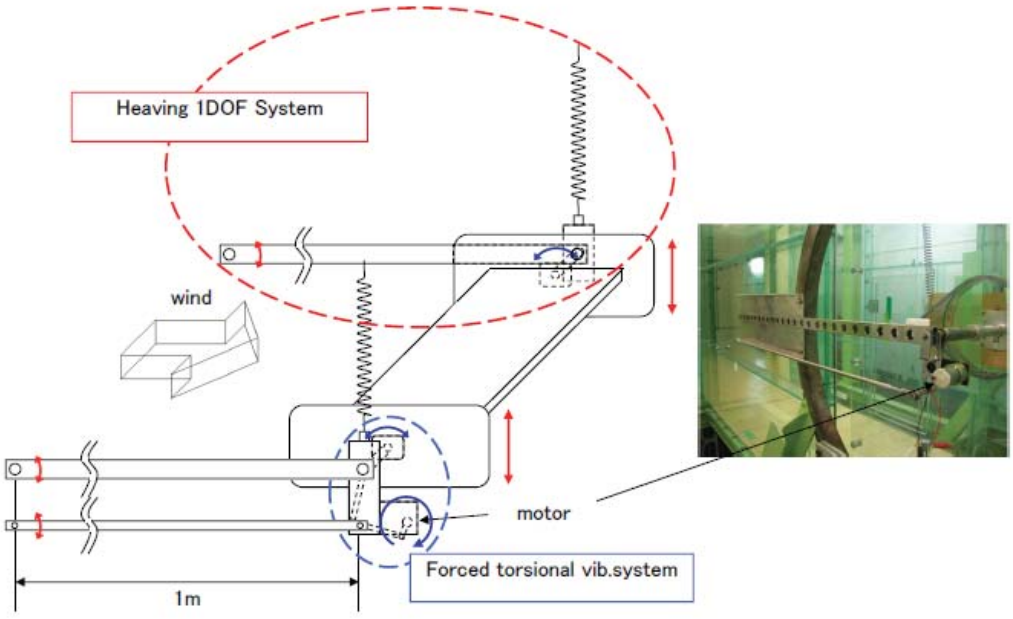

Fig.29 Flutter Power Generation System (Model: Rectangular cylinder with B/D=20 (Matsumoto[2006])

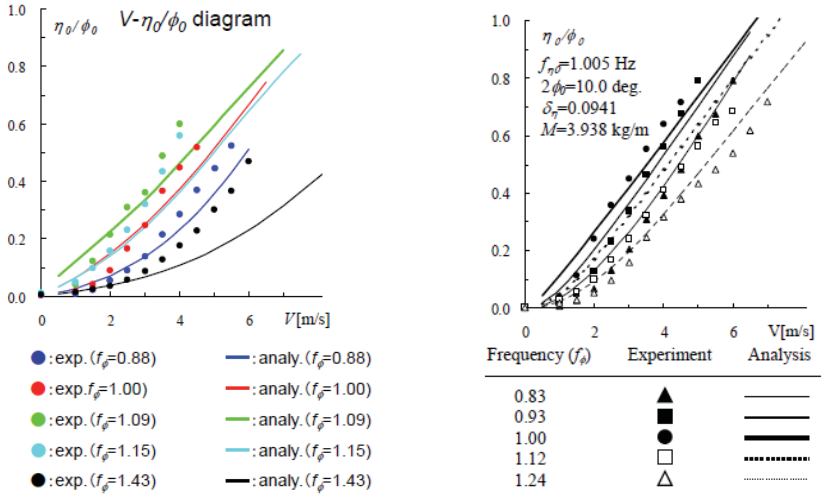
Its system in wind tunnel is shown in Fig.29. The of amplitude ratio between heaving response and forced torsional vibration for rectangular cylinder with B/D=20 measured FPG experiment under forced torsional vibration with p-p amplitude of $10^0$is compared with analytical results in Fig.30.



(a) Rectangular Cylinder with B/D=20 (b)Rectangular Cylinder with B/D=5

Fig. 30 Comparison of Amplitude Ratio in FPG of Experimental results and Analytical ones for B/D=20 and 5, under Forced Torsional Vibration with p-p Amplitude of 10^0. (Matsumoto[2006])

It should be noted that FPG system uses naturally appearing coupled flutter in H-90 flutter mode. In Ship navigation system with flapping plate has significant advantage in saving power for driving coupled motion to the flapping plate. The detail is described below.

5.5 *Advantage of Flapping plate System for Ship Navigation*

In order to generate the positive propulsion force by coupled torsional and heaving motion, equations (5.9) and (5.10) are definitely satisfied. Therefore naturally generated coupled flutter of plate-like sections cannot generate positive propulsion force, because in amplitude ratio between heaving and torsional motion, η_0/φ_0 v.s. velocity diagram, equation (5.9) is not satisfied as shown in Fig.27. This η_0/φ_0-velocity diagram is same one in Fig.15 (or Fig18(a)). In another words, natural coupled flutter must generate negative propulsion force, which means generation downstream-ward force fluctuation during coupling motion. In particular, this peak of negative propulsion force appears twice, because of twice appearance of $|d\eta/dt|_{max}$, in one cycle flutter motion, it means f_{Fp}(propulsion force frequency) is twice of f_F(flutter frequency). During heaving and torsional 2DOF coupled flutter with frequency of f_F, windward vibration with $2f_F$ can be excited.

By the way, for ship navigation by the flapping plate, when ship starts from still state, initial power to generate the coupled motion, which satisfied equations (5.9) and (5.19), then ship moves with certain velocity, V. At this moment in getting velocity V, given torsional motion can generate heaving motion by the mechanism of Flutter Power Generation, therefore, to get continuously the positive propulsion force to navigate a ship, the lack heaving amplitude, ηlack, should be added to satisfied equations (5.9) and (5.10). Namely in ship navigation with flapping

plate, once ship starts, rather mount power would be saved aided by the mechanism of flutter power generation as illustrated in Fig.28.

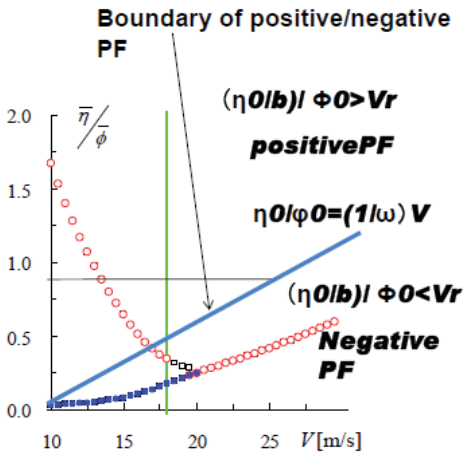


Fig.31 Critical Boundary to get Positive PF

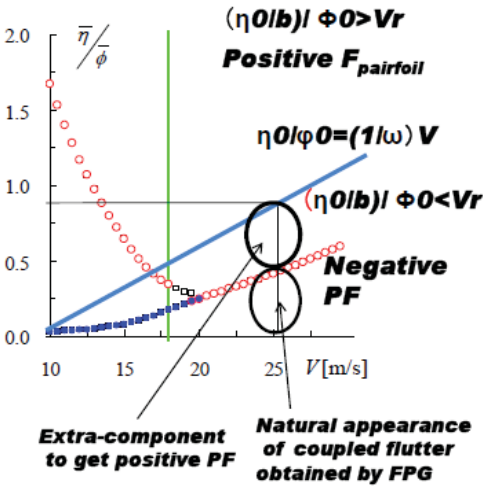

Fig.32 Illustration of Power Saving by use of FPG in Flapping Plate System

A lot of further studies for needed for practical realization of ship navigation with flapping plate, however there must be significant advantage in ship navigation with flapping plate from the point of power saving.

6 CONCLUSIONS

In this paper, fundamental of flutter phenomena, including galloping, torsional flutter and coupled flutter, has been introduced and as application, it is explained that propulsion force can be intelligently produced by use of the fundamental flutter mode, H-90.

Finally, author would like to acknowledge to Dr. Hiroshi Ishizaki(Hanshin Express way Technical and Maintenance Research Institution) for his valuable advises to this study. Furthermore, he should express acknowledge to Dr. Tomomi Yagi (Kyoto University), Mr.Rikuma Shijou(Mitsubishi Heavy Industry), Mr.Kazumasa Ookubo(Kajima corporation), Yoshiaki Ito(Shimizu Corporation), Hisato Matsumiya(Cetral Research Institute of Electric Power Industry), Mr. Michio Hashimoto(Shimizu corporation), Mr.Keisuke Mizuno(JR West Corporation), Dr. Kotaro Hori(Numerical Flow Design Corporation), Miss. Yuki Kawashima (All Nippon Airline) for their contribution on numerous experiments related to flutter fundamentals. Furthermore, on ship navigation test, author should express acknowledge to Prof N.Ishii, Mr. S.Kometani (former graduate student of OTCU) and Mr.T.Tsuji (graduate student of OTCU) and to Dr. Kouji Isogai of Professor Emeritus of Kyushu University, Japan, and Dr. Oleksandr Barannyk and Professor Peter Oshkai of University of Victoria, Canada, for offering various valuable data through personal communications.

Wind induced effects on bluff bodies in turbulent flows: nonstationary, non-Gaussian and nonlinear features

Ahsan Kareem [a], Teng Wu [a]

[a] *Nathaz Modeling Laboratory, University of Notre Dame, Notre Dame, IN, USA*

ABSTRACT: Notwithstanding the developments made in recent decades in bluff body aerodynamics and aeroelasticity, which have enhanced our abilities to better understand and capture the effects of turbulenct wind on structures, we are at an appropriate juncture to reflect on these developments, reassess their merits and shortcomings, and identify the need for embarking on different modeling philosophies and paradigms. In this context, there is a need to revisit the current paradigms and to look for improved understanding concerning the nature of wind fields, the associated aerodynamics and the resulting load effects in recognition of the following emerging realities: non-stationarity/non-homogeneity/transient wind events; non-Gaussianity; nonlinearity of structural and aerodynamic origins; unsteady/transient aerodynamics. Also, one needs to take note of recent advances in analysis and identification tools, and modeling frameworks, which promise to offer better understanding of the underlying complexities associated with the preceding themes. This paper discusses these issues and illustrates their significance in bluff body aerodynamics and aeroelasticity from the perspective of wind effects on built infrastructure.

KEYWORDS: Turbulence; Bluff body; Nonstationarity; Non-Gaussianity; Nonlinearity; Modeling

1 INTRODUCTION

The assurance of structural safety and reliability under wind loads requires accurate modeling of wind load effects relying heavily on our understanding of bluff body aerodynamics and aeroelasticity. The intractability of wind-structure interactions amidst complex urban topography has precluded analytical treatment of the subject with rather few exceptions such as buffeting effects (Davenport 1967; Zhou and Kareem 2001; Kwon and Kareem 2009). Therefore, physical modeling of wind effects in boundary layer wind tunnels has served as a most effective tool for ascertaining these load effects (Cermak 1975). Accordingly, the last few decades have witnessed significant advances in wind tunnel technology, full-scale monitoring, sensors/transducers, instrumentation, data acquisition systems, data fusion and mining strategies, laser Doppler-based technologies, geographical information and positioning systems (GIS) & (GPS) and information technologies, which have increased our ability to better monitor and process gathered information for improved understanding of the complexities and nuances of how wind interacts with structures, the attendant load effects and their modeling. On the other hand, in the last few decades, there have been major developments in the computational area to numerically simulate flow fields and their effects on structures. Developments in computational methods, e.g., stochastic computational mechanics, have led to useful tools to further advance the role of numerical analysis. The availability of high-speed computers, individually, in networked clusters, or in the cloud has enhanced the portability and interoperability of computational codes, to most research laboratories and design offices. Rapid advances on all fronts have accordingly led to advances in our understanding of aerodynamics and aeroelasticity and associated load effects and, as a consequence, have improved the prospect of developing the next generation of load simula-

tion facilities and wind tunnels, database enabled design aids, web-based e-technologies and codes and standards.

These developments have undoubtedly enhanced our abilities to better understand and capture the effects of wind on structures. It is appropriate time, however, to reflect on these developments, reassess their merits and shortcomings, and identify the need for embarking on different modeling philosophies and paradigms as called for by the recent observations. In this context, the rest of this paper will identify and discuss a few selected frontiers in bluff body aerodynamics and aeroelasticity with particular reference to wind loads on structures and the challenges these pose to the fluid dynamics and wind engineering communities. These topics include non-stationarity/non-homogeneous/transient wind events; non-Gaussianity; nonlinearity of structural and aerodynamic origins; unsteady/transient aerodynamics and the relevant modeling frameworks and identification tools. Improved understanding of turbulence effects on bluff bodies is stressed.

2 NONSTATIONARY/TRANSIENT WINDS

Most extreme wind events are nonstationary in nature and are often highly transient, e.g., wind fields in hurricanes, tornadoes, downbursts and gust fronts. Therefore, the most critical issue in wind field characteristics concerns the transient wind events, e.g., gust-fronts generated by downdrafts associated with thunderstorms. The significance of these transient wind events and their load effects can be readily surmised from an analysis of thunderstorms databases both in the U.S. and around the world, which suggest that these winds actually represent the design wind speed for many locations (Twisdale and Vickery 1992; Brooks et al. 2001).

The mechanics of gusts associated with convective gust-fronts differs significantly from conventional turbulence (driven by momentum) both in its kinematics and dynamics. A survey of full-scale studies in the meteorological field suggests that winds spawned by thunderstorm, both on the updraft side as tornadoes and on the downdraft side as downburst, fundamentally differ from the synoptic winds in neutrally stable atmospheric boundary layer flows. The key distinguishing attributes are the contrasting velocity profile with height and the statistical nature of the wind field. In gust-fronts, the traditional velocity profile does not exist; rather it bears an inverted velocity profile with maxima near the ground potentially exposing low- to mid-rise structures to higher wind loads (e.g., Wood and Kwok 1998; Letchford and Chay 2002; Butler et al. 2010). This is compounded by the inherent transient nature of energetic convective gusts, raising serious questions regarding the applicability of conventional aerodynamic loading theories. Although the size of gust-fronts may be relatively small and their effects rather local, the fact remains that they can produce significantly damaging winds. The famous Andrews Air force base downburst of 1983 clocked peak gusts of 67 m/s, whereas, ASCE Standard provisions list 50-year recurrence winds of 40-45 m/s in this region (Fujita 1985). Accordingly, one should question the appropriateness of a design based on conventional analysis frameworks in codes and standards, which generically treat these fundamentally different phenomena in the same manner.

The major challenge in this area is at least twofold, i.e., firstly, the nature of flow fields in rain bands, the eye wall of hurricanes, downdrafts and gust fronts needs to be better quantified, and secondly, analysis and modeling tools to capture these features need to be established. Design loads are based on the mean wind speed for a given site and direction and rely on the assumption that the fluctuations in the mean are characterized by a statistically stationary process, which has led to useful and practical simplifications. The gust-fronts generated in thunderstorms/downdrafts differ from the large-scale (extratropical/ depressional) storms as the mean wind speed exhibits sharp changes and in some cases changes in wind direction. This leaves the assumption of stationarity open to serious criticism.

Besides this departure in statistical attributes of the wind field, gust-fronts are likely to be associated with rapid and substantial changes in the local flow around structures and will likely be correlated over a larger area. These changes in the kinematics and dynamics of the flow field would potentially result in higher aerodynamic loads. These attributes further complicate the concept of "gust factors" which in some forms are central to most wind load assessments. The gust factor concept used for extratropical winds must be revisited as the period used to evaluate average wind speed for thunderstorm winds must be shortened to obtain meaningful results. Longer periods, such as an hour, if used for thunderstorm winds may result in gust factor values almost 2-3 times the corresponding values in extratropical winds. Current efforts toward gleaning information regarding the thunderstorm outflow characteristics through modeling non-stationary winds would aid in better capturing the salient features of winds in transient events (Gast et al. 2003; Wang and Kareem 2004a; Chen and Letchford 2005a). In a recent study, Kwon and Kareem (2009) presented a new framework to capture the flow field in a gust front and its attendant load effects.

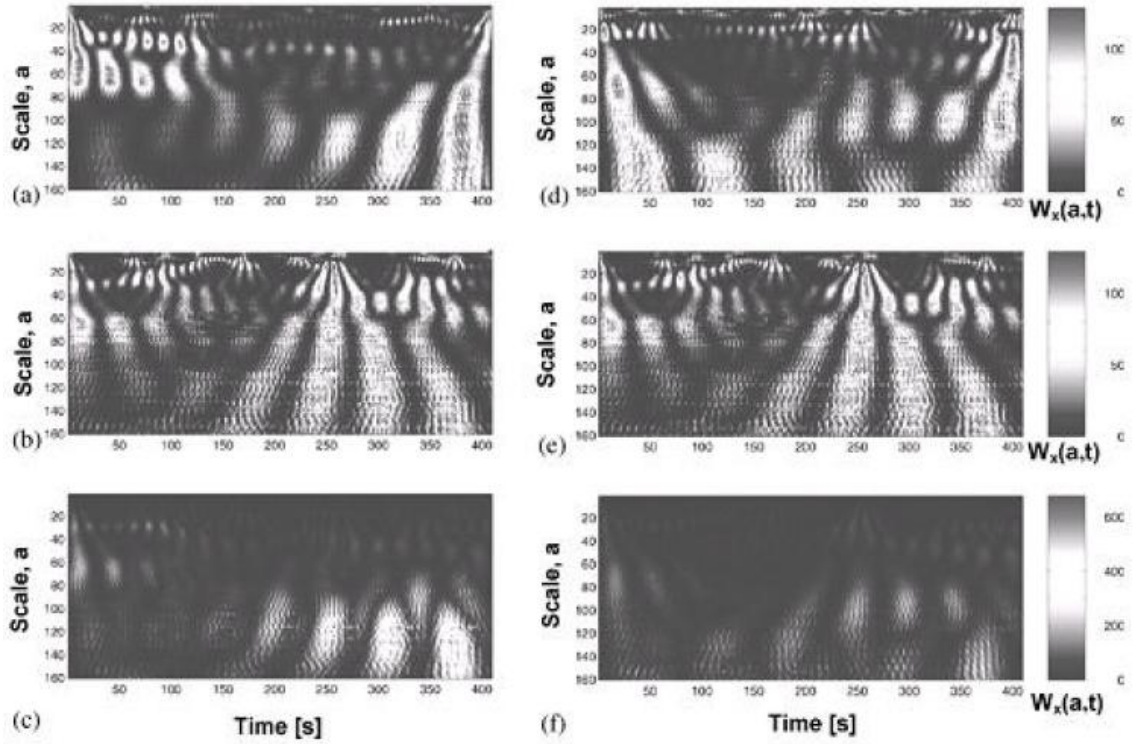

Figure 1: (a) Scalogram of upstream wind velocity 1; (b) scalogram of rooftop pressure; (c) coscalogram of these two correlated processes; (d) scalogram of upstream wind velocity 2; (e) scalogram of rooftop pressure: (f) coscalogram of these two uncorrelated processes (after Gurley and Kareem, 1999)

Simulation of non-stationary events like gust fronts and hurricane wind fields can be accomplished by the generic summation of trigonometric time series approaches, but it is computationally inefficient, since, due to lack of ergodicity, ensemble averaging requires simulation of a large number of time series. The (proper orthogonal decomposition) POD based approach offers computational expediency, but thus far has been explored to only account for the amplitude modulations (Chen and Letchford 2005b). The wavelet-based simulation offers an alternative, which may better capture both time and frequency modulations (Wang and Kareem 2004a; 2004b; 2005). The dual nature of wavelet transforms, being a simultaneous transform in time and frequency, justifies its recent extension to civil engineering applications. The transform can be

adapted to a number of situations where Fourier transforms (for frequency domain analysis) or Hilbert transforms (for time domain system identification) are traditionally used to define quantities of interest. When considering the time and frequency information in tandem, wavelets can be used to determine the times and frequencies at which signal energy content is strongest by examining scalograms and co-scalograms (Gurley et al. 1997; Gurley and Kareem 1999; Kareem and Kijewski 2002). Fig. 1 displays a coscalogram comparison for full-scale pressure measured on a building and the two upstream wind velocity records. The first record is monitored simultaneously with the pressure time history under consideration and the second is from a different wind event. Fig. 1 (a-c) shows the scalogram and coscalograms of wind pressure and the first wind velocity, which is knowingly correlated. Note the pockets of white beyond 250 seconds revealing timevarying pockets of correlation in different frequency bands. This may be compared to a similar analysis for wind pressure and velocity that is known to be uncorrelated, for which no marked white pockets, indicative of correlation, are present. The presence of subtle light pockets, indicative of spurious correlation, present in both the correlated and uncorrelated examples in Fig. 1 is due to a lack of ensemble averaging (Kareem and Kijewski 2002).

3 NON-GAUSSIANITY

The wind velocity could be well represented as a Gaussian process, which is verified by numerous experiments and field observations. As a result, with the assumption of linear relationship between the input (wind velocity) and output (structure response), many of the studies encompassing analysis and modeling of wind effects on structures have assumed that the involved random processes are Gaussian. In general, for large structures the assumption of Gaussianity may be valid as a consequence of the Central Limit Theorem. However, the regions of structures under separated flows experience strong non-Gaussian effects in the pressure distribution characterized by high skewness and kurtosis. Fig. 2 illustrates the nature of pressure fluctuations on the windward and roof regions, where the rooftop region distinctly exhibits non-Gaussian features as noted in the time history of pressure fluctuations. It is also noteworthy that the bending moments (bottom time history) at the supports also exhibit non-Gaussian features despite the fact that the bending moments result from the summation of several force components. The departure from the Central Limit Theorem stems from the fact that the loads over the structures are correlated, which is in contradiction to the premise of the theorem.

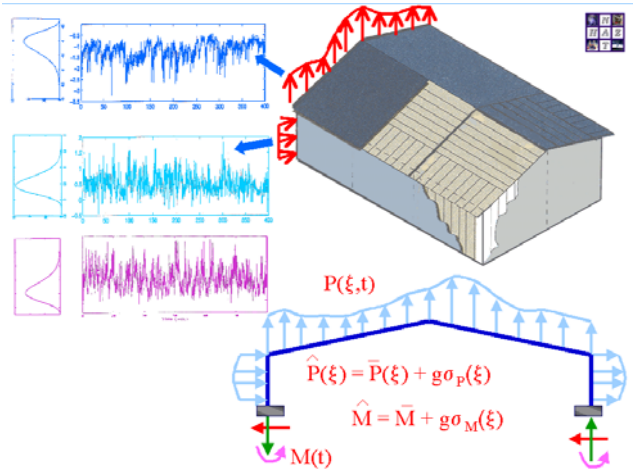

Figure 2: Schematic of pressure fluctuations on a building envelope

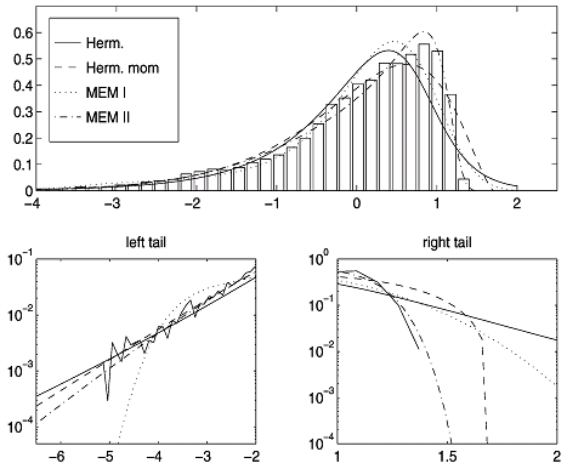

Figure 3: Top - PDF of pressure fluctuations in a separated region; Bottom – Close up of the tail regions (after Gurley et al. 1997)

The probability density function (PDF) of pressure fluctuations with large skewness observed in separated flow regions is critical to the modeling of loads on cladding and components, as well as loads on main load-resisting systems (Fig. 3). Often researchers have attempted to use the lognormal distribution for pressure fluctuations, but this fails to represent the tail region with high fidelity (Gurley et al. 1997). Among different alternatives, including the Maximum Entropy based model, it is noted in Fig. 3 that the Hermite moment-based distribution provides the best match to the data, especially for the negative tails (Gurley et al. 1997). This model also captures the significance of non-Gaussian pressure fluctuations for determining the equivalent constant pressure for glass design (Gurley et al. 1997), while providing a useful format to account for non-Gaussianity in the estimation of wind induced fatigue damage, as characterized by a correction factor (Gurley et al. 1997). The non-Gaussian effects result in enhanced local loads and may lead to increased expected damage in glass panels and higher fatigue effects on other components of cladding (Gurley et al. 1997).

Progress in quantifying and simulating the non-Gaussian effects of wind on structures has been elusive due to the limitations of traditional analytical tools (Gurley et al. 1996; Grigoriu 1998). Earlier work based on correlation distortion has been based on an inverse mapping of the desired PDF, a summary of which may be found in Gurley et al. (1996). In Gurley and Kareem (1997), a simulation approach, which is significantly more robust than the correlation distortion schemes, was presented. The non-Gaussian features and the frequency contents in the form of the first four moments and the target power spectral density (PSD) of the process were used; alternatively analytical expressions or other estimates of the distribution may be employed. The approach is named the spectral correction method relying on a few iterations to match both the spectral and probabilistic features. Fig. 4 shows an example of a simulation run based on a measured time history of a highly skewed full-scale pressure measurement. Also included are the PDF and PSD of the target and the simulated records which show good agreement. Additional follow-up work in this broad framework can be found in Grigoriu (1998), Deodatis and Micaletti (2001) and Masters and Gurley (2003). This approach has been extended to multi-variate processes including conditional simulations and random fields (Gurley and Kareem 1998a; 1998b; Gurley et al. 2001).

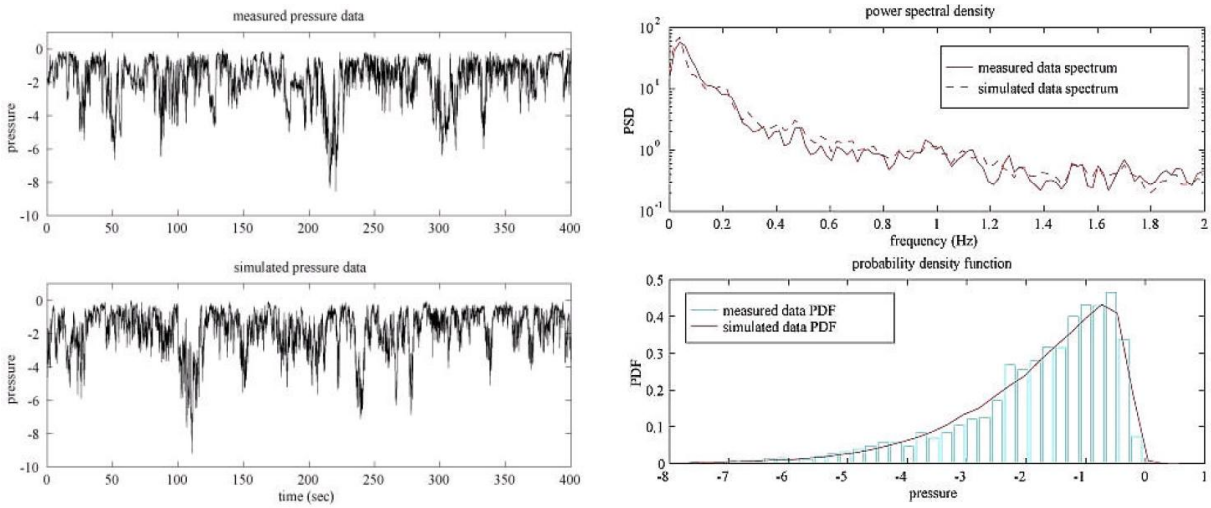

Figure 4: Left - Measured and simulated pressure time histories; Right - Comparison of PSD and PDF of simulated and measured time histories (after Gurley, et al. 1997)

Inasmuch as these techniques are based on static transformations, they may fail to encapsulate any memory that may be present in the target signals. A Volterra series-based scheme offers

an alternative that ensures preservation of memory. However, the Volterra kernels needed for such simulation may not always be available (Gurley and Kareem 1997). A class of single point non-Gaussian processes, e.g., pressure fluctuations at a location, can also be simulated through manipulation of the phase and utilization of neural networks (e.g., Gurley et al. 1996; Seong and Peterka 1998).

4 NONLINEARITY

In the area of wind effects on structures there are three types of nonlinearities that are generally experienced, i.e., geometric, material and aerodynamic. The geometric nonlinearity is most prevalent in cable-suspended and guyed structures, i.e., suspension and cable stayed bridges and guyed towers and masts, and pneumatic structures. The material nonlinearities may arise from materials of construction, e.g., concrete and composites that do not follow linear constitutive relationships. These effects can be adequately modeled for most structures using finite element models.

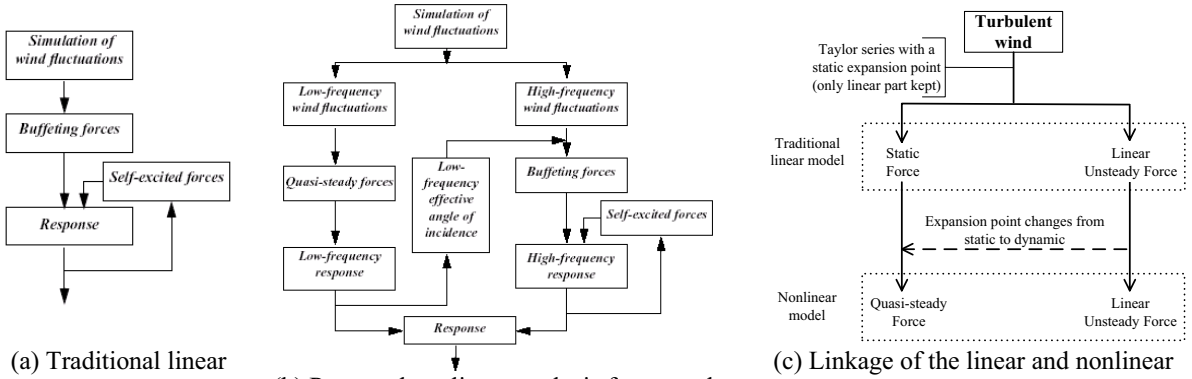
The nonlinearity of aerodynamic and aeroelastic origins are prevalent in wind effects on structures. Customarily, in these situations, linearized solutions are invoked, e.g., the widely used gust loading factor in codes and standards is based on the Gaussian framework, thus the term containing the square of the velocity fluctuations is dropped from the formulation. Kareem et al. (1998) presented a gust loading factor, which included the square velocity term, using the Hermite moment-based distribution in place of the Gaussian distribution. Earlier attempts to capture this effect using Edgeworth series did not adequately represent the tail regions of the distribution.

A linear assumption is often used to compute the response of structures to buffeting forces when nonlinearity in aerodynamic loading arises from the squared velocity term, as alluded to previously and due to dependence of aerodynamic coefficients on the angle of attack. Currently, reliance on the quasi-steady theory is a method of choice to take into account aerodynamic nonlinearities. According to the quasi-steady (QS) assumption, aerodynamic forces on structures are expressed as a nonlinear memoryless transformation of the flow-structure relative velocity and the angle of attack, which are variable in time due to oscillation of the body and the presence of turbulence in the incoming flow. The projection of the aerodynamic forces on the shape-functions employed in the finite element or Galerkin discretization of the structure requires approximating the nonlinearities by polynomial expressions. This can be carried out through a Taylor series expansion (Denoël and Degée 2005) or by an optimization procedure aimed at minimizing some error measure (Carassale and Kareem 2010).

On the other hand, one of the challenges in aeroelastic analysis remains in the modeling of wind-induced forces that take into consideration nonlinearities in both structural dynamics and aerodynamics in an unsteady analysis framework. As the measured information utilized in the traditional analysis framework, e.g., flutter derivatives, wind spectra, and aerodynamic admittances, are all natural functions of frequency, the aerodynamic issues are conventionally analyzed in frequency-domain (Scanlan and Tomko 1971). These frequency-domain analysis approaches are not suitable for accommodating the computational challenges of the nonlinear considerations.

In order to consider the unsteady effect in time domain, the indicial function approximation (Scanlan et al. 1974) or rational function approximation (Bucher and Lin 1988) is utilized. One of the earliest performance of the bridge aerodynamic/aeroelastic unsteady analysis in time domain is carried out by Beliveau et al. (1977) based on the indicial function approximation. Recently, Chen et al. (2000) and Chen and Kareem (2001) conducted the bridge aerodynamic/aeroelastic unsteady analysis in time domain based on the rational function approximation.

The proposed time domain analysis framework by Chen et al. (2000) and Chen and Kareem (2001) incorporates the frequency-dependent characteristics of aerodynamic forces that have been often neglected in most of the previous studies in time domain aeroelastic analysis, potentially impacting the accuracy of the response estimates.



(a) Traditional linear analysis framework (b) Proposed nonlinear analysis framework (c) Linkage of the linear and nonlinear analysis frameworks

Figure 5: Traditional and nonlinear analysis frameworks ((a) and (b)after Chen and Kareem 2003)

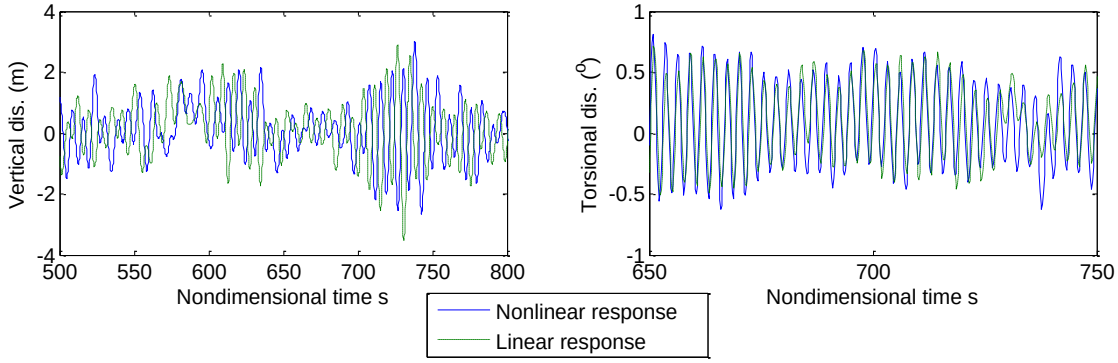


Figure 6: Time history of linear and nonlinear bridge deck responses

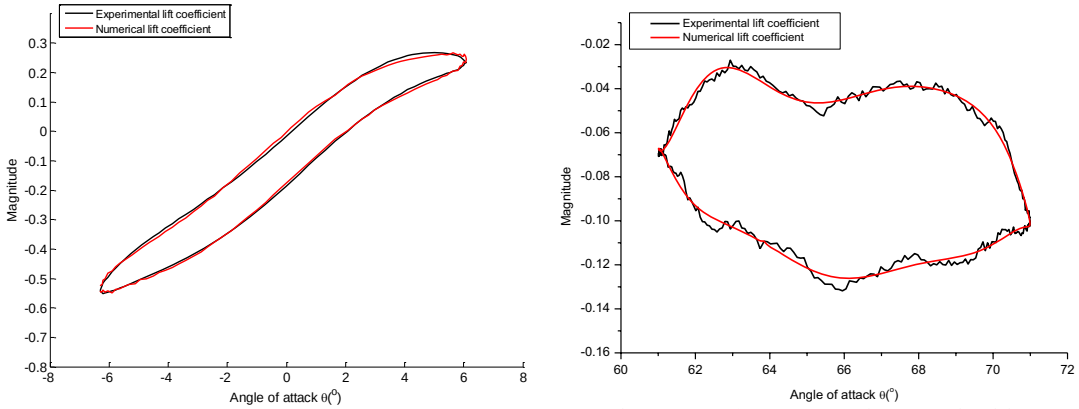
Furthermore, an advanced nonlinear aerodynamic force model and attendant analysis framework has been presented by Chen and Kareem (2003) that focused on the needs for modeling of aerodynamic nonlinearity of long span bridges. This nonlinear analysis framework transforms the problem into a full-time-domain formulation by means of a rational-function approximation and solves the equations of motion in the time domain through among others an integrated state-space approach. The aerodynamic forces are separated into the low- and high-frequency components in accordance with the effective angle of incidence corresponding to the frequencies lower than and higher than a critical frequency, e.g., the lowest natural frequency of the bridge. The low-frequency force component can be modeled based on the QS theory due to its high reduced velocity, while the high–frequency force component is separated into self-excited and buffeting components which are modeled in terms of the frequency dependent unsteady aerodynamic characteristics at the low-frequency spatiotemporally varying effective angle of incidence. Beside, this nonlinear scheme, proposed by Chen and Kareem (2003), has a clear connection with the traditional linear analysis framework. The traditional linear and advanced nonlinear analysis frameworks are summarized in Fig. 5 along with the basic relationship between these two analysis schemes. Actually, the advanced nonlinear scheme uses expansion of the aerodynamic force term about a dynamic position of the deck as opposed to a static position,

which represents the mean displaced position of the deck as employed in a traditional linear scheme. In other words, this nonlinear analysis framework represents piecewise linearization in a dynamic scheme as opposed to the static approach (Wu and Kareem 2011). The time histories of the nonlinear aerodynamic responses, namely vertical and torsional displacements for a long span bridge are presented in Fig. 6 compared with the traditional linear results.

5 HYSTERETIC NONLINEAR BEHAVIOR

The hysteretic nonlinear phenomenon is well known in vortex induced vibration of bluff bodies since it was initially observed experimentally by Feng (1968). Recently, the hysteretic phenomenon in the aerodynamic/aeroelastic forces on both the bridge decks and the cables of cable-stayed bridges has been a focus of interest (Diana et al. 2010; Wu and Kareem 2012a). The hysteretic behavior that appears in bridge aerodynamics/aeroelasticity suggests a higher-order memory in the system. Details of the hysteresis phenomenon, common to many fields, may be found in the literature (e.g., Brilliant 1958). The examples carried out by the authors indicate that the wind-induced responses of a typical modern bridge deck and of a stayed cable are significantly increased by introducing the hysteretic behavior in the respective response prediction schemes (Wu and Kareem 2012b; Wu et al. 2012). The hysteretic phenomenon could be modeled through a rheological model (Diana et al. 2010) or through a more generalized higher-order polynomial model based on the Moore-Penrose pseudoinverse identification scheme (Wu and Kareem 2012a). Fig. 7 presents the hysteretic phenomena observed in the lift forces acting on a bridge deck and on a typical stay cable based on wind-tunnel studies together with the numerically fitted model utilizing Moore-Penrose pseudoinverse identification scheme which shows a good agreement (Wu and Kareem 2012a).



(a)) Hysteretic effect on the bridge deck (b) Hysteretic effect on the stayed cable

Figure 7: Modeling the hysteretic behavior related to the lift coefficient (after Wu and Kareem 2012a)

However, both of these schemes are based on a unique independent variable, namely the effective angle of attack. In other words, these schemes assume that all other interacting components (bridge deck motions and turbulences) that are represented by this unique independent variable have equal weighting on the bridge aerodynamic behavior, which poses an unwarranted constraint in the aerodynamic force description (Wu and Kareem 2011). On the other hand, Wu and Kareem (2011) proposed a neural network model to simulate the hysteretic nonlinear behavior, which can be easily expanded for a single term input parameter to several input parameters through introduction of added weights and neurons as illustrated schematically in Fig. 8.

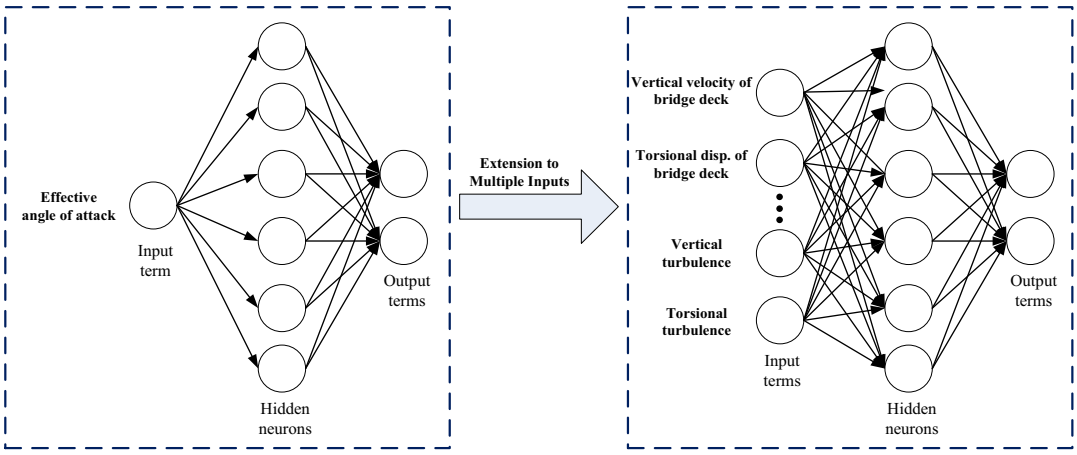


Figure 8: Schematic of the neural network for hysteretic nonlinear phenomenon

This data-driven model is determined by input-output information, which automatically captures intrinsic aerodynamic/aeroelastic nonlinearity and structural nonlinearity of the wind-bridge interaction system, as shown in Figure 9. Besides, the hysteretic nonlinearity modelling capability is enhanced through the higher-order neurons in the hidden layer, which results from the power terms of the first-order terms themselves as well as their cross terms. The cellular automata optimization scheme is applied to determine the configuration of the neural network with the aim of modelling bridge aerodynamics and aeroelasticity (Wu and Kareem 2011).

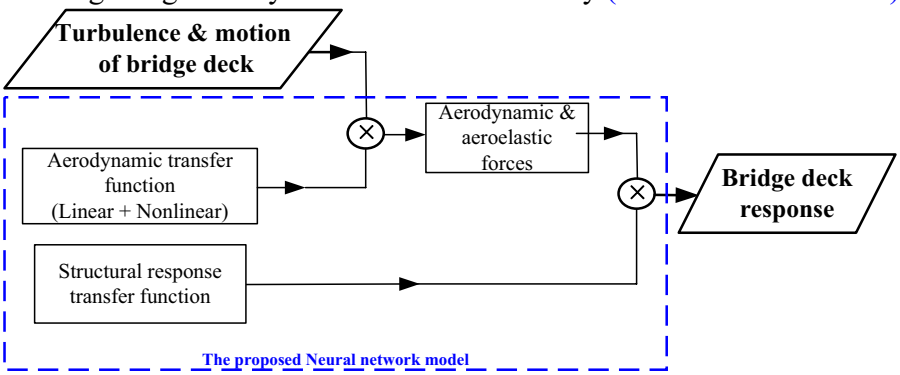

Figure 9: Integration of structural and aerodynamic nonlinearities via neural network model

6 ROLE OF TURBULENCE

The role of turbulence in the aerodynamics of stationary bluff bodies has been extensively documented in the literature (e.g., Gartshore 1973; Lee 1975; Kareem and Cermak, 1979; Saathoff and Melbourne 1989; Nakamura 1993). More recent studies investigating the effects of turbulence on rectangular sections have focused on both stationary and/or oscillating prisms with applications to improved understanding of building and bridge aerodynamics to turbulence (Larose 1993; Haan and Kareem 2009). Studies have shown that the flow around bluff bodies is governed by the separation and reattachment of the shear layers and by vortex shedding. The shear-layer thickness and the body size are length scales associated with these two phenomena, respectively. Turbulent eddies on the order of these scales are most effective at altering flow structure. The main effect of small-scale turbulence is to cause earlier reattachment of the flow through enhanced mixing in the shear layers. Turbulence in the range of the body scale can enhance or weaken vortex shedding depending on the body geometry. A schematic diagram of the multi-

scale fluctuations involved in typical bluff body wind interactions is shown in Fig. 10. Clearly there are three distinct bands of frequency characterized by the incident, shear layer or near wake and the wake fluctuations.

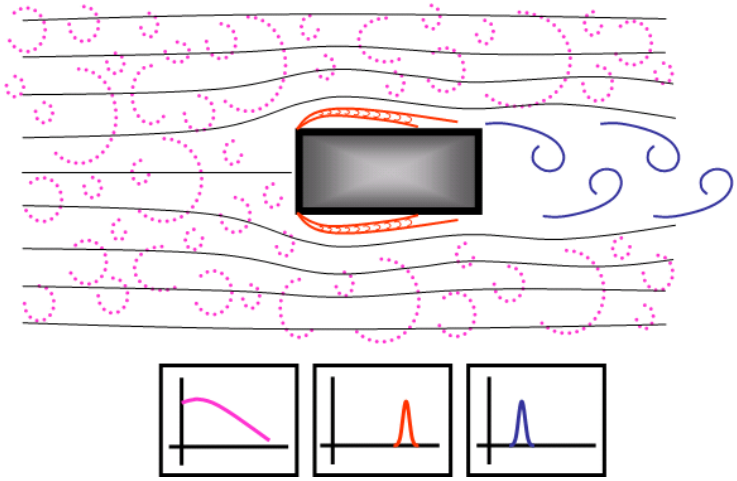

Figure 10: Schematic of flow around a bluff cross-section highlighting three distinct regions of fluctuations

Current fundamental and applicable research in turbulence effects on bluff bodies is summarized in Fig. 11, while only a selected few topics will be discussed in the following sections.

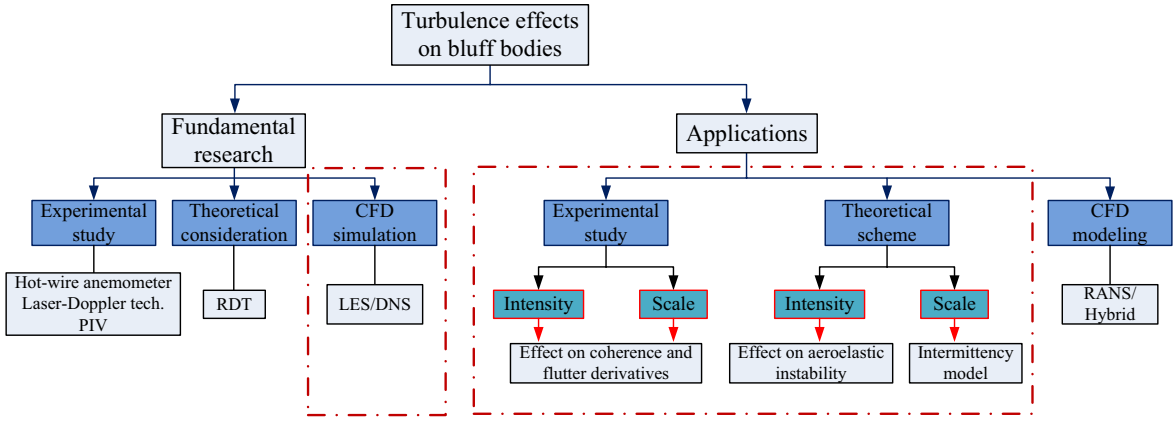

Figure 11: Current studies of turbulence effect on bluff bodies

6.1 *Fundamental research*

Although the "rapid distortion theory" (RDT) presents promising features to simplify the nonlinear nonlocal turbulent flow controlled by Navier-Stokes equation, this linear partial differential equation is still mathematical intractable as applied to the bluff bodies (Hunt et al. 1990). While current fundamental understanding of turbulence effect on bluff bodies mainly relies on the experimental studies involving significant improvement of the data acquisition systems, such as the Hot-wire anemometer, Laser-Doppler based technologies and particle image velocimetry (PIV), there have been remarkable developments in the area of computational wind engineering centered on the flow around bluff bodies involving 2-D and 3-D prisms and the role of turbulence (e.g., Murakami and Mochida 1999; Yu and Kareem 1997; Tamura and Ono 2003). The Large

Eddy Simulation (LES) framework is emerging as a numerical scheme of choice for the solution of Navier-Stokes equations (Murakami and Mochida 1999). For example, recent studies have shown that the simulated pressure field around prisms has convincingly reproduced experimentally-observed characteristics. This is true with respect to variations in the mean and RMS pressure coefficients of the drag force and regions of flow reattachment, even as the aspect ratio of the prism is varied (Murakami 1999; Yu and Kareem 1997). Other computational schemes like detached eddy and hybrid simulation schemes are offering other opportunities for improved simulations (Wei and Kareem). Fig. 12 shows instantaneous contours of vorticity for prisms of aspect ratios: 3:1 and 1:3 based on 3D LES schemes. In Fig. 13 time histories of the drag and lift forces along with their respective PSD and time-frequency scalograms are shown. Examination of the drag and lift force time histories for the selected aspect ratios reveal distinctive features both above and below the critical aspect ratio of 0.62. For aspect ratios below the critical value intermittent behavior (periods of low and high drag force) occurs, while beyond the critical value, the drag force has less intermittence. The corresponding spectral descriptions show a global distribution of energy. The scalograms (Fig. 14) reaffirm the intermittent bursts of energy for aspect ratio 3:1 and relatively more evenly distributed fluctuations for the 1:3 prism.

One of the challenges remaining in this field entails the inclusion of surrounding structures to capture the influence of flow modification, shielding and interference, as well as the simulation of inflow turbulent boundary layer flow conditions. Recently, advances have been made in these areas, including modeling of aeroelastic instabilities, CFD techniques for practical applications, and modeling of urban roughness and terrain effects (Tamura et al. 2002; Tamura and Ono 2003). Coupled with computer aided flow animations, such simulation techniques may in the near future provide “numerical wind tunnels” to analyze the evolution of flow around structures and estimate attendant load effects. More recently, developments in CFD on the cloud are evolving (vortex-winds.org).

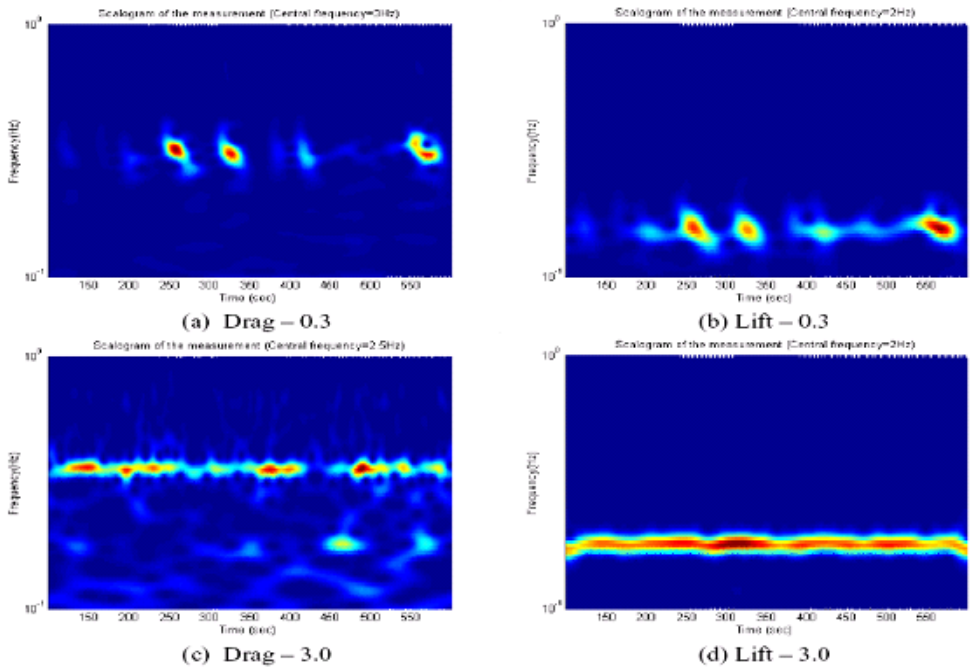

Figure 14: Wavelet based scalogram of drag and lift fluctuations for aspect ratio 0.3 (a, b) and 3.0 (c, d), respectively, (after Yu et al. 2006)

6.2 *Applications*

While the turbulence simulation based on LES or direct numerical simulation (DNS) is limited to a relative low Reynolds number due to the extremely computational consumption together with the intricacies of the inlet turbulence modeling, applications of CFD modeling based on various turbulence models have been developed in bluff body aerodynamics. However, the following sections will focus on the improved understanding of the turbulence effects on bluff bodies based on the experimental studies and on the theoretical schemes.

6.2.1 *Experimental study*

Because bridges and buildings often have rectangular or near rectangular shapes, a notable amount of wind tunnel work has been done studying varieties of rectangular bodies and the shear layers separating from them. Most of this work has been done for stationary bodies, but some has been for prisms in motion. While experimental studies focusing on the effects of turbulence on bridge aerodynamics (e.g., Scanlan and Lin 1978; Huston 1986; Matsumoto et al. 1991; Larose et al. 1993; Haan et al. 1999) have typically noted an increase in critical wind velocity with added turbulence, several studies have reported destabilizing trends associated with turbulence (Matsumoto et al. 1991; Huston 1986). The cause of these disagreements remains to be conclusively determined and signifies the limitations in current understanding of the problem (e.g., Scanlan 1997; Chen et al. 2000; Haan and Kareem 2009).

Recent experimental studies put significant attention on the turbulence effects on the flutter derivatives and on the correlation of the wind-induced forces. Scanlan and Lin (1978) first investigate the turbulence effect on the bridge aeroelasticity experimentally by utilizing the flutter derivatives under turbulence wind condition. Observation indicates there is no distinct difference of flutter derivatives resulting from laminar and turbulent flow conditions. It should be noted that the turbulence in wind tunnel cannot reproduce the natural condition accurately. Specifically, the

turbulence integral scale in wind tunnel will be very small compared with the reasonable one based on the scale law.

It is well known that not only the turbulence intensity but also turbulence scale will contribute the effect on the bluff body. Gartshore (1973) investigate the turbulence scale effects on various prisms by emphasizing the modification of the shear layer. Besides, Nakamura (1993) pointed out the small-scale turbulence could influence torsional flutter through resulting in earlier reattachment of flow on the solid surface. Recently, a detailed investigation of the turbulence effects on the aerodynamics of an oscillating prism in wind tunnel indicates the turbulence intensity and turbulence scale will simultaneously affect the flutter derivatives with different mechanisms (Haan and Kareem 2009). The former mainly changes the flutter derivatives which are sensitive to the pressure phase such as A_2^* (weighting the contribution to the moment from torsional velocity) while the latter mainly changes the flutter derivatives which are sensitive to the pressure amplitude such as A_3^* (weighting the contribution to the moment from torsional displacement) (Haan and Kareem 2009).

Instead of directly dealing with the turbulence effect on the flutter derivatives, Haan and Kareem (2009) investigated the distribution of the pressure field around the prism in both chordwise and spanwise directions, including their correlations and in bridge related studies the correlation of the pressure field in comparison with upstream turbulence. In the following, a summary of some of the findings of this recent study, which has not been widely reported in the literature thus far, is presented. It brings out some useful observations and important ramifications for the current state of the art of aerodynamic analysis of long span bridges (Haan and Kareem 2009). In this study, grid generated turbulence was used to study the effects of both turbulence intensity and turbulence scale on aerodynamic forces. By examining the unsteady pressure distributions over the bridge model rather than the flutter derivatives alone, a clearer understanding of how turbulence affects the unsteady forces was obtained. Both increasing turbulence intensity and turbulence scale decreased the amplitudes of self-excited pressure fluctuations. The basic shape of the chordwise distributions of pressure amplitude—a single hump shape—is shifted upstream with increasing intensity of the free stream turbulence. This shift, however, was only slightly affected by the turbulence scale. Fig. 15 shows a space time portrait of the pressure distribution highlighting this observation.

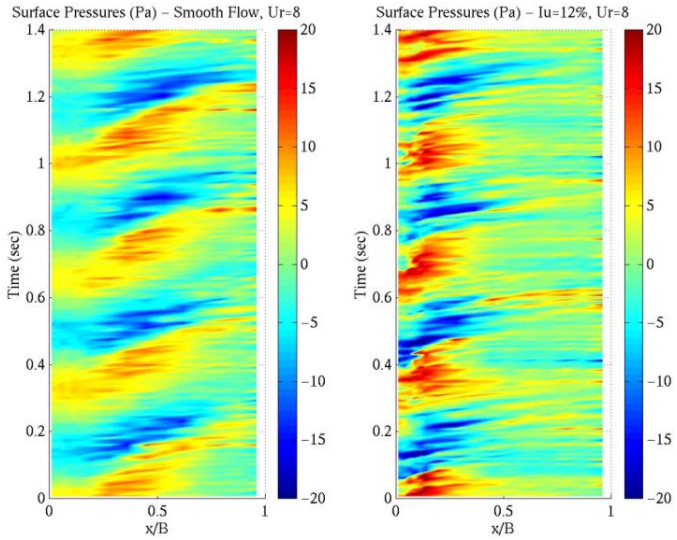

Figure 15: Surface plots of the temporal and spatial evolution of the surface pressure on a rectangular prism undergoing torsional oscillations (X/B - streamwise direction/deck width; left - smooth flow; right - turbulent flow) (after Haan 2009)

Haan and Kareem (2009) also observed that the phase values of the self-excited pressure (with respect to the body motion) had several regimes in the streamwise direction. Near the leading edge, phase was nearly constant. Downstream of this locale was a region where phase increased rapidly. Beyond this rapidly increasing phase zone was a region where the phase values leveled off and even decreased in some cases. While scale had little discernible effect on this phase value, turbulence intensity shifted the region of rapidly increasing phase toward the leading edge. The stabilizing effects of turbulence observed in the flutter derivatives were related to these turbulence-induced shifts in the pressure amplitudes and phase distributions. By tracking the integrands of expressions for lift and moment, specific changes in pressure amplitude and phase were linked to flutter derivative modifications. In addition, this upstream shifting in the unsteady pressure on the oscillating models was found to be similar to the behavior observed for pressure distributions over stationary models. This suggests that the vast amount of research done in bluff body aerodynamics on stationary bodies may aid in the understanding of oscillating body problems as well.

Prior to this study, no experimental study had justified the conventional analysis technique in which the aerodynamic forces are separated into flutter and buffeting components. Pressure measurements made on oscillating models allowed experimental assessment of this assumption. Overall, the assumption is quite close. Examination of the lift and moment spectra showed close agreement throughout the frequency range considered. Where the stationary and oscillating model spectra did not agree, however, the oscillating model values were larger. This oscillation-induced increase in the broadband energy occurred mainly for frequencies above $fD/U = 0.1$ although some differences were observed for lower frequencies as well. Quantitative analysis of these differences showed that oscillating model buffeting forces could have RMS values as much as 10% higher than their stationary model counterparts. This difference decreased for increased turbulence intensity and increased turbulence scale. For the flow with the highest intensity and scale considered, these differences were only around 2-3%. Observation of the streamwise distribution of such differences revealed that the location of oscillation-induced broadband increase was upstream of reattachment—for this case, this meant upstream of the location of the maximum RMS pressure value. This implies that bodies which experience separation over smaller portions of their surface may exhibit less significant differences between stationary and oscillating model buffeting levels.

Through both coherence measurements and correlation calculations of self-excited force components, the self-excited forces were found to have near unity coherence over the entire spanwise separation range considered. It was noted that cases with larger turbulence length scale showed a slightly lower correlation than those of smaller scales, the estimated 95% confidence intervals of ±0.03 puts all results within the statistical spread of the others suggesting no influence of length scale. The conventional assumption of self-excited forces being fully correlated in the spanwise direction was thus supported by the results of this study. Of course, this also means that the often-suggested hypothesis that a decrease in spanwise correlation of the self-excited forces causes the turbulence-induced increase in the critical flutter velocity is not supported by the current results. Although the stabilizing effect of spanwise correlation loss may be apparent for single-mode torsional flutter (Scanlan 1997), it is not obvious that this will apply to multi-mode coupled flutter cases. Correlation loss along the span may stabilize a deck by reducing negative damping effects, and yet it may destabilize a deck by reducing favorable damping (Chen and Kareem 2003). This issue will become even more important as bridge spans grow longer and multi-mode flutter becomes more probable. A conclusive investigation of self-excited force coherence would require much longer span lengths to observe whether appreciable changes occur for longer spanwise separations. Coherence calculations also showed that the broad band

coherence of the oscillating model matched that of the stationary model to within the uncertainty of the experiment.

While spanwise correlation of pressure and buffeting forces on static models in turbulent flows have been measured by a number of researchers, little if any experimental work has been done on the spanwise behavior of the self-excited forces. Full correlation of the self-excited forces is generally assumed in the response analysis, as alluded to earlier by findings in Haan et al. (1999). This suggests, however, that the turbulence-induced behavior of full-bridge models mentioned previously cannot be explained entirely due to a decrease in self-excited force coherence. In view of this, there is a clear need for improved knowledge of the basic physical phenomenon. Analysis framework based on recent developments in bridge aerodynamics may facilitate improved understanding in the subject area (Chen and Kareem 2006a; 2006b; Wu and Kareem 2011)

6.2.2 *Theoretical scheme*

Although both the effects of turbulence in the incoming flow and the signature turbulence should be taken into account, there is no well developed scheme to account for the effect of signature turbulence except utilizing the CFD technique. On the other hand, the incoming turbulence effect can be well represented utilizing the theoretical Küssner function or Sears function for streamlined structures, or employing the measured admittance function for bluff bodies. However, the incoming turbulence effects on aeroelastic instability is not able to be considered based on these schemes. With some ad hoc assumptions, turbulence intensity effect on the aeroelastic instability could be considered either based on randomizing the dynamic pressure and invoking stochastic approaches, or through the incorporation into the effective angle of attack based on the QS concept.

Lin and Ariaratnam (1980) and Bucher and Lin (1988) theoretically demonstrated the turbulent intensity effect on aeroelastic instability by solving the linear stochastic differential equations based on Itô's differential calculus. The second-moment stability is emphasized in this analytical scheme. It is proved that the turbulence with small intensity has uncertain (either "stability" or "destability") effect on the bridge aeroelasticity while the turbulence with larger intensity has "destability" effect on the bridge aeroelasticity. However, this analytical scheme has some obvious limitations, such as the turbulence is assumed to be Gaussian stationary process with small turbulence intensity and the solutions are assumed as Markov processes. More importantly, only the along-wind turbulence component is considered while the vertical turbulence component is neglected which is usually considered as more important role contributing to turbulence effect.

On the other hand, the QS theory based models can also take into account the turbulence intensity effect after integrating the fluctuation into the effective angle of attack. For many innovative bridge sections, even at low levels of turbulence, the effective angle of attack due to structural motion and incoming wind fluctuations may vary to a level such that the nonlinearities in the aerodynamic forces may no longer be neglected. However, the QS assumption based model is a well-known memoryless system, where the unsteady effect is not considered.

The nonlinear analysis framework proposed by Chen and Kareem (2003) could incorporate the effects of turbulence on long span bridges. In this analysis framework, the low frequency force component can be modeled based on the quasi-steady theory, while the high–frequency force component can be modeled by utilizing the traditional unsteady scheme. Actually, the effects of low-frequency turbulent fluctuations are taken into account analytically through the QS concept with the effective angle of attack and the effects of high-frequency turbulent fluctuations could be considered experimentally through the measured flutter derivatives under turbulent wind condition.

Flutter studies utilizing full-bridge models have often shown critical velocity boundaries to be sharply defined in smooth flows and higher or nonexistent in turbulent flows. Under turbulent wind condition, there are some observations that the flutter instability will not happen suddenly with a distinct flutter boundary as the Scanlan's linear analysis predicts. One possible illustration of this phenomenon is the turbulence, not only the oncoming turbulence but also the signature turbulence, build up the exchange of energy between different structural modes with more complicated manners, which leads to the gradual incidence of flutter (Scanlan and Jones 1990). The proposed analysis framework by Chen and Kareem (2003) is able to investigate this behavior quantitively. Within this framework, the effects of turbulence on flutter are modeled through the changes in the effective angle of incidence caused by turbulence and its influence on the self excited forces and the flutter instability. The application of this framework to a long span suspension bridge, with aerodynamic characteristics sensitive to the angle of incidence, revealed a gradual growth in response with increasing wind velocity around the flutter onset velocity, which is similar to the wind tunnel observations of full-bridge, aeroelastic models in turbulent flows (Fig. 16).

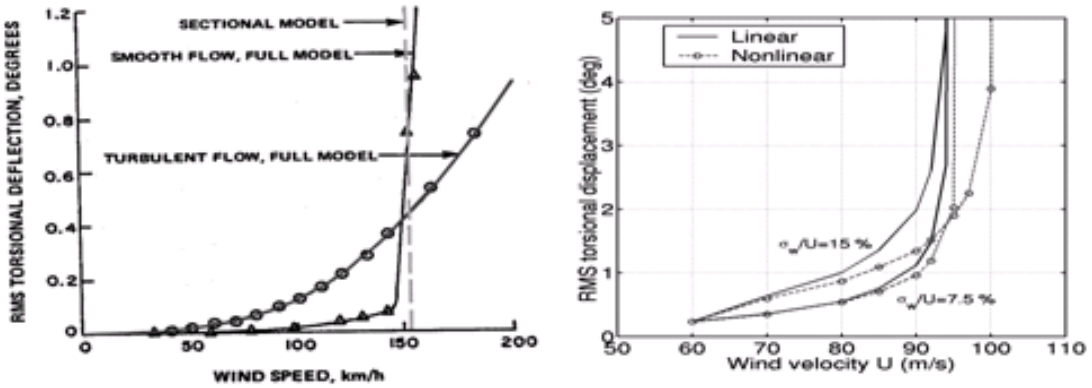

Figure 16: Left - Torsional response of Lions' Gate Bridge (Irwin 1977); Right - Linear and nonlinear predicted response of a bridge (after Chen and Kareem 2003a)

Currently there is no theoretical consideration of the turbulence scale effect on the bluff bodies. However, recently development of the intermittency modeling in turbulent flows may shed some light on this consideration. As a violent discontinuous nature of turbulence, internal intermittency seems only change the velocity statistics slightly (a slightly wider PDF compared with Gaussian distribution), while it has significant effects on the statistics of the velocity difference (a considerably larger PDF tail compared to Gaussian distribution). Conventional simulation scheme such as spectral representation cannot consider the multi-scale property of turbulence while the wavelet based expansion has been applied to simulate the intermittency with promising results (Kitagawa and Nomura 2003; Yin et al. 2012). The simulated PDFs of different scales (represented by the wavelet coefficients) in turbulence are presented in Fig. 17 compared with the measured results. These tails of PDFs can make significant contributions to higher-order moments, which impact the rare events. The simulation with intermittency consideration will directly contribute to the inlet turbulence modeling. Though the small scales contains little energy, it is well known that the intermittency in turbulence has significant effect on the transport and diffusion of material by the turbulence (Ecke 2005), which could be important to the environmental wind engineering community. The QS assumption may describe adequately the effects of large scales, which has high accuracy in galloping modeling. On the other hand, there is no theoretical analysis to investigate the effect of small scales on the bluff bodies. While it is reasonable to ignore the turbulence effects with the scale significantly smaller than the struc-

tural dimensions, there is demand to advance the analysis approach for the turbulence effects with comparative scale sizes. The simulated turbulent flow with intermittency consideration could be utilized in the analysis of aerodynamics and aeroelasticity in time domain, where the turbulence scale effect could be investigated in detail.

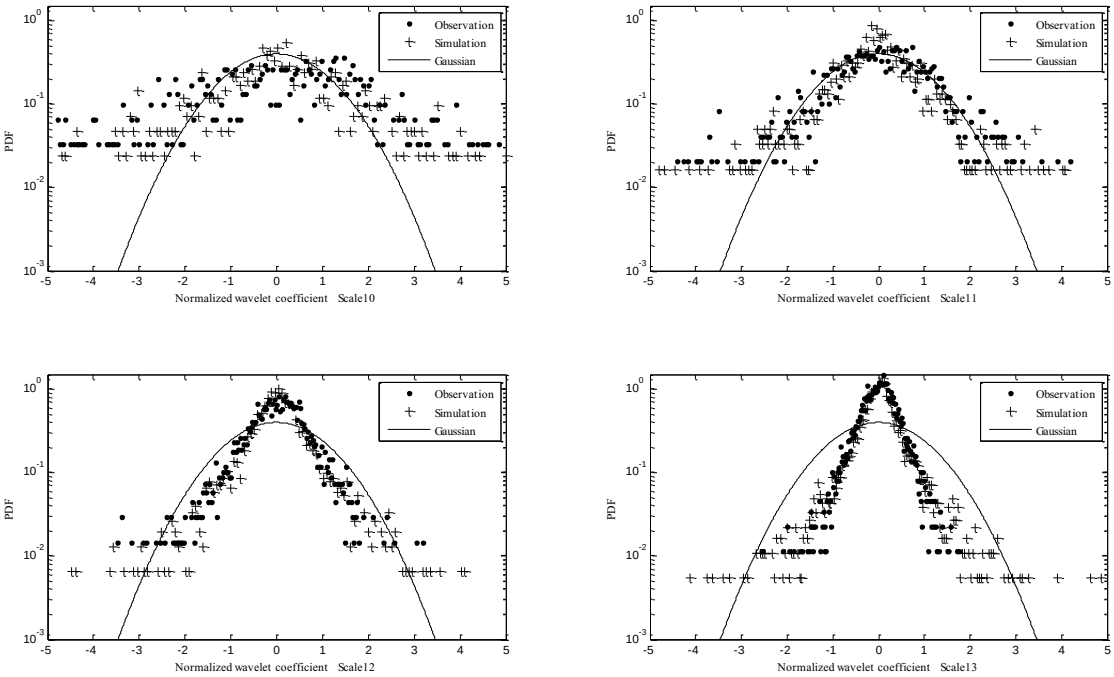

Figure 17: PDFs of wavelet coefficients at typical scales

In closing this section, it is very important to note that the preceding anthology of the role of turbulence on the bluff body aerodynamics of prismatic bodies, with applications to buildings and bridges, excluded a vast amount of literature concerning circular cylinders which is available in a number of review articles. On the other hand, although there is strong correlation between the circular cylinder and the bluff bodies with prismatic shape, the difference between them is unnegligible. For example, bridge deck, which features a significant afterbody, has fixed separation points instead of moving separation points varying as Reynolds number and oscillation frequency and amplitude. Besides, the torsional force induced by the wake vortices may be more important for prismatic bodies since this structural geometry possesses a long afterbody. Hence, wake-vortex-induced effect of prismatic bodies may differs significantly from that of the circular cylinder.

7 CHANGING DYNAMICS OF AERODYNAMICS

The subject of aerodynamics has been treated traditionally by invoking quasi-steady and strip theories and has been extended to unsteady aerodynamic theories for loads originating from wake aeroelastic effects. The current challenges are to address aerodynamics in transient flows. In the following, a brief discussion of these areas is provided with an outlook for their treatment of transient conditions, and lessons one may learn from aerodynamics in nature.

7.1 *Quasi-steady Aerodynamics*

Quasi-steady and strip theories offer reliable estimates of load effects when the dominant mode of loading is attributed to buffeting, e.g., surface pressure responding to large-scale, low frequency turbulence for the alongwind buffeting load effects. The quasi-steady theory fails to relate the approach flow and the ensuing pressure fluctuations on surfaces in separated flow regions. The shortcoming of the theory stems from the fact that it does not account for the wind-structure interactions at several scales, which may introduce additional components, thus highlighting the need for unsteady aerodynamics. The quasi-steady theory has been successfully applied to the analysis of galloping behavior of structures, often observed in structures exposed to winds at high reduced velocity, e.g., ice coated transmission line cables and cables experiencing skewed winds.

An obvious shortcoming of QS theory is that it cannot take into the unsteady effect of fluid-structure interaction. In order to take into account the fluid memory effects based on the static wind-tunnel tests, Steinman (1950) introduced phase correction factors resulting from pressure distribution graphs of stationary titled straight models (for the effects of vertical velocity and wind angle of attack) and horizontal curved models (for the effects of angular velocity). A more familiar approach to consider the fluid memory effects is to modify the steady-state coefficients based on the unsteady effects measured in the wind tunnel and hence to improve the simulation accuracy (Diana et al. 1993). This corrected QS theory could partially include the fluid memory consideration, which indicates that the flow around a structure is not only dependent on the instantaneous relative states (structural motions and flow fluctuations) but also on their previous time history. Actually, it is difficult to select an appropriate frequency to calculate the reduced wind velocity in the corrected QS scheme especially as the bridge aerodynamic effects involved. In order to overcome this shortcoming of the corrected QS theory, a more detailed scheme named "band superposition" was proposed by Diana et al. (1995), where the aerodynamic/aeroelastic forces are linearized about a reference value of the effective angle of attack.

7.2 *Unsteady Aerodynamics*

Notwithstanding the improved knowledge of wind effects on structures over the past few decades, our understanding of the mechanisms that relate the random wind field to the various wind-induced effects on structures has not developed sufficiently for functional relationships to be formulated. Not only is the approach flow field very complex, the flow patterns generated around a structure are complicated by distortion of the wind field, flow separation, vortex formation and wake development. Nonlinear interaction between the body motion and its wake results in the 'locking in' of the wake to the body's oscillation, resulting in vortex-induced vibrations over a range of wind velocities. The stability of aeroelastic interactions is of crucial importance (Matsumoto 1999). In an unstable scenario, the motion-induced loading is further reinforced by the body motion, possibly leading to catastrophic failure. Depending on the phase of the force with respect to the motion, self-excited forces can be associated with displacement, velocity, or acceleration. Furthermore, aeroelastic effects can couple modes that are not coupled structurally, leading to more complex issues in bridge aerodynamics as discussed earlier. The intractability of these unsteady aerodynamic features has led to experimental determination of these effects using scale models in wind tunnels. These measurements have led to loading characterizations in terms of spectral distributions of local and integral load effects and aerodynamic flutter derivatives, which, when combined with structural analysis, yield measures of overall structural behavior.

Concerning building aerodynamics, the most widely used wind tunnel technology involving the high frequency base balance (HFBB) does not include motion induced loads. Kareem (1982) noted in a validation study concerning the crosswind spectra derived from statistical inte-

gration of surface pressure that the response estimates computed by using the measured spectra began to depart from the estimated values based on aeroelastic model test of the same building at reduced velocities above 6. The damping estimates from the aeroelastic model suggested a constant increase in the negative aerodynamic damping. By including the negative aerodynamic damping, the response predictions provided a better comparison with the aeroelastic tests at higher reduced velocities. It is also important not to simply attribute all motion induced effects to aerodynamic damping. Indeed the motion of a structure also modifies the flow field around it. Particularly it tends to enhance the spanwise pressure correlation, which may lead to an increased forcing in comparison with that measured by a force balance. A recent study critically evaluates the role of several modeling parameters needed to accurately model aeroelastic effects for base pivoted models (Zhou and Kareem 2003).

In attempts to relate the incident turbulence to pressure fluctuations in separated regions, higher-order modeling via bispectral approach has been utilized, which has identified some correlation although it has not provided a functional relationship. It is noteworthy that that the intermittent nature of the unsteady aerodynamic relationship is vitiated using Fourier based analysis (Gurley et al. 1997). Higher-order bispectral analysis utilizing a wavelet basis offers promise to capture intermittent relationship between the incident turbulence fluctuations and the attendant pressures under separated flows (Gurley et al. 2003). Thus, challenges remain in establishing transfer functions that could relate, at higher-orders in a localized basis, the complexities inherent to bluff body aerodynamics.

7.3 *Transient Aerodynamics*

Both earlier and more recent studies in fluid dynamics have pointed out an overshoot in aerodynamic/hydrodynamics loads on cylinders in unsteady flows (Sarpakaya 1963). It has also been noted that for the analysis of structures in non-stationary atmospheric turbulence, the traditional stationary analysis fails to account for possible transient overloads, e.g., the sharp changes in gusts were found to cause a transient aerodynamic force on a bridge model, which cannot be explained by a stationary statistical analysis. This clearly points at the need to critically assess the impact of abrupt changes in the wind field magnitudes and associated modifications in aerodynamics of structures and appraises the need for refining the current load descriptions.

7.4 *Aerodynamics in Nature: Some Lessons*

Natural objects with bluff profiles like trees, plants and jellyfish experience forces in a flowing medium like air or water. Often these objects have the ability to minimize drag by shape reconfiguration, e.g., palm trees bend and through their compliant action survive the fury of hurricanes. This is not an option available to most of the built environment as their shapes are fixed In architectural and structural communities tapered, twisted and tilted towers are being built. The fixed shapes used in man-made structures are arrived at on the basis of aerodynamic considerations, but are undertaken a priori and the possibilities of changes in real-time during wind storm are not available. Other possible avenues of managing flow around buildings are possible by using biomematics through introducing scalloped leading edges like whale flippers, which act like vortex generators.

Unfortunately, these fundamental phenomena in nature may not benefit the built environment. As in nature, more flexibility may help survive adverse environmental conditions through excessive bending, however, tall buildings or bridges may not be able to afford this luxury as they may lose their functionality, e.g., occupants of a building experiencing large excursions of motion may get symptoms of sea sickness leading to discomfort and in extreme cases nausea and

vertigo. However, such flexible behavior has been utilized in offshore drilling platforms, where the human comfort considerations are not as stringent.

8 IDENTIFICATION TOOLS

The higher-order spectrum is the Fourier transform of the higher-order correlation. It identifies nonlinear interactions among frequency components and also preserves the phase information, which is generally a more sensitive marker to identify the departure from linearity as compared to information related to amplitude (Ueda and Dowell 1984). For a linear system, the second-order information embedded in a power spectrum represents distribution of energy at different frequencies which fully characterizes a linear system in the frequency domain. The normalized value of the cross-power spectrum captures the phase relation at the same frequency between two different signals. However, for nonlinear system higher-order spectrum is needed because the power spectrum cannot portray the energy transformation between different frequency components which is a typical feature of nonlinear systems. Among these higher-order spectra, the bispectrum, the Fourier transform of triple correlation can capture quadratic nonlinearities. Further higher-order interactions can be tracked by trispectra and beyond, but each additional order adds significantly to the computational demand and need for added length of data sets. (e.g., Kim and Powers 1979; Gurley et al. 1996; Tognarelli 1999; Hajj and Silva 2004). A bispectrum is easy to visualize since it can be displayed as a three-dimensional (3-D) plot, whereas, further higher-order spectra can be only viewed in 3-D by slicing the hyper-dimension at different frequencies.

The auto-/cross-bispectrum and auto-/cross-bicoherence could be applied to both the pressure signal or the force signal obtained in wind-tunnel experiments. Fig. 18 presents the second-order spectrum of an aerodynamic force acting on a typical bridge deck obtain in a wind tunnel. The nontrivial values in the figure indicate nonlinear interactions between the frequency components, suggesting the presence of such interactions in the aerodynamics of bridge decks.

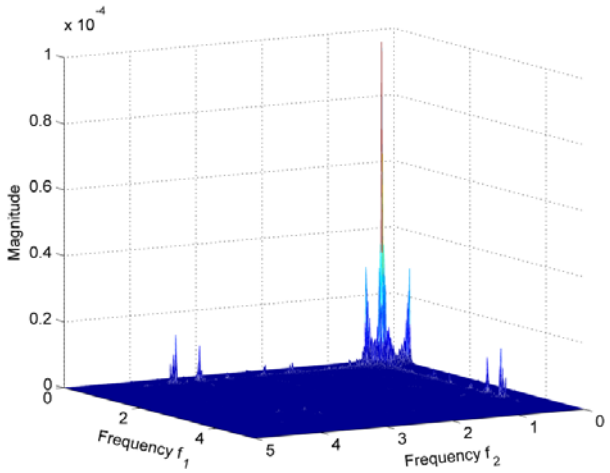

Figure 18: Auto-bispectrum of aerodynamic force on a bridge deck (after Wu and Kareem 2012a)

On the other hand, the evidence of nonlinear input-output relationship could be obtained in time domain through the second-order Volterra kernel, which corresponds to the double inverse Fourier transform of the higher-order transfer functions of the nonlinear system. Fig. 19 presents the linear and nonlinear Volterra kernels of a simulated bridge aerodynamic system, where the nontrivial values of the second-order kernel indicate that nonlinearity exists in the system.

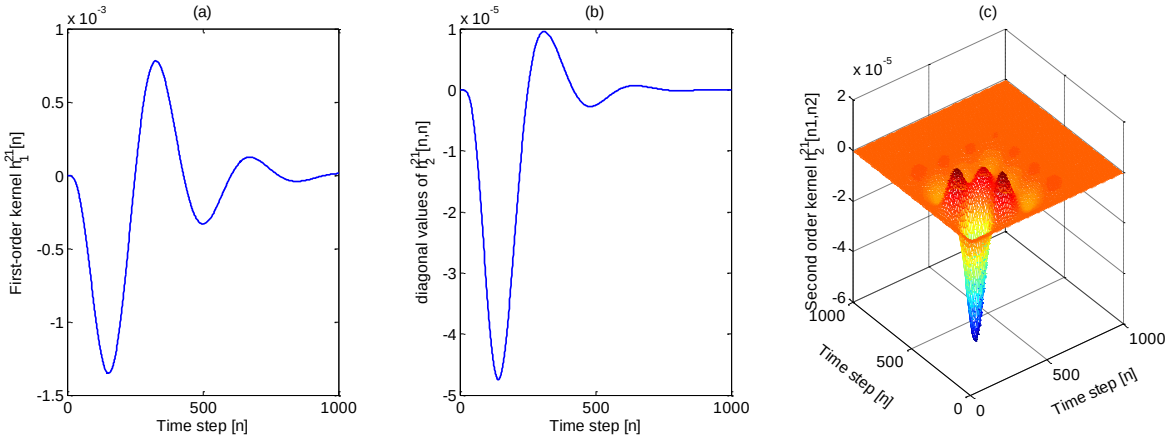

Figure 19: Linear and nonlinear Volterra kernels of a simulated bridge aerodynamic system (after Wu and Kareem 2012c)

More specific insights into the linear and quadratic interplay between two signals in both time and frequency can be gained utilizing wavelet coherence and bicoherence measures (Gurley et al. 2003). However, by exploiting the dual potential of wavelets, other analyses based primarily in either the time or frequency domain can also be performed. By tracking the variation of wavelet transform coefficients in the time domain, system identification can be readily performed (Kijewski and Kareem 2003). Similarly, the distribution of wavelet coefficients with frequency at a window in time provides a familiar spectral representation whose evolutionary properties can be monitored to provide insights into nonlinear behavior (Kareem and Kijewski 2002).

9 CONCLUDING REMARKS

This paper reflected on recent developments in aerodynamics and aeroelasticity of bluff bodies with a viewpoint concerning turbulent wind effects on structures. Some of the overarching issues for the future encompass the modeling and impact of imperfect correlation, transient/nonstationary effects, non-Gaussian and nonlinear features involving recent development of the modeling frameworks and identification tools. Improved understanding of turbulence effects on bluff bodies is stressed. Advances in experimental and theoretical methods with improved sensing capabilities based on wireless sensors, smart sensors, GPS, laser Doppler based technologies and optical and sonic systems would aid in effectively addressing some of the needs highlighted. With foundations steeped in bluff body aerodynamics and aeroelasticity theories and projected research paths imbued in advanced and e-technologies, our abilities will certainly be lifted up to a higher level of understanding, modeling, analysis, design and monitoring of wind effects on structures.

10 ACKNOWLEDGEMENTS

The author gratefully acknowledges the support provided in part by NSF Grant CMMI 0928282. The support in part for the study was also provided by the Global Centre of Excellence at Tokyo Polytechnic University: *New Frontier of Education and Research in Wind Engineering* funded by the Ministry of Education, Culture, Sports, Science and Technology (MEXT), Japan. The author is deeply indebted to the intellectual contributions of his former and present graduate students, post-doctoral and visiting researchers.

Wind tunnel tests and numerical approach for long span bridges: the Messina bridge

Giorgio Diana, Giuseppe Fiammenghi

Dipartimento di Meccanica, Politecnico di Milano, Via La Masa, 1 – Milano, Italy
Società Stretto di Messina, Via Marsala, 27 - Rome, ITALY

ABSTRACT: An overview of the wind tunnel activities and methodologies to support the design of long span suspension bridges is proposed. The most important aspects of the wind-bridge interaction are investigated considering the aerodynamic phenomena affecting the different parts of the bridge (mainly deck and towers). The experimental activities and results are proposed in the framework of a synergic approach between numerical and experimental methodologies that represents the common practice in defining the full scale aeroelastic behavior of the bridge starting from scaled reproduction of the wind-bridge interaction. Static and dynamic wind loads, aeroelastic stability, vortex induced vibrations will be investigated.

KEYWORDS: wind tunnel tests, bridge aerodynamics, aeroelasticity, numerical approach

1 INTRODUCTION

The definition ‘long span bridge’ is usually related to bridges with the main span of the order of one thousand meters or longer. For these bridges the flexibility is high and the first natural frequencies are of the order of 0.1 Hz or lower. Increasing the span length over 1 km, the bridges are classified as very long span bridges and the their natural frequencies are decreasing with the inverse proportion of the span length. For the 3.3 km of the Messina bridge main span, the first natural frequency is 0.03 Hz. These bridges are really sensitive to the wind action and for them the wind becomes the major problem affecting the overall design.

The maximum span length of a cable stayed bridge is 1.1 km: all the bridges with longer spans are suspension bridges. Actually the longest bridge is the Akashi in Japan, with its main span of 1990 m. Considering the bridges at the stage of the detailed final design, the longest is the Messina in Italy.

For these very long span bridges, as already said, the wind plays the most important role in the bridge design. In the following, we will make reference mainly to suspension bridges.

Many problems must be faced to guarantee the bridge performance to the wind action: the major are:

1) Static load, due to the average component of the wind blowing on the structure
2) Dynamic load, due to the incoming wind turbulence
3) Instability of the bridge
4) Vortex shedding on the tower, deck and cables.

The handling of these problems required the development of special analytical models. These models need tests in wind tunnel to identify the aerodynamic and aeroelastic behaviour of the different bridge components. Various types of wind tunnel tests are needed:

- on models of the deck, tower and cables
- of the full aeroelastic bridge model: this is the final check.

The analytical methods and the experimental tests in the wind tunnel are strongly correlated and some of the wind tunnel tests are dedicated to the identification of the aerodynamic and aeroelastic parameters used in the computation programs.

The paper is mainly aimed at describing the numerical tools and the type of wind tunnel tests that are used to design a long span bridge in order to guarantee the correct performances.

It is useful to mention that the Specifications used for the design of the Messina Bridge describe in the detail the type of tests to be carried out in the wind tunnel together with the analyses to be performed. These Specifications can be considered as a Standard for long span bridges design.

The present paper is organized in the following paragraphs:

1) Introduction
2) Analytical methods for the analysis of the bridge response to the wind
3) Wind Tunnel tests
4) Numerical results
5) Conclusions.

2 ANALYTICAL METHODS FOR THE ANALYSIS OF THE BRIDGE RESPONSE TO THE WIND

It is common practice to develop finite element schematizations of the bridge (Figure 1) to identify its response to the different actions of interest: wind, earthquake and traffic.

For what concerns the wind action, generally beam elements are used for deck and tower, while taut string or tensioned beam elements are used for the cables. These models are generally used to compute the global behavior of the bridge to the different actions and they can be non linear or linear, as a function of the type of excitation.

A non linear approach is used to identify the static position of the bridge under the permanent load, or static load, like the traffic and the wind loads due to the average wind [1].

For what concerns the dynamic load, a linear approach is generally used, being the linearization performed around the static equilibrium configuration [1], [2], [3], [4].

To compute the stress induced by the dynamic load – or local effect – a more sophisticated schematization of the deck and tower is used, employing plate elements. In Figure 2 the finite element schematization of the Messina deck is reported together with the drawing of the deck section. This FEM has been used to assign the stresses on the boxes welding, in order to verify the fatigue problem.

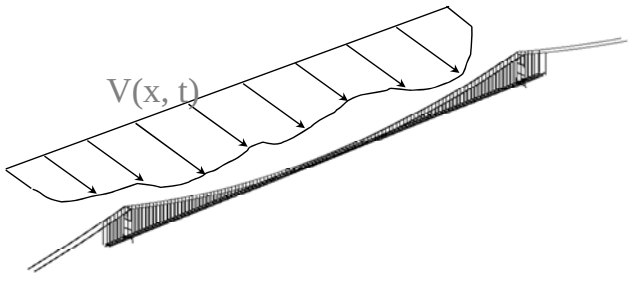

Figure 1. Global FEM schematization of the Messina Bridge and incoming wind.

The global bridge FEM (Figure 1) is used to compute the bridge natural frequencies (Figure 3), which are fundamental for the analysis of the bridge response to the wind action.

The ratio between the torsional and vertical frequencies of the same mode is very important for the flutter instability problem: the greater this ratio, the higher the flutter velocity.

In order to reproduce the bridge response to the turbulent wind, the dynamic load due to the incoming turbulence has to be applied to the FEM schematization.

Knowing the structure of the wind in the site surrounding the bridge, it is possible, by special tools [5][6], to reproduce a space and time wind distribution, as shown in Figure 1.

The forces acting on the bridge are a function of the incoming turbulence.

On the other hand, the bridge motion produces aerodynamic forces which are motion dependent.

As a consequence, the aerodynamic forces acting on the bridge are functions both of the incoming turbulence and of the bridge motion.

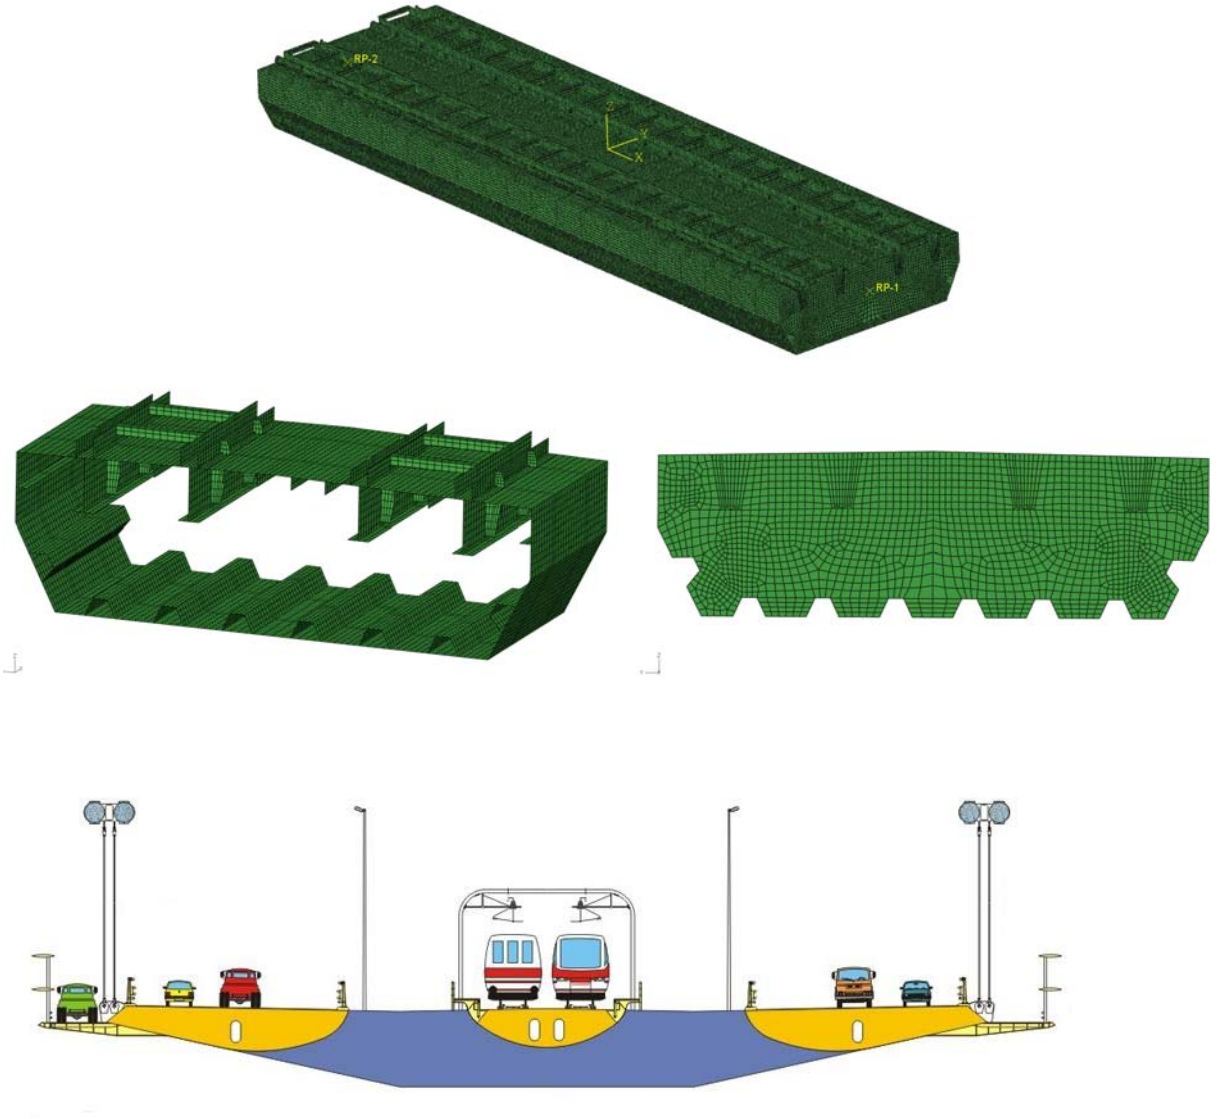

Figure 2. FEM schematization of the Messina deck and deck drawing.

I vertical mode. f = 0.06 Hz

I torsional mode. f = 0.081 Hz

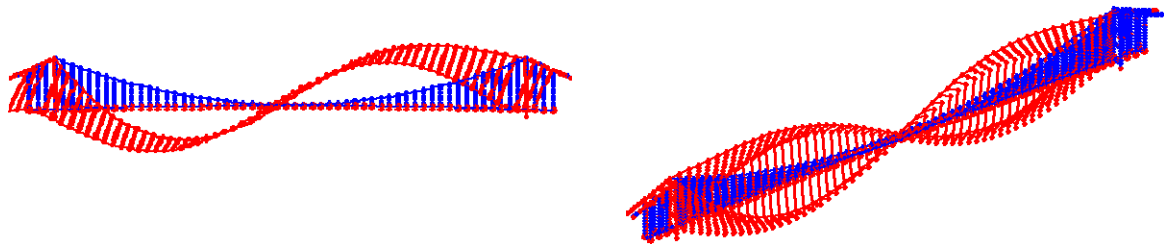

Figure 3. Vertical and torsional mode shapes of the Messina Bridge.

In order to reproduce the over mentioned wind forces in the bridge FEM, the following equation have to be considered:

$$M_s \ddot{X} + R_s \dot{X} + K_s X = F_a\left(X, \dot{X}, s(t)\right) \tag{1}$$

where M_s, R_s, K_s are mass, damping and stiffness matrices of the bridge structure linearized in the neighbourhood of the static equilibrium position, X is a vector containing the bridge degrees of freedom.

The X vector defines the motion of the bridge components: deck, towers, cables.

F_a is the vector defined by the aerodynamic forces acting on the different sections of the bridge deck, towers, cables.

F_a is function, as previously said, of the bridge motion X and of the associated velocity $\dot{X}$, as well as of the incoming turbulence vector s(t).

The identification of this non linear function through wind tunnel tests is a complex matter and it is for sure one of the most advanced topics of the research in this area[7], [8], [9].

2.1 *Linear approach*

The most used approach consists in linearizing the aerodynamic forces in the neighborhood of the static equilibrium position of the bridge X_0, identified by a given average wind V_m. This leads to:

$$\begin{aligned} &M_s \ddot{X} + R_s \dot{X} + K_s (X - X_0) = F_{a0}\left(X_0, 0, V_{m0}\right) \\ &+\left(\frac{\partial F_a}{\partial X}\right)_{X_0,0,V_{m0}} (X - X_0) + \left(\frac{\partial F_a}{\partial \dot{X}}\right)_{X_0,0,V_{m0}} \dot{X} + \left(\frac{\partial F_a}{\partial s}\right)_{X_0,0,V_{m0}} \left(s(t) - V_{m0}\right) \end{aligned} \tag{2}$$

being s(t) a vector containing the incoming wind turbulent velocity in the different sections of the bridge, where F_a is applied.

The aerodynamic forces F_a and the associated derivatives must be identified through suitable wind tunnel tests on the deck, towers and cables, as will be better explained in the next paragraphs. The aerodynamic forces playing the most important role in the bridge motion and stability are those acting on the deck.

The aerodynamic forces acting on a deck section (Figure 4) are as already said function of the vertical (z), the horizontal (y) and the torsional (θ) deck motion, as well as of the incoming wind turbulent velocity.

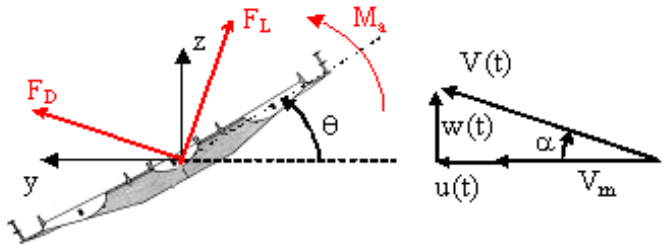

Figure 4. Aerodynamic forces acting on the deck

As usual, the aerodynamic forces due to the incoming turbulence are defined by a lift component normal to the direction of the wind V(t) and a drag component parallel to V(t), both applied at the center of the section, plus a moment of the aerodynamic forces M_a, as in Figure 4.

Coming back to equation (1), the lift, drag and moment on each section of the deck represent a sub-vector of the vector containing all the lift, drag and moment forces applied to all the bridge sections while X is the vector of all the section displacements and $\dot{X}$ of all the section velocities.

If we use a linearised approach as in (2) with the notation:

$$\left(\frac{\partial F_a}{\partial X}\right) = -K_a; \quad \left(\frac{\partial F_a}{\partial \dot{X}}\right) = -R_a; \quad \left(\frac{\partial F_a}{\partial s}\right) = A_m$$

equation (2) can be written in the following way:

$$M_s \ddot{X} + (R_s + R_a)\dot{X} + (K_s + K_a)X = A_m\left(s(t) - V_{m0}\right) \tag{3}$$

where $s(t)-V_m$ is a vector defined by the w,u, v components of the wind turbulence in the different points of the structure.

R_a and K_a are the equivalent damping and stiffness matrices due to the aerodynamic forces.

In other words, the linearization of the aerodynamic forces produces an equivalent elastic and damping system that is added to the structural one, changing the natural frequencies and the overall damping. An aeroelastic system is produced.

The K_a matrix, as well as the R_a matrix, are non symmetric and can give rise to flutter instability.

R_a, if non positive defined, can give rise to the so called one degree of freedom instability according to a torsional or vertical motion when the slope of the lift or moment coefficients is not positive.

A_m is the so called Admittance matrix.

All the parameters needed to define the K_a , R_a and A_m matrices must be identified through wind tunnel tests in order to reproduce the bridge response to the turbulent wind.

Equation (3) can also be solved in the frequency domain [3], [4],[10]: in this case the wind input is the spectrum of the incoming turbulence.

2.2 *Non Linear approach*

Even if linear approaches are the widest adopted method to study the bridge aerodynamic stability and response of the bridge to turbulent wind they are not able to deal with the important non linear effect intrinsically present in the aeroelastic problem. As already presented, the dependence of the aerodynamic forces from the deck motion and from the turbulent wind velocity components is fully non linear (see equation 2).

$$M\,\underline{\ddot{X}} + R\,\underline{\dot{X}} + K\,\underline{X} = \underline{F}_A\left(\underline{X}, \underline{\dot{X}}, V_m, v(t), w(t)\right) \tag{4}$$

The two main causes of non-linearities are the dependence of the aerodynamic forces on the angle of attack and on the reduced velocity. The QST [10] is able to take into account the dependence on the mean angle of attack in a non linear way but it is valid only at high reduced velocities. On the contrary the linear approaches are able to take into account the dependence on the reduced velocity through the flutter derivatives and the admittance function coefficients but they represent a solution around a fixed mean angle of attack. Measurements performed on full scale bridges highlighted that during the common operating condition the relative angle of attack between the bridge deck and the wind direction may reach large values that make the linear hypothesis not applicable. Some non linear approaches have been developed [7] [8] [9] to deal with the fully non linear aeroelastic problem. In this section we can only introduce the basic ideas of the "Band Superposition" approach and of the "rheological model" approach, and refer the reader to the literature for a more exhaustive description.

The "Band Superposition" approach relies on the possibility of separating the low frequency and the high frequency contributions of the wind spectrum. The idea is that the low frequency part of the wind spectrum is responsible for the larger fluctuations of the angle of attack and it acts at high reduced velocity. A correct QST [11] is therefore proposed to account for this part taking into account the non linear dependence on the angle of attack. The part of the wind spectrum at high frequency is characterised by smaller amplitudes and lower reduced velocity. To consider the effects induced by this part of the wind spectrum, the aeroelastic forces are linearized around the angle of attack that is instantaneously computed by solving the low frequency part of the problem. The problem becomes linear in the high frequency range, but with coefficients changing with the time.

An alternative approach is to consider the whole wind spectrum effects in a single time domain model as represented by the "rheological model". This approach is based on a numerical model that is able to consider both the angle of attack and the reduced velocity dependence in a single time domain approach. To identify the numerical model parameters, aerodynamic hysteresis loops are measured on deck sectional models in wind tunnel by changing the instantaneous angle of attack. The variation of the angle if attack is produced by moving the sectional model or by using the active turbulence generator with high amplitudes at different frequencies [7].

3 WIND TUNNEL TESTS

The procedures adopted for the most important long bridges at the design or construction stage will be described. These represent the state of the art on the subject. The tests on deck, towers and cables will be separately considered because the adopted approach is, even if in a small amount, different.

3.1 *Aerodynamic tests on the deck*

The procedure generally adopted for the wind tunnel tests on the deck is herein after described:

1) Static tests on the deck section, in order to measure the lift, drag and moment coefficients as a function of the angle of attack (α). This part is covered in section 3.1.1.
2) Optimization of the deck shape, in order to fulfill the bridge stability requirements, analyzing the slope of the lift and moment coefficients obtained by the static tests (section 3.1.1). This part is described in section 3.1.2.
3) Verification of the vortex shedding excitation, analysing the vibration level as a function of the Scruton number. This will be described in section 3.1.3. If the vibration level fulfils the Specifications at the real bridge Scruton number, the optimization procedure is closed, otherwise the deck shape is changed in order to control vortex shedding and the procedure must be repeated, starting from step 2).
4) Once the deck optimization has been completed, dynamic tests in order to identify the flutter derivatives and the admittance functions should be performed, as reported in detail in section 3.1.4.

The optimization procedure from point 1) to 3) is generally performed with small changes of the deck geometry with respect to the preliminary design, such as modification of the wind barriers, if present, or modification of the traffic barriers or parapet screens, or addition of special devices to control the wind flow.

3.1.1 *Deck static tests*

The most important test for the deck, as well as for the other components, is the definition of the static aerodynamic coefficients as a function of the angle of attack.

This test is made in a wind tunnel on a sectional model of the deck (Figure 5)

The sectional deck model is placed on a dynamometric system (Figure 5) generally placed outside the wind tunnel test section [12],[13].

The model can rotate around a deck longitudinal axis and the lift, drag and moment aerodynamic forces are measured as a function of the wind angle of attack, by changing the deck angle of rotation.

Some laboratory uses a deck sectional model with a dynamometric central part (Figure 6).

This type of device is also very useful to measure the dynamic aerodynamic forces, as it will be better explained in the following.

The output of this type of tests is shown in Figure 7 for different deck types (taken from [14]).

Figure 5. Deck sectional model in wind tunnel (external balance).

Figure 6. Deck sectional model in wind tunnel (internal balance).

The static forces, due to the average wind, on all the bridge components can be derived from Figure 7 and similar ones for towers and cables. The static forces on all the bridge due to the average wind can be computed in order to define, through a FEM simulation, the deflection of the bridge and the related stresses.

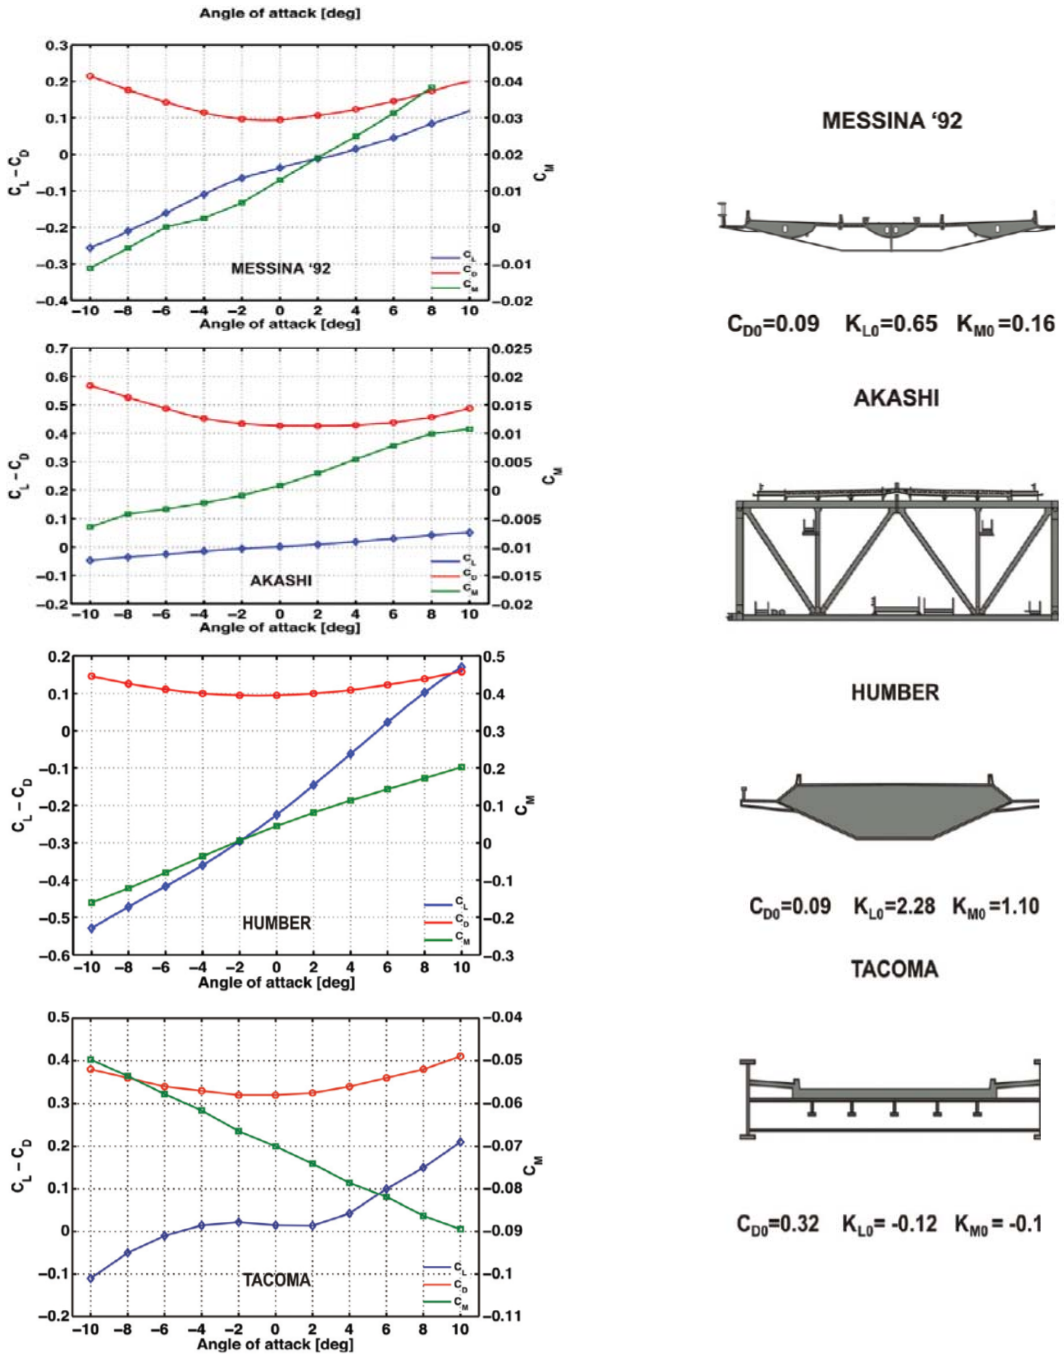

Figure 7. Aerodynamic coefficients of different deck geometry.

3.1.2 *Aerodynamic optimization of the deck*

The lift, drag and moment coefficient figures are very important for the bridge deck optimization.

The moment and lift coefficient slopes are very important for the bridge stability. They must be positive, with the conventions set in Figure 4, to avoid one-degree-of-freedom instability and, in order to have a high flutter velocity, their slopes must be as much as possible lower than the values of a flat plate: 2π for the lift coefficient and $\pi/2$ for the moment coefficient.

The slope value to guarantee stability is a function of the ratio between the bridge torsional and vertical frequencies. This ratio is decreasing with the span length: see Figure 8.

In the Messina Specifications the ratio between the first torsional and the first vertical frequencies is 1.36, leading to a prescription for a value of the moment coefficient derivative comprised between 1/5 $\pi/2$ and 1/10 $\pi/2$ and for a value of the lift coefficient derivative comprised between 1/5 2π and 1/10 2π.

The final reason for this requirement is that the positive slope of the moment coefficient produces a negative torsional stiffness which decreases the torsional frequency, such making it equal to the vertical one and producing the two-degrees-of-freedom flutter instability.

Another important issue is to take the deck drag as low as possible, because the drag forces on the deck are the most important and are transferred to the top of the towers by the hangers and the main cables, producing a moment that affects the overall tower design.

In order to fulfill these requirements, for a very long span bridge – over 2000 m – it is mandatory to use a multi box section.

A long optimization work is needed to obtain positive lift and moment coefficients with small slopes for all the wind angles of attack, or at least for a ± 4 degrees portion.

For the Messina bridge deck, the optimization involved the railway box shape and the wind barriers shape and porosity both for the road and railway box girders.

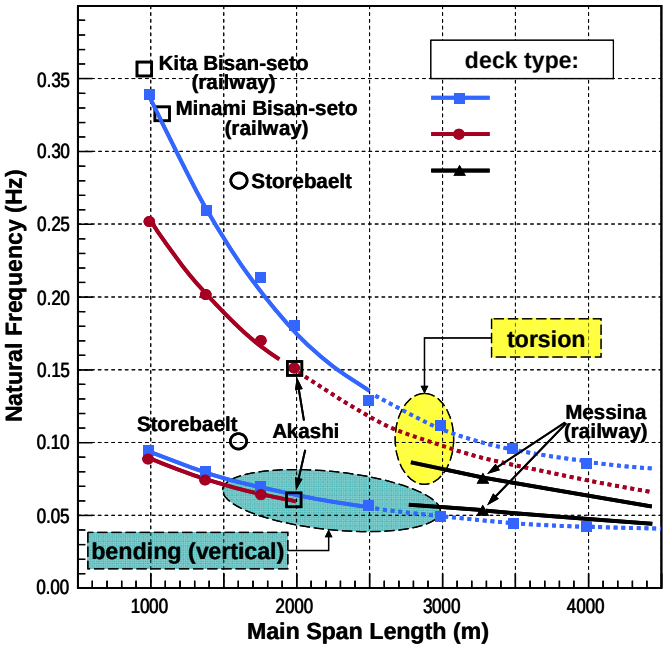

Figure 8. Bridge torsional and vertical frequency as a function of the span length

3.1.3 *Vortex shedding*

Vortex induced vibrations (VIVs) represent one of the most important aspects of the deck shape design. Even though the bridge deck of the last generation have an airfoil like geometry, flow separation occurs in correspondence of the deck sharp corners, in presence of adverse pressure gradients and of wind shields that are usually adopted to protect traffic. VIV is a serious problem that took also a part in the collapse of the Tacoma Narrow Bridge and has to be carefully analyzed. In fact, even if it can be separated from the stability problem for the modern bridges, it can lead the deck to reach very large vibration amplitudes in case of low Scruton numbers

$$Sc = 2\pi \frac{mh_s}{\rho B^2} \tag{5}$$

where m is the mass per unit length, h_S is the structural damping, B is the deck chord and ρ is the air density, also at very low wind speeds having a high probability of occurrence.

Nevertheless the problem is widely known and studied, past and present experiences highlighted that it represents one of the major concerns in the bridge design. In 2010 Russian authorities shut down the Volga River bridge because of the VIV. For the Storebealt bridge, guide vanes were installed close to the bottom plate/lower side panel joints, for mitigation of the vortex-induced oscillations occurred during the final phases of girder erection. The solution was identified after an ad hoc monitoring activity on the bridge at full scale and a specific wind tunnel activity, and its realization required a specially designed gantry/working platform.

Wind tunnel tests are performed on elastically suspended models (Figure 9). Special attention is paid, in wind tunnel tests, to keep the Scruton number as low as possible by using light models with low structural damping, in order to better highlight vortex shedding phenomena.

The model response in the lock-in range is usually measured in order to define:

1) the oscillation amplitudes reached at regime condition throughout the lock-in range
2) the amount of energy that the flow is able to insert in the system, that may be expressed by a negative value of the aerodynamic damping coefficient measured during build-up tests performed by releasing the deck model under mean wind condition and measuring the growing vibration amplitude starting from rest.

Figure 9. Free motion experimental set-up: Suspension system, tensioned steel stays and spring system.

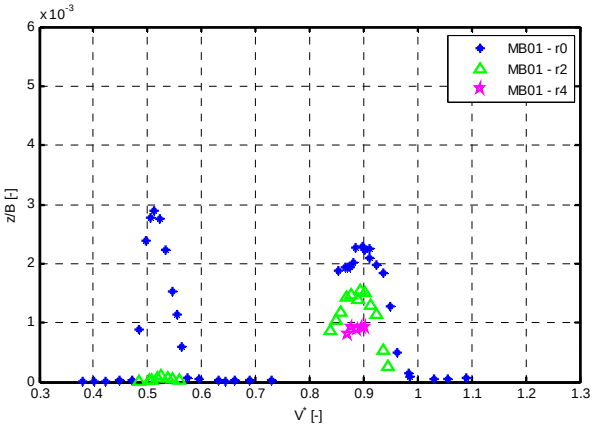

Figure 10. Steady state response: non dimensional oscillation amplitude, flexural motion as function of the reduced velocity varying the Scrouton number (r0=0.007; r2=0.022; r4=0.033).

While single box deck shapes generally shows a single mechanism of vortex shedding, basically related to the vortexes detached in the girder wake, multi box decks may present different vortex shedding phenomena because of the different possibility of flow interactions between the wake of the upwind box and the other boxes.

The different vortex shedding mechanism may excite both the heaving and the torsional motion of the bridge.

As an example Figure 10 presents the two lock-in ranges for the flexural motion of the Messina Bridge multi box deck section for different Scrouton number:

From the maximum values of the amplitudes measured in the lock-in range at different Sc, it is possible to define a figure that reports the non-dimensional amplitudes as a function of Sc.

In Figure 11, the vertical amplitudes of the deck divided by the deck chord B are reported as function of Sc – solution MB02. From this type of figure, it is possible to identify what is the damping of the real structure able to control VIVs. Making reference to Figure 11, the 3 vertical dashed lines represent 3 different values of Sc that for the Messina bridge correspond to 3 different levels of non-dimensional ratios of structural damping equal to: $2\ 10^{-3}$, $3\ 10^{-3}$ and $5\ 10^{-3}$. In order to avoid VIVs the structural damping of the Messina bridge should be greater than $3\ 10^{-3}$.

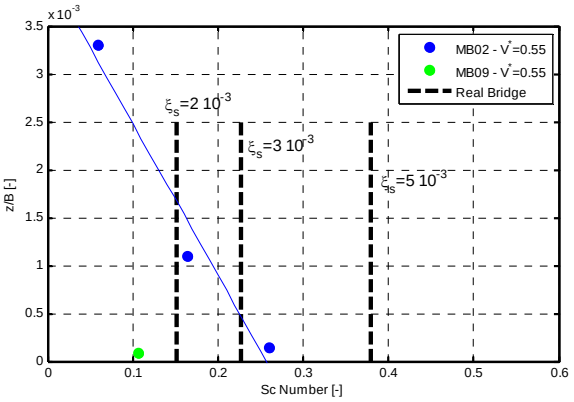

Figure 11. Steady state response: non dimensional oscillation amplitude, MB02 and MB09 configurations, flexural motion as function of Scruton Number.

To avoid VIVs also for lower values of structural damping, that are not expected, the solution is to adopt porous screens between the railway box and the road boxes (solution MB09 reported in Figure 12). In this case no VIVs are produced even for very low damping.

Measurements of the surface pressure distribution on each single box represent a valuable tool to a better understand of the vortex shedding phenomenon.

In Figure 13 the pressure distribution measured on the Messina bridge model when it experiences the largest vibrations (lock-in) is reported in terms of the magnitude of the pressure coefficient C_P fluctuations at the vortex shedding frequency:

$$C_P = \frac{p}{\frac{1}{2}\rho U^2} \tag{6}$$

where p is the pressure and U is the wind speed. The arrows that are pointing outwards the deck profiles are proportional to the value of the pressure coefficient amplitude.

It is possible to appreciate how the vortex shedding is mainly related to the capability of the flow to be attached or separated on the curvilinear profile of the upwind box that is run over

by an undisturbed flow. , It is clear where the vortex are generated and it is clear that there is a strong pressure fluctuation in the gap between the downwind roadway girder and the railway girder. The aerodynamics of the downwind boxes is, in fact, strongly influenced by the disturbances introduced in the flow by the wind interaction with the upwind box and by the gap between the boxes.

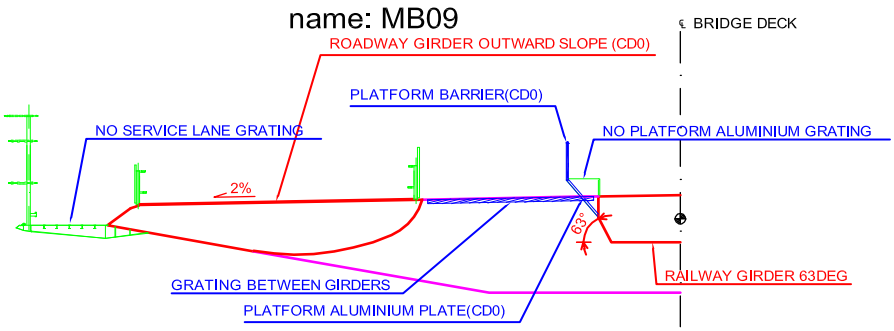

Figure 12. Solution MB09: deck with porous screens between the boxes

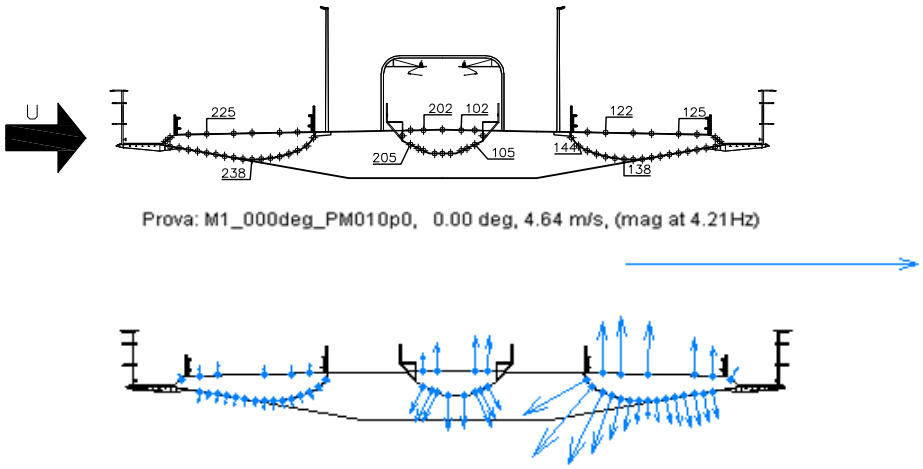

Figure 13. C_p magnitude at f=4.21 Hz.

3.1.4 *Dynamic tests on the deck*

To define the aerodynamic forces as a function of the deck motion and the incoming turbulence, as reported in the previous paragraph, the lift, drag and moment forces have to identified as a function of the y, z and θ coordinates representing the deck motion and of the w an u velocity components defining the incoming wind turbulence.
For what concerns the forces identification as a function of the bridge motion, two methods are available: the free motion method and the forced method.

3.1.4.1 Free motion method

During free motion tests the deck sectional model is let free to vibrate under the mean wind speed action, by means of an elastic supporting system. The response of the system to imposed initial condition is measured and flutter derivatives coefficients are defined by computing the

variation of the structural re response at a given wind velocity compared to the values obtained in still air.

3.1.4.2 Forced motion method

This method is more expensive than the previous, but is much more reliable.

A deck sectional model is forced to vibrate, as in Figure 14, in the three y, z and θ directions and the lift, drag and moment forces are measured for a given constant velocity V_m.

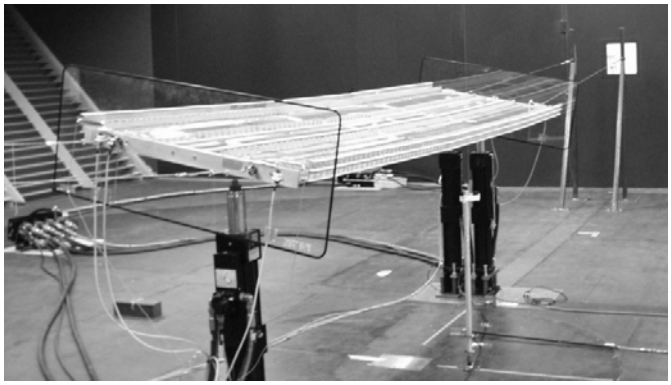

Figure 14. Sectional model on oil dynamic actuators driving its rigid vertical and torsional motion

As already said, the forces are non linear functions of the motion.

More in detail, for the deck (see Figure 4):

$$Lift = F_L = \frac{1}{2}\rho V^2 S C_L(X, \dot{X})$$

$$Drag = F_D = \frac{1}{2}\rho V^2 S C_D(X, \dot{X})$$

$$Moment = F_M = \frac{1}{2}\rho V^2 S B C_M(X, \dot{X}) \qquad (7)$$

being:

$$X = \begin{Bmatrix} y \\ z \\ \vartheta \end{Bmatrix}$$

The identification of the C_L, C_D, C_M coefficients, non linear functions of $X, \dot{X}$, as already said, is not an easy task and represents a research topic.

Methods have been developed by some researchers and are reported in [7] and [8]: for those based on rheological models and in [9] for those based on neural network algorithms.

What is generally done is to linearize the forces around a static equilibrium position of the deck identified by X_0 (equation 2).

$$F = \begin{Bmatrix} F_D \\ F_L \\ F_M \end{Bmatrix} = \frac{1}{2}\rho V^2 S\left(\left[K_a\right]X + \left[R_a\right]\dot{X}\right) \tag{8}$$

The 3x3 K_a and R_a matrices contains the flutter derivatives coefficients:

$$\left[R_a\right] = \frac{1}{2}\rho V^2 S\begin{bmatrix} -p_5^*\frac{1}{V} & -p_1^*\frac{1}{V} & -p_2^*\frac{B}{V} \\ -h_5^*\frac{1}{V} & -h_1^*\frac{1}{V} & -h_2^*\frac{B}{V} \\ -a_5^*\frac{B}{V} & -a_1^*\frac{B}{V} & -a_2^*\frac{B^2}{V} \end{bmatrix} \left[K_a\right] = \frac{1}{2}\rho V^2 S\begin{bmatrix} p_6^*\frac{\pi}{2V_\omega^{*2}}\frac{1}{B} & p_4^*\frac{\pi}{2V_\omega^{*2}}\frac{1}{B} & p_3^* \\ h_6^*\frac{\pi}{2V_\omega^{*2}}\frac{1}{B} & h_4^*\frac{\pi}{2V_\omega^{*2}}\frac{1}{B} & -h_3^* \\ a_6^*\frac{\pi}{2V_\omega^{*2}} & a_4^*\frac{\pi}{2V_\omega^{*2}} & -a_3^* B \end{bmatrix} \tag{9}$$

As a matter of fact, the identification of the flutter derivatives is not an easy task. The best results are obtained, imposing a harmonic motion and measuring the aerodynamic forces on the central part of the sectional model. From these tests the derivatives value as a function of the frequency of the motion, as well as of the static equilibrium position angle θ_0 around which the tests are done, can be derived.

The frequency is generally reproduced by the reduced velocity

$$V_r = \frac{V}{fB} \tag{10}$$

where B is the deck width, f is the frequency of the imposed motion and V is the velocity at which the test is performed.

As an example, the h_3^* value of the expression (9) for the Messina deck are reported in Figure 15.

The reduced velocity is reported in the abscissa and the different curves presented for each one of the coefficients of equation 6 are related to different angles of attack θ_0 around which the harmonic motion is applied.

3.1.4.3 Identification of the Admittance matrix

A method used in our wind tunnel and also by Chinese researcher [12] to identify the aerodynamic forces as a function of the incoming turbulence is to generate a well defined wind turbulence by an active device of the type shown in the Figure 16.

The airfoil can rotate around a fixed axis with a given motion, which is generally harmonic, with different frequencies. This generates a given fluctuation of the incoming wind, that can be measured through suitable anemometers, like the hot-wire or multi hole pressure probes anemometers. The aerodynamic forces are measured on a sectional deck model for a given average angle of attack θ_0 and the coefficients of the admittance matrix are identified, in a similar way as the flutter derivatives.

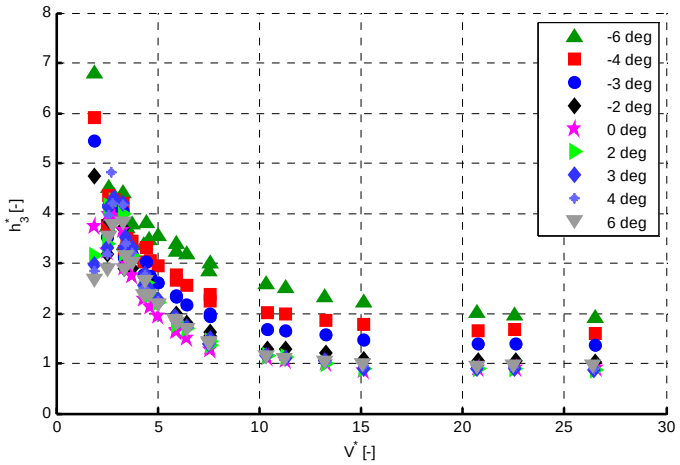

Figure 15. Flutter Derivatives (Messina bridge).

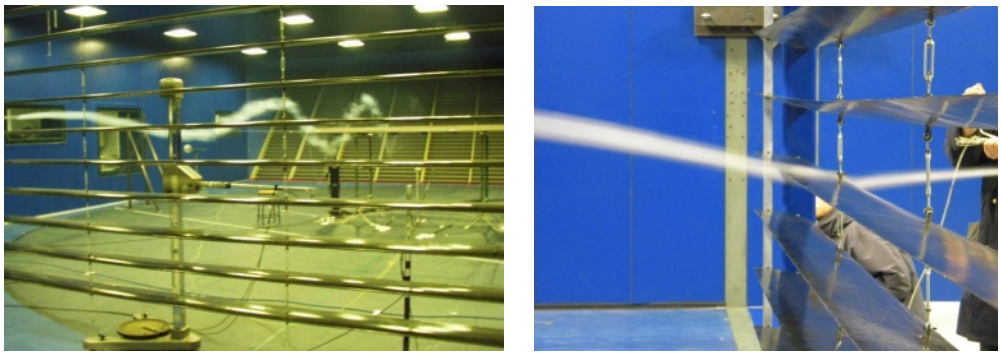

Figure 16. Active turbulence generator.

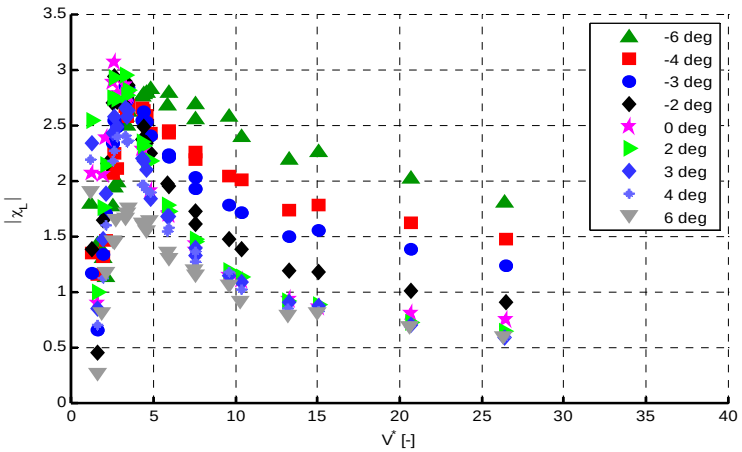

Figure 17. Admittance function (Messina bridge).

The admittances are functions of θ_0 and of the reduced velocity at which the test is performed. As an example, one of the admittance function coefficients is reported in Figure 17.

They are related to the following expressions of the aerodynamic forces:

$$F = \frac{1}{2}\rho V^2 S[\chi_a]w$$

$$\begin{aligned} F_y &= \frac{1}{2}\rho V^2 S\left[\mathrm{Re}\left(\chi_{y,w}\frac{w}{V}\right) + \mathrm{Im}\left(\chi_{y,w}\frac{w}{V}\right)\right] \\ F_z &= \frac{1}{2}\rho V^2 S\left[\mathrm{Re}\left(\chi_{z,w}\frac{w}{V}\right) + \mathrm{Im}\left(\chi_{z,w}\frac{w}{V}\right)\right] \\ F_\vartheta &= \frac{1}{2}\rho V^2 SL\left[\mathrm{Re}\left(\chi_{\vartheta,w}\frac{w}{V}\right) + \mathrm{Im}\left(\chi_{\vartheta,w}\frac{w}{V}\right)\right] \end{aligned} \qquad (11)$$

3.2 *Tower*

The main problem that has to be addressed during the aerodynamic design of bridge towers is VIV both if we consider cable stayed bridges that usually have single leg or reversed Y-shape towers or suspension bridges that have H-shape towers with two legs connected by one or more transverse beams. In both cases specific wind tunnel tests are performed using sectional or aeroelastic models. The usual wind activities on towers are

1) The measurement of the static aerodynamic coefficients on tower sectional model;
2) The measurement of VIV response using elastically suspended tower sectional models
3) The measurement of VIV response using aeroelastic models.

Figure 18. Cable stayed bridge tower sectional model in the wind tunnel test section: measure of static aero-dynamic coefficients.

Figure 19. Free standing tower.

Static coefficients are measured in a similar way of what is done on the deck, adopting sectional models with internal or external dynamometers and measuring the aerodynamic forces at different angles of attack. Figure 18 shows a tower sectional model during the wind tunnel tests.

For towers with two legs and transversal beams, the aerodynamic coefficients are measured separately on each leg by using a model that represents a tandem arrangement of the two legs where transversal beams are not present.

VIV of bridge towers are investigated in the wind tunnel by measuring the dynamic response of sectional models that are elastically suspended in the flow in a similar manner of what already described for the deck or of aeroelastic models.

While the vortex shedding phenomenon is basically two-dimensional on the deck, on the contrary, for the tower, it is affected by the three dimensional end effects at top and by the presence of the transversal beams along the height. Wind tunnel tests performed on aeroelastic models are therefore aimed to represent the full 3D tower geometry and the related aerodynamic effects.

Aeroelastic models are moreover used to investigate the different construction stages (Figure 19) of the tower, since its dynamic characteristics may largely vary from the free standing condition to the bridge completion condition. If wind tunnel test results highlighted that VIV may reach dangerous values, suitable countermeasures have to be implemented and design on the basis of the experimental results that have also to consider the dynamic effects of all the scaffolding and cranes that are connected to the structure and participate to the dynamic response of the system.

It is not easy to optimize the shape of the tower in order to avoid vortex shedding excitation. The final output of the analysis is similar to the deck one and the VIVs are reported as a function of Scrouton number. Tuned mass dampers (TMD) are generally used to control VIV of the towers.

3.3 *Reynolds effect*

The scaled reproduction of the wind-structure interaction must necessarily consider Reynolds number effects. To keep the correct ratio between the inertial and the viscous forces, the Reynolds number parameter:

$$\mathrm{Re} = \frac{VB}{\nu} \tag{12}$$

where B is a reference length for the deck width and ν is the air kinetic viscosity, should be same of the full scale condition. Due the practical limitations in the possibility to manage the single parameters, this request is commonly not satisfied and in the usual wind tunnel practice a sensitivity analysis on the Reynolds number dependency is performed. Reynolds number dependency is tested by comparing results obtained at different wind speed and/or on models with different scaling factor.

As an example, in Figure 20, the static aerodynamic coefficients of the Messina bridge deck are reported for different Reynolds numbers. The deck model is in 1:45 scale, being the model width B equal to 1.33m. Both the drag coefficient and the aerodynamic moment coefficient show, even in a very small amount, a univocal trend of modification increasing the Reynolds number parameter. For the maximum wind speed of 45m/s, the Re number value is $4\ 10^6$.

In some cases, dealing with curvilinear shapes, it is possible to modify the surface finishing by using an increased roughness in order to simulate at lower Re similar fluid dynamic effects of higher Reynolds number conditions (Figure 21).

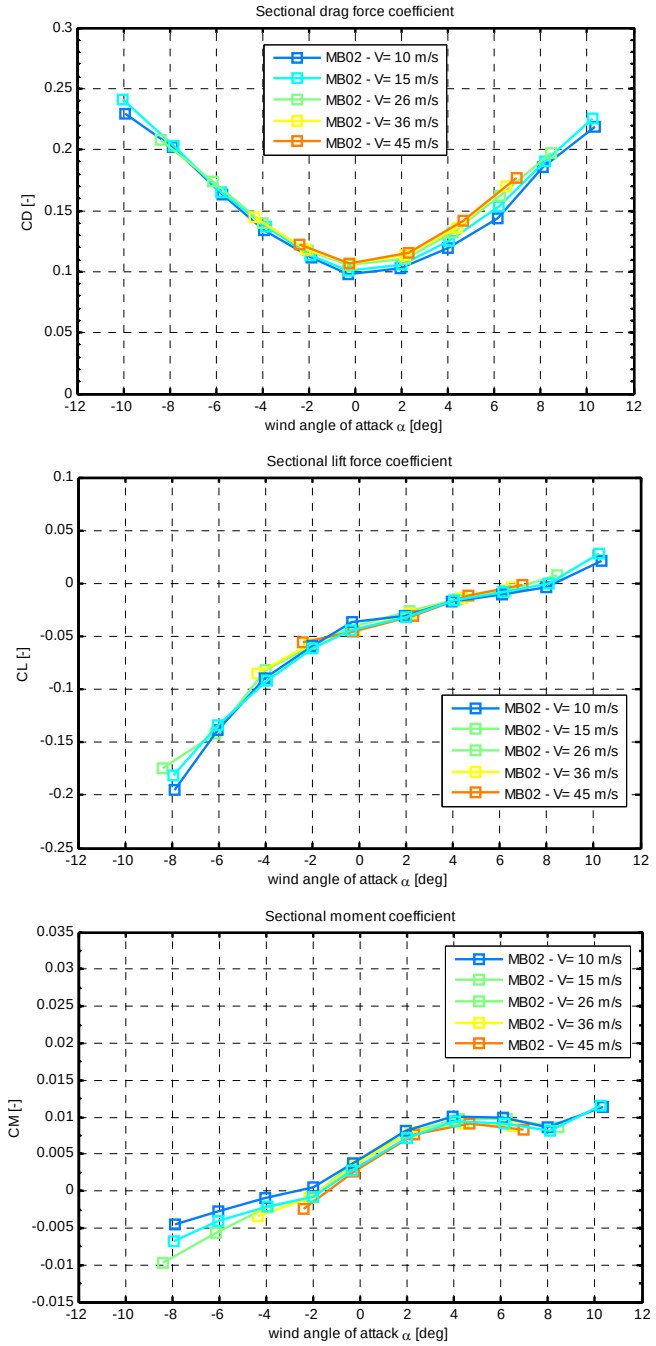

Figure 20. Reynolds number dependency of the deck aerodynamic coefficients varying the wind speed.

This wind tunnel practice allows to develop on a smaller model similar boundary layer conditions to what is produced at higher Reynolds number. Comparing the results of Figure 20 with those reported in

Figure 22, obtained at the same wind speed on the same deck sectional model with increased surface roughness, it is possible to observe how the slope of the lift and of the aerodynamic mo-

ment coefficient tends to increase at higher Reynolds number. The values obtained with smooth surface are very close to those obtained at low speed (10 m/s) with rough surface. In any case, with rough surface, for velocity above 36 m/s, Re=3.2 10^6 and more, these values should represent the value to be considered representative of the real situation. This is mainly due to the different fluid dynamic behavior that is present on the curvilinear part of the upwind box as reported in Figure 23, where the pressure distribution for the nominally smooth and for the rough model are overlapped.

Another parameter that has to be controlled during the wind tunnel tests on scaled models, trying to respect the Reynolds number similitude is the turbulence characteristics of the flow. Different incoming turbulence conditions may lead on the same model to different results in terms of aerodynamic coefficients obtained at the same wind speed. Nominal wind tunnel smooth flow conditions are actually low turbulence conditions that depends on the quality of the flow of the wind tunnel facility (0.2<Iu<2%).

Although the value of turbulence intensity is very small, in some cases, it may play an important role and it could explain the discrepancies that sometimes arise between results obtained in similar conditions in different wind tunnel plants.

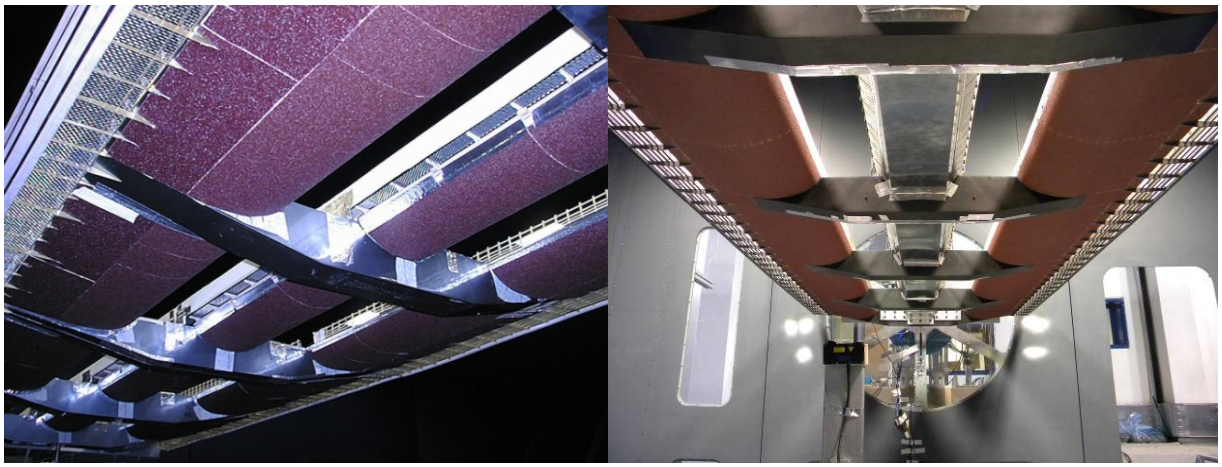

Figure 21. Deck sectional model with increased surface roughness.

4 NUMERICAL RESULTS

Once all the above described aerodynamic tests have been completed, it is possible to compute the bridge response to the turbulent wind.

First of all the static equilibrium position of the bridge under the turbulent wind must be computed as already explained.

For each section of a bridge a time history of the turbulent wind must be generated. The spectrum of the single time history can be identified and the equation (3) can be solved, for instance, in the frequency domain, taking into account that the flutter derivatives and the admittance function are frequency dependent.

Other methods are available to solve this problem in the time domain [15], generally with modal approach [1], and some of these methods, as already mentioned, take into account also the non linear effects of the aerodynamic forces [11], [16].

Some example of output result are reported in the following.

Figure 24 reports the static deflection of the Messina bridge deck under the action of mean wind forces for different mean wind speeds.

Figure 25 reports RMS values of the vertical acceleration of the different deck section along the bridge axis of the Messina bridge deck under the action of turbulent wind.

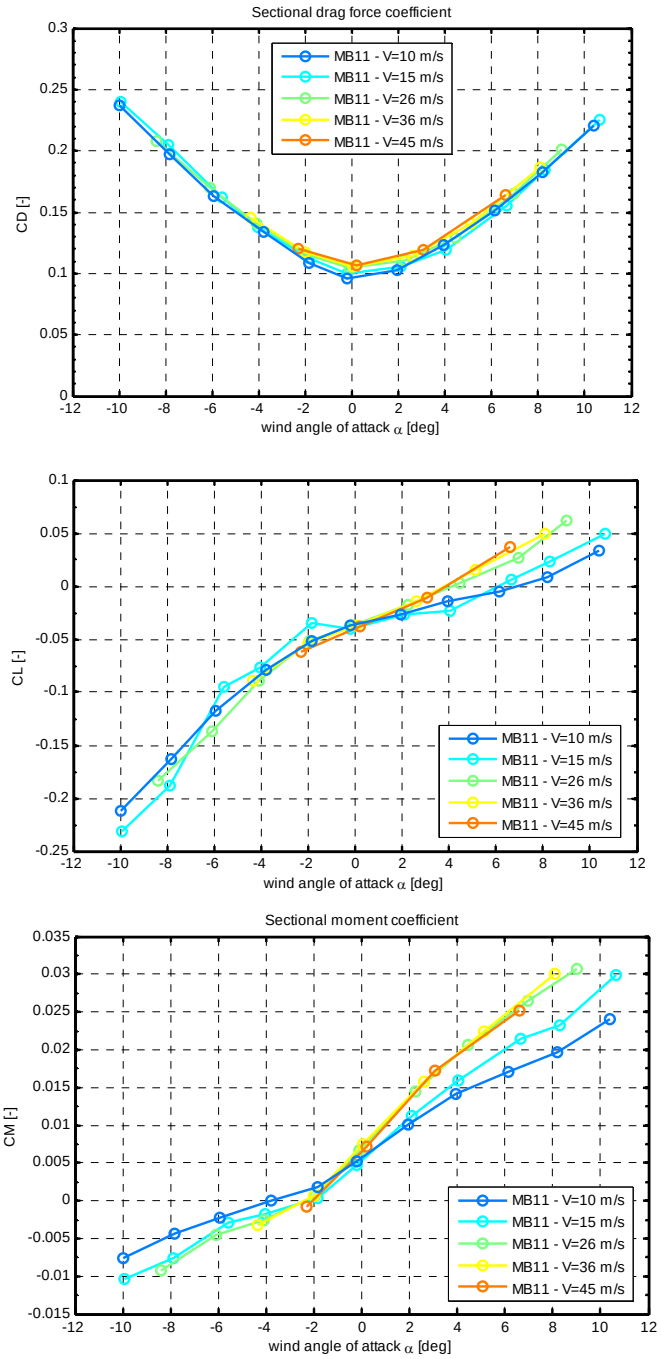

Figure 22. Reynolds number dependency of the deck aerodynamic coefficients varying the wind speed (model with increased surface roughness).

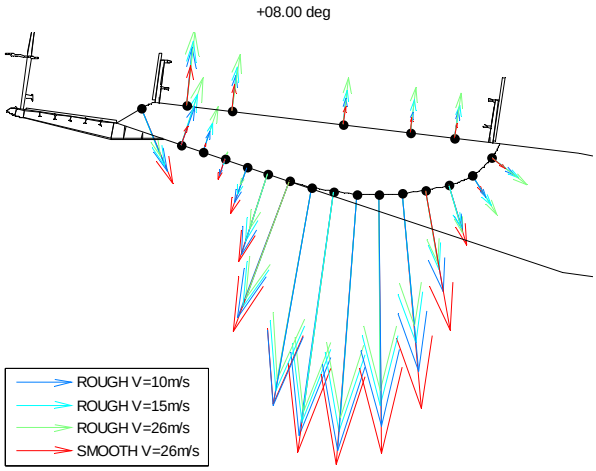

Figure 23. Different boundary layer development (Surface pressure distribution, smooth vs rough model surface, different incoming wing speeds, angle of attack +8deg).

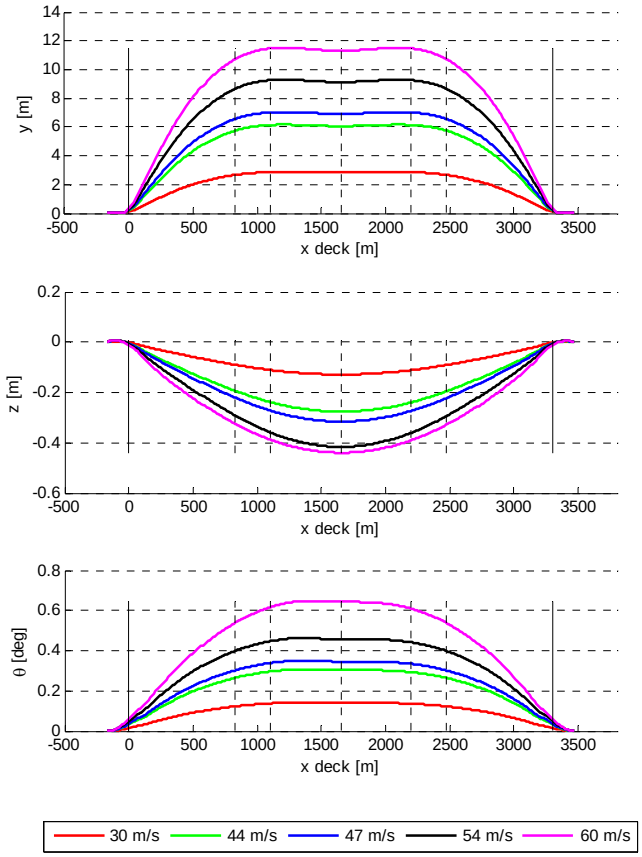

Figure 24. Static deformation under different mean wind speeds.

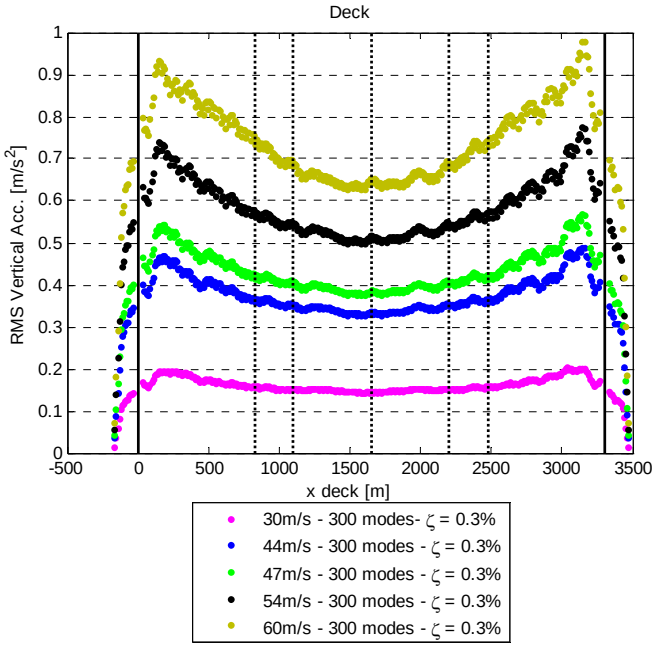

Figure 25. RMS values of the vertical acceleration of the different deck section along the bridge axis.

For the locations reported in Figure 26, The stress in the road boxes for a wind speed 30 m/s and Iu=13.8% are reported in Figure 27 in terms of standard deviation of the normal stresses on the downwind road box (y>0) of the only fluctuating part at point A:

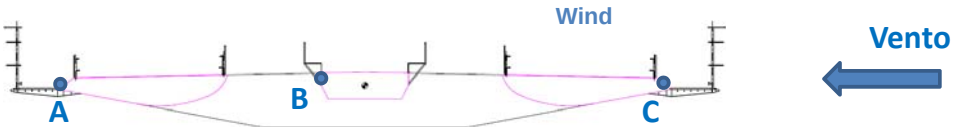

Figure 26. Considered point on the road and railway boxes of the Messina bridge deck section.

5 CONCLUSIONS

The common approach to design very long span bridges is to adopt a combined methodology relying on both wind tunnel tests on scaled models and numerical models of the wind-bridge interaction.

Wind tunnel tests on sectional models allows to measure:

- the aerodynamic static coefficients that are used for the definition of the static wind loads and for the check if one degree of freedom instability conditions may occur
- the aerodynamic coefficients (flutter derivatives) that are used for the definition of the buffeting response and for defining the flutter critical wind speed
- the response of deck and tower to vortex induced vibrations as a function of the Sc number.

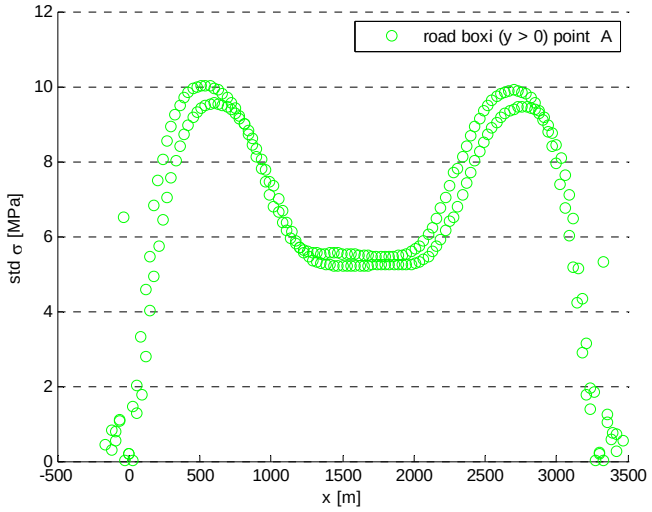

Figure 27. Standard deviation of the stresses at the point A of the different deck sections along the bridge axis.

The same quantity is reported in Figure 28 for the point B located on the railway box in Figure 26:

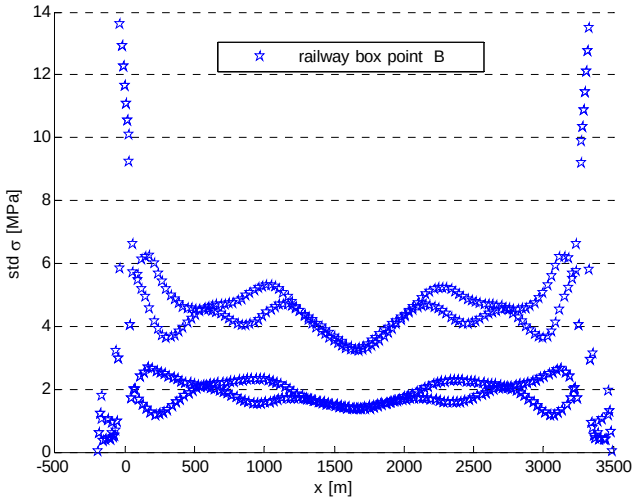

Figure 28. Standard deviation of the stresses at the point B of the different deck sections along the bridge axis.

Wind tunnel results with numerical models are able to drive in the early stage the optimization of the aerodynamic design of the deck and tower geometry the designer choice for the most important aeroelastic problems that are the aerodynamic stability of the bridge and the VIV of the deck, tower and cables.
The most promising solution is therefore analysed most in detail through aeroelastic full bridge models in wind tunnel.
The results of the full aeroelastic model are compared with the numerical simulations in order to control all the design procedure.

6 ACKNOWLEDGEMENTS

I want to express my first acknowledgements to the staff of the wind engineering group of the Mechanical Department of the Politecnico di Milano: Ferruccio Resta, Alberto Zasso, Fabio Fossati, Marco Belloli, Daniele Rocchi, Sara Muggiasca, Tommaso Argentini and to the Wind Tunnel team: Luca Ronchi, Stefano Giappino, Lorenzo Rosa.
Special acknowledgments are also due to Società Stretto di Messina, who promoted relevant investigations on bridge aero elasticity.

Aerodynamic optimization in super-tall building designs

Jiming Xie

RWDI International China Inc. 24D-838 Zhangyang Road, Pudong, Shanghai, China

ABSTRACT: To ensure the structure safety in strong winds and control the wind-induced motion of super-tall buildings, aerodynamic optimization is considered to be the most efficient way, because the aerodynamic optimization is aimed at the source of problems. However, aerodynamic optimization can be at the cost of other design aspects, such as increased construction cost, reduced usable space and/or increased construction difficulties. Therefore, the aerodynamic optimization can only be reached by interdisciplinary collaboration between wind engineers and architects. This paper summarizes the aerodynamic approaches that have been used in building design, and discusses the principles and effectiveness of these approaches. To provide a guideline for building aerodynamic optimizations, this paper proposes an approach of assessing the effects of tapering, twisting and set-back, three common schemes in super-tall building design for wind response reductions with limited wind tunnel tests.

KEYWORDS: building aerodynamics, across-wind response, vortex shedding, wind tunnel tests, wind spectrum, super-tall buildings.

1 INTRODUCTION

Wind effects are the challenges that designers have to deal with in super-tall building design. In association with high slenderness, low natural frequencies, low inherent damping level and high wind speed at upper lever, super-tall buildings are more susceptible to winds, particularly to vortex shedding excitations. Not only wind loads, the wind-induced building motions are also within the scope of design to ensure the building's safety as well as performance, such as comfort level for building occupancy. It is well known that the behavior of wind response is largely determined by building shapes. Considerations on aerodynamic optimization in early architectural design stage is proved to be the most efficient way in wind-resistant design.

Wind-resistant design and aerodynamic optimization are the modern topics in building design community. However, its practice and success projects can be traced back a long time ago.

Figure 1. Three pagodas, Dali, Yunnan Province, China

In ancient China, tall buildings appear to be traditional pagodas. Some of them even meet the modern definition of super-tall shape.

Figure 1 shows one of the tallest ancient pagodas in China. These three pagodas located in Chong-Sheng Temple (崇圣寺), Dali, Yunnan Province, China, were built 1180 years ago (824-859AD). The tallest one is 69.13m in height with the base width of 9.9m (square), the slenderness (height/width ratio) being 7. The two identical shorter pagodas also have a height of 42.19m. Over the long period of extreme climates and natural disasters, the original temple buildings which were built after the pagodas were destroyed but the original pagodas have survived with wonder. In addition of extremely strong earthquakes (in 1514 and 1925), the pagodas also experienced strong winds in history. Dali

is located in the western part of the Yunnan-Guizhou Plateau where the East-Asian monsoon and southwest monsoon alternately affect the region. Due to its special topography, Dali is well-known as "windy city" with occurrence of strong winds being more than 35 days per year. Statistics show that the return period winds are even higher than those in Shanghai, a typhoon prone coastal city of China. Figure 2 shows the comparison of return period basic wind speeds between Dali and Shanghai. These survived ancient structures at least revive two important concepts for modern design practice.

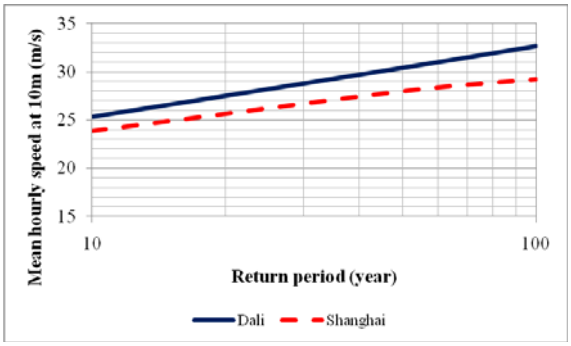

Figure 2. Comparison of wind speed between Dali Shanghai

(1) Being masonry structures, the ancient pagodas cannot compete in strength to modern structures that are built with steel and pre-stressed concrete. However, the shortcoming in strength seems to be largely compensated by increased inherent damping, which is more effective for dynamic loading.

(2) All these pagodas have their width tapered along the height and also have sizeable overhanging eaves. These features significantly reduce the potential across-wind oscillations that are commonly seen in super-tall buildings. Without these important features, these pagodas might have been damaged several times by severe vortex-induced oscillations at critical vortex shedding speed.

One of the major achievements in modern building design practice is to understand the underlying principles that may have been contained in historical wonders by coincidence and explore more creative ways to apply these principles in design.

Many investigations have been conducted on building aerodynamic optimizations. A pioneer work on building aerodynamics was done by Davenport (1971) who investigated the shape effects by using aerodynamic model tests. With super-tall's booming in 1990's, many more investigations have been done, which include building corner modifications and their impact on aerodynamic forces (Kwok 1988, Dutton and Isyumov 1990, Tamura 1998 and Miyagi 1999), effects of openings and slots (Isyumov 1992, Miyashita et al. 1993), and effects of twisting (Xie et al. 2009). The potential impacts of these aerodynamic modifications on economical aspects (cost and usable space) are also investigated (Tse et al. 2009).

Although aerodynamic shape plays important role for super-tall building design, aerodynamic optimization cannot be reached without considering other design aspects. The major challenge in building aerodynamic optimization is not only to find out the best shape for wind response, but also to find out the best balance between all the design aspects, including architectural concept, economical outcomes, etc. Aerodynamic optimization may therefore be classified into two categories:

Aerodynamic modification: an approach that is applicable to buildings which require mitigations for wind response but cannot have significant geometry changes on overall building concepts. Corner treatments, such as chamfering, slotting and roundness are common approaches in this category. The challenge with this category is that given the available/feasible aerodynamic modifications, the level of improvement may not be enough to meet the design objective. Structural measures or supplemental damping devices are still need in many cases.

Aerodynamic design: an approach that is integrated with architectural design in early stage. All the aerodynamic measures are available in this stage and the outcomes can be most efficient. However, the challenge with is category is to have reasonable estimates on the effects of various aerodynamic schemes on wind response reductions, so that an optimized balance between many

design aspects can be achieved. A series of wind tunnel tests are generally required to serve this purpose.

This paper is to summarize various schemes of aerodynamic approaches in super-tall building design and to discuss the principles of these schemes. To serve the needs of aerodynamic design, a method is proposed in this paper. This method is used to assess the effectiveness of aerodynamic optimization schemes, such as tapering, twisting and set-back, the three common schemes in super-tall building design, with limited amount of wind tunnel tests. The proposed method is approximate and comparative. Detailed wind tunnel tests are still needed for super-tall building designs. However, with ability of parametric analysis for aerodynamic effectiveness, the proposed method can provide a reasonable aerodynamic guideline for architectural design.

2 GENERAL APPROCHES OF AERODYNAMIC OPTIMIZATION

2.1 *Along-wind and across-wind responses*

For wind-resistant design of buildings, it's important to identify the type of wind response that governs the design. For most super-tall buildings, it is often found that the across-wind dynamic response dominates the design wind loads and/or cause excessive motions. Figure 3 presents a typical wind loading azimuth plot where the magnitude of the inertial loads caused by building motions in across-wind direction is much higher than the mean wind loads plus dynamic loads along the wind direction.

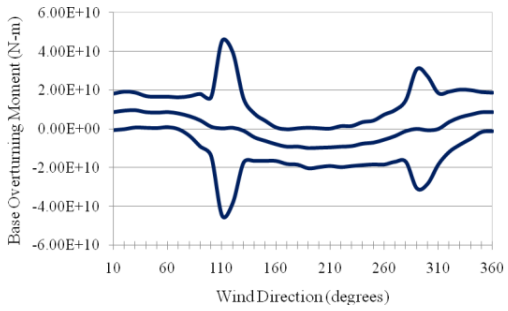

Figure 3. Illustration of across-wind loading at 110°

The main reason that across-wind can dominate the design for super-tall buildings is explained by Figure 4. Figure 4 shows a typical across-wind spectrum in comparison with an along-wind spectrum. While the along-wind spectrum reflects the approaching wind turbulence properties, the across-wind spectrum is determined by flow separation off the building, so called "signature turbulence". The peak of the across-wind spectrum corresponds to the effective Strouhal number of the building. Compared with along-wind response, across-wind response is more sensitive to wind speed. In lower wind speed, the along-wind loads normally dominant but with increase of wind speed the across-wind loads take over. Due to relatively lower building natural frequency of super-tall buildings (or higher building natural period) plus high wind speed at upper level of the boundary layer, the reduced frequency of a super-tall building at design wind speed can be very close to the peak of the across-wind spectrum. For example of a typical super-tall building, the building width is about 60m and the first sway period is around 8 seconds or higher, the vortex-induced resonance can happen at about 60m/s winds at upper level for a rectangular building or 33m/s at standard 10m height.

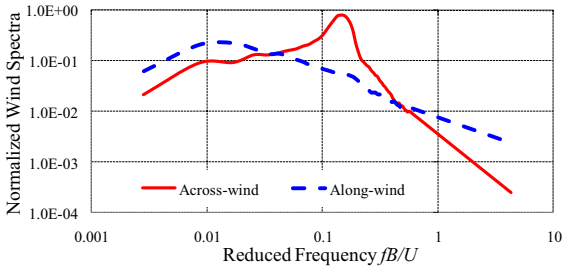

Figure 4. Comparison of along-wind and across-wind spectra

The aerodynamic optimization approaches tend to be different when dealing with along-wind or across-wind response. Although some approaches that can benefit both, many approaches focus on one type or other.

For optimization of along-wind response, a basic approach is to reduce the drag coefficient by modifying building corners, such as round or chamfer. Opening is also an option. Adjustment of building orientation to an optimized position where the direction of highest drag coefficient is far away from the local prevailing wind directions is also an effective approach.

For across-wind response, the aerodynamic optimization can be classified into two basic approaches: (1) to reduce the magnitude of wake excitation by modifying the building's cross-section such as corner recession or opening; and (2) to reduce the synchronization and correlation of fluctuating excitation by varying building's shape along the height such as tapering or twisting.

Since across-wind dynamic response is normally the main source that causes excessive wind loading and discomfort for occupants. The following discussion will focus on the aerodynamic optimizations for across-wind dynamic response.

2.2 *Modification of cross-sections*

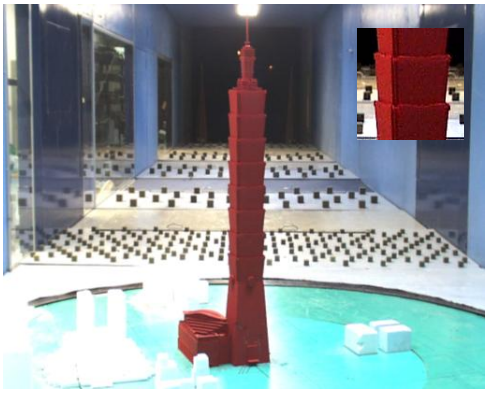

Figure 5. Corner recession

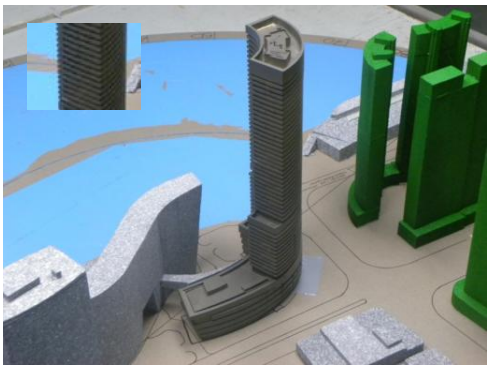

Figure 7. Corner balconies

A few examples of aerodynamic modifications for building cross-sections are shown in Figures 5 through 7. These modifications are proved to be effective for reducing across-wind response. The corner of Taipei 101 Tower, shown in Figure 5, was designed during wind tunnel testing, which effectively reduces the overall design wind loads by about 25% compared with the original design of square section.

During the wind tunnel tests of Taipei 101, other type of corner modifications are also investigated, shown in Figure 6. With the dimension of modifications being about 0.1B (10% of building width), the effects of these modifications are similar. The final selection of the corner modification was basically the choice of architects.

Figure 6. Corner modifications considered in Taipei 101 design

Helical strike is a traditional device to suppress vortex excitation to chimney stacks. However, few of these devices are used for buildings due to aesthetical concern. However, it has been found that commonly designed corner balconies can perform similar roles in suppressing vortex shedding (Brown et al. 2005). The concept was used again in a recent tall building in a very strong typhoon area, shown in Figure 7, and proved to be able to reduce design

wind loads by about 20%. The overhang eaves shown in ancient pagodas, Figure 1, are also the examples

Opening is not commonly used in design practice due to potential impact on useable spaces. However in some cases the corner slot can not only significantly reduce the across-wind excitation, but also make internal space design more logical, shown in Figure 8.

Figure 6. Corner slot

2.3 *Modification of building elevations*

The basic concept of this approach is to increase the variation of building shape alone the height, either in section geometry, or in section dimension, or in section orientation. There are four basic forms of elevation modification:

1) tapering, as shown in Figure 9
2) twisting, as shown in Figure 10
3) Setting back, as shown in Figure 11
4) Sculpture top, as shown in Figure 12

A combination of all these basic forms is shown in Figure 13.

These forms share a common mechanism in reducing wind response. Due to various building geometry along the height, the properties of vortex shedding are also varies with height, leading to much less correlated excitations for across-wind response. The study conducted for twisting effects, shown in Figure 10, indicates that effectiveness increases with the increase of twisting angles within the range of 100^{o} to 180^{o}. However, to balance between the aerodynamic benefits and potential complication on cladding system, the 120^{o} twist from base to top is selected as final version that represents about 15% reduction on wind loading.

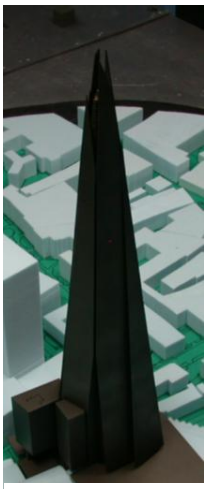

Figure 9. Tapering

Figure 10. Twisting

Figure 11. Set-back

Figure 12. Toping

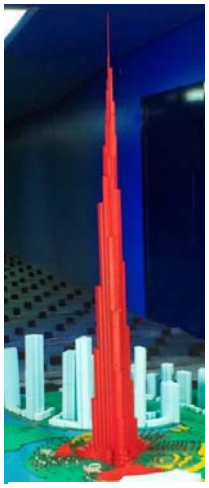

Figure 13. Combination

The effects of tapering in reducing across-wind response can be explained in a similar manner as for the twisting. Since the vortex shedding frequency is inversely proportional to a building width, the tapered width causes the outstanding frequency of wake excitation varies along the building height so that the outstanding frequencies of excitation are spread out to a wide range.

As mentioned before, modifications on building elevations are much more dramatic in visual impacts and can lead to a totally different design. Therefore modifications on building elevation are more suitable during the early stage of architectural design.

While aerodynamic modifications bring in benefits for reduced design wind loads and vibrations, these modifications often create conflicts with other design aspects. A good design is to reach optimized balance among many design aspects. For this reason, it is important to have an approach to estimate the level of effects with different modification schemes, so that the pros and cons of these aerodynamic modifications can be assessed and an overall optimized balance can be reached. A series of wind tunnel tests to examine various modification schemes is technically feasible but financially expensive and time consuming.

The next section is to discuss a method that is based on minor wind tunnel tests and major numerical analysis. This method is especially useful at early stage of architectural design to assess the aerodynamic improvements by tapering, twisting or set-back.

3 DILEMMA AND CHALLENGES IN OPTIMIZATION PRACTICE

3.1 *Expression of sectional wind loads at level z*

Basic parameters that describe sectional wind loads acting at level *z* of a building include:
Reference wind pressure:

$$q_z = \frac{1}{2}\rho U_z^2 = q_0 V_q(z) \tag{1}$$

Reference dimension (building width):

$$B_z = B_0 V_B(z) \tag{2}$$

Building twisting:

$$\theta(z) = \theta_0 V_\theta(z) \tag{3}$$

A common case is considered in the paper that the basic shape of building cross section remains the same along the height, but its dimensions and orientations vary. The varied dimension represents tapered width and varied orientation characterizes twisting. Some special set-back scheme can also be addressed with this typical case. The basic aerodynamic properties at Level *z* are given as follows.
Static drag coefficient:

$$C_D(z) = C_{D0} V_{Cd}(z) = C_{D0} V_{Cd}(\theta(z))$$

Static Lift coefficient:

$$C_L(z) = C_{L0} V_{Cl}(z) = C_{L0} V_{Cl}(\theta(z))$$

Dynamic Lift coefficient:

$$\tilde{C}_L(z) = \tilde{C}_{L0} V_{\tilde{C}l}(z) = \tilde{C}_{L0} V_{\tilde{C}l}(\theta(z))$$

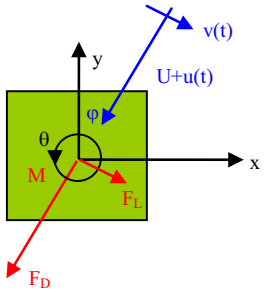

Figure 14. Wind loads on Level *z*

The sectional drag and lift force can be expressed by

$$F_D(z,t) = \frac{1}{2}\rho(U_z + u_z(t))^2 B_z\left(C_D(z) + \frac{dC_D(z)}{d\alpha}\alpha\right) \tag{4}$$

$$F_L(z,t) = \frac{1}{2}\rho(U_z + u_z(t))^2 B_z\left(C_L(z) + \frac{dC_L(z)}{d\alpha}\alpha + \tilde{C}_L(z,t)\right) \tag{5}$$

where

$$\alpha = -\frac{v_z(t)}{U_z} \qquad \frac{dC_D(z)}{d\alpha} = C'_{D0}(z) \qquad \widetilde{C}_L(z,t) = \widetilde{C}_L(z)T(t)$$

The mean loads are given by

$$\overline{F}_D(z) = q_z B_z C_D(z) = \left(q_0 B_0 V_q(z) V_B(z)\right) C_D(\theta_z) \tag{6}$$

$$\overline{F}_L(z) = q_z B_z C_L(z) = \left(q_0 B_0 V_q(z) V_B(z)\right) C_L(\theta_z) \tag{7}$$

The dynamic portion can be expressed in the form of power spectra, i.e.,

$$S_D(f,z) = \left(q_0 B_0 V_q(z) V_B(z)\right)^2 \sigma_D^2(\theta_z) S_D^*(f_z^*, \theta_z) \tag{8}$$

$$S_L(f,z) = \left(q_0 B_0 V_q(z) V_B(z)\right)^2 \sigma_L^2(\theta_z) S_L^*(f_z^*, \theta_z) \tag{9}$$

where $f_z^* = \dfrac{fB_z}{U_z}$

With simultaneous pressure measurements, the above non-dimensional aerodynamic properties can be easily determined, including C_D, C_L, $\sigma_D^2 S_D^*$, and $\sigma_L^2 S_L^*$.

3.2 *Overall wind loads on building structures*

The overall mean loads can be determined by simply integration as follows.

Mean along-wind loads: $$\overline{F}_D = q_0 B_0 \int_h V_q(z) V_B(z) C_D(\theta_z) \cdot dz \tag{10}$$

Mean across-wind loads: $$\overline{F}_L = q_0 B_0 \int_h V_q(z) V_B(z) C_L(\theta_z) \cdot dz \tag{11}$$

The overall dynamic along-wind and across-wind loads are given by

$$S_D(f) = \left(q_0 B_0\right)^2 \iint_H V_q(z_1) V_q(z_2) V_B(z_1) V_B(z_2) \sigma_D(\theta_{z1}) \sigma_D(\theta_{z2}) \sqrt{S_D^*(f_{z1}^*, \theta_{z1}) S_D^*(f_{z2}^*, \theta_{z2})} C_{HD}(f, \Delta z_{12}) \cdot dz_1 dz_2 \tag{12}$$

$$S_L(f) = \left(q_0 B_0\right)^2 \iint_H V_q(z_1) V_q(z_2) V_B(z_1) V_B(z_2) \sigma_L(\theta_{z1}) \sigma_L(\theta_{z2}) \sqrt{S_L^*(f_{z1}^*, \theta_{z1}) S_L^*(f_{z2}^*, \theta_{z2})} C_{HL}(f, \Delta z_{12}) \cdot dz_1 dz_2 \tag{13}$$

Although the expressions for the along-wind and across-wind are similar, they can be very different in properties. The spectrum *S** and cross-coherence C_H are governed by approaching wind turbulence for along-wind, but by signature turbulence for across-wind. Most interesting portion for aerodynamic optimization of super-tall buildings is to examine the generalized forces excited by across-wind excitations, which can be expressed by

$$S_j(f) = \left(q_0 B_0\right)^2 \iint_H V_q(z_1) V_q(z_2) V_B(z_1) V_B(z_2) \sigma_L(\theta_{z1}) \sigma_L(\theta_{z2}) \sqrt{S_L^*(f_{z1}^*, \theta_{z1}) S_L^*(f_{z2}^*, \theta_{z2})} C_{HL}(f, \Delta z_{12}) \Phi_{j,z1} \Phi_{j,z2} \cdot dz_1 dz_2 \tag{14}$$

where Φ_j is the *j*-th mode shape.

The effectiveness of shape variations on across-wind response can thus be assessed by comparing the difference of the spectra as follows:

$$R = \sqrt{\frac{S_j(f_j)}{S_{0j}(f_j)}} \tag{15}$$

where $S_{0j}(f_j)$ is the spectrum for a reference building geometry.

4 CONCLUSION REMARKS

Aerodynamic optimization is an important portion of super-tall building design. Two categories of optimization are discussed in the paper: aerodynamic modifications which are mostly considered as remedial measures with a limitation of not making significant changes on building's overall geometry or visual image; and aerodynamic designs which are feasible only with collaboration with architects in early design stage and can be very effective. While aerodynamic modifications mostly involved building corner treatments, aerodynamic designs have much more freedom in building geometry including overall building elevation optimizations, such as tapering, twisting, opening, set-back, top sculpture, etc. But aerodynamic designs are also limited by other design aspects, such as cladding, internal spacing, etc. The method proposed in this paper can be used to assess the effectiveness of various aerodynamic optimization schemes in order to achieve a balance between aerodynamic satisfaction and fulfillment of other design aspects.

Bluff body aerodynamics of simplified bridge decks for aeroelastic optimization

S. Hernández [a], F. Nieto [a], J. A. Jurado [a], I. Pérez [a]

[a] *School of civil Engineering, University of La Coruña, Campus de Elviña, A Coruña, Spain*

ABSTRACT: Long span bridges need to be designed to accomplish tensional, deformational and aeroelastic constraints. However the geometry of a bridge deck aimed to fulfill adequately conditions on stresses and displacements is very different than the shape that provides good aeroelastic behaviour. The necessity to satisfy all these considerations leads usually to a sequence of intermediate prototypes worked out by trial and error procedures. Then, the performance under wind flow of a given design is tested in wind tunnel laboratories. In this paper a technique that allows to obtain the optimum design of several deck shapes from the structural point of view is presented. Afterwards the flutter speed for each optimum design is obtained. It is demonstrated that a combined optimization procedure that takes in account jointly both structural and aeroelastic constraints will be able to identify the optimum bridge deck shape. An application example of a simplified deck of a cable stayed bridge is used to describe the capabilities of this methodology.

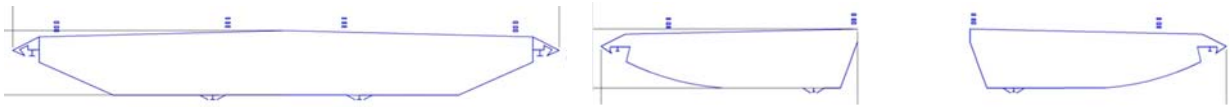
KEYWORDS: Bridge deck, long span bridges, computational fluid dynamics, flutter speed, design optimization.

1 INTRODUCTION

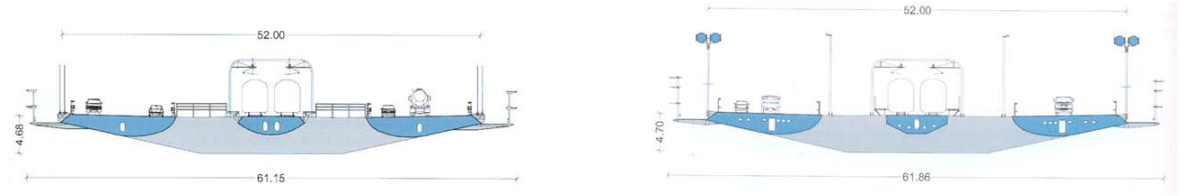
Cable stayed bridges are designed currently with ever longer spans. Therefore these structures are very flexible and the required limits to vertical displacements under static loads must be maintained. This leads to the evaluation of the necessary stiffness that is obtained by providing the proper value of inertia modulus of the cross section. The easiest way to do it is by defining very depth decks because this approach will reduce the amount of material. In that case the design is driven by stiffness.

On the other hand long span bridges are prone to aeroelastic phenomena so their design needs to be aeroelastically sound and instabilities as flutter must be avoided. Hence, decks should be as much aerodynamic efficient as possible and thus prototypes with small depth are preferred. In that regard the design is driven by the aeroelastic behavior. But decks having small depth need more material to maintain the required value of inertia so the solutions for a bridge deck from the stiffness perspective and the aeroelastic approach are contradictory and enhancing the aeroelastic response implies reducing bridge deck and thus increasing the cross section area and deck cost.

Commonly the final design for the configuration of the deck of a long span bridge is a process that requires many intermediate prototypes that represent alternatives evaluated to figure out their capabilities. Along the way they are refined or discarded, until a decision is made and the deck shape is finally fixed. In figure 1 two different alternatives of the deck of two very well known bridges that were considered along the design process are presented.



a) Alternatives for the Forth Replacement Crossing



b) Alternatives for the Messina Strait Bridge

Figure 1. Deck design of the Forth Replacement Crossing and Messina Strait bridge

2 DECK DESIGN OF CABLE SUPPORTED BRIDGES

Commonly, in the design process of a bridge deck, after fixing the necessary stiffness (the value of inertia modulus) and the aeroelastic constraint related to flutter (the value of flutter speed) the final solution is carried out by trial and error methods until a good enough prototype is obtained. Nevertheless it should be interesting to identify the shape of a bridge deck that possesses the minimum amount of material possible for accomplishing the previously mentioned requirements.

This can be done by an optimization procedure. This methodology uses numerical optimization algorithms to find out the best solution of a problem. Texts describing this technique have been written by Haftka [1], Vanderplaats [2] or Arora [3] and it has been used extensively in some technological fields as aerospace, mechanical or car engineering. A book by Hernandez and Fontan [4] relates several practical examples in these disciplines. Applications in bridges are scarce but works by Hernandez et alt. [5] or by Baldomir et alt. [6] can be mentioned. A pioneer initiative in aeroelastic design of bridges aimed to optimize the mechanical parameters of the deck in long span suspension bridges considering kinematic and flutter considerations was carried out by Nieto and others [7].

A flowchart of the iterative process carried out in design optimization is presented in figure 2.

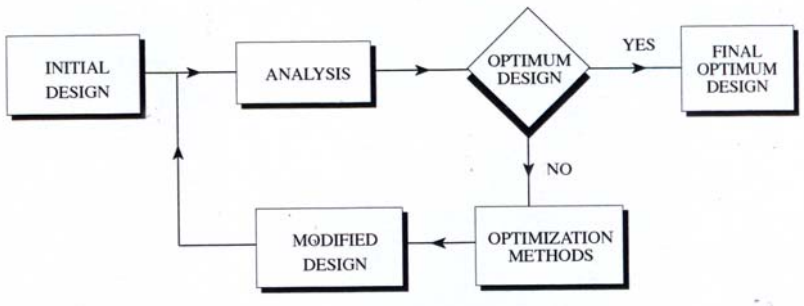


Figure 2. Flowchart of optimization methodology.

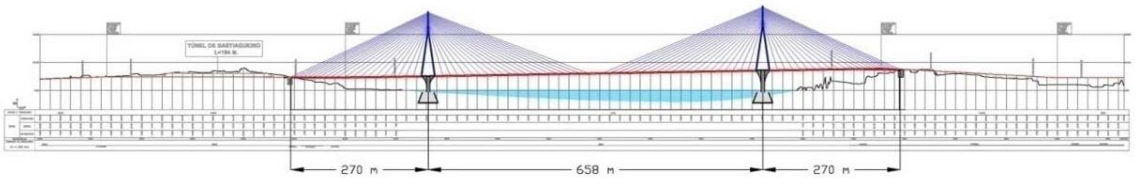
3 OPTIMUM DESIGN OF BRIDGE DECK

The goal of the research concluded by the authors is to obtain, for a given bridge geometry, the cable supported bridge that has the minimum weight and fulfills the required stress and kinematic constraints while also accomplishing the requested flutter response.

3.1 *Definition of the cable-stayed bridge and the simplified box girder*

The Miradoiros Cable-Stayed Bridge currently designed in Spain has been chosen as a study case. It is a 658 m main span bridge which is not symmetric as the deck has some slope in elevation (see figure 3).



a) Elevation

b) Computer picture

Figure 3. Elevation of the Miradoiros Cable-Stayed Bridge

Due to the academic purpose of the research the cross-section of the aerodynamic box girder of the original design has been substituted by a simplified cross section (see figure 4). Dimension B= 34 m that represents deck width is fixed while corner angle β is allowed to change, thus the deck cross-section shape depends on a single parameter β which is the design variable responsible for the change in the deck cross-section geometry. The corners are not perfectly sharp as a radius of curvature r/B= 0.0075 has been considered for all shapes studied.

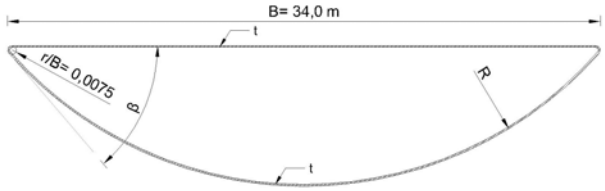


Figure 4. Simplified cross-section of deck

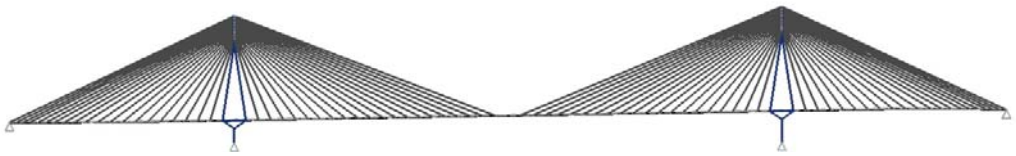
4 STRUCTURAL OPTIMIZATION OF SIMPLIFIED BRIDGE DECK

In this part of the research the goal was to obtain the bridge of minimum weight considering two situations: the bridge during construction at the final stage of the balanced cantilever construction and the bridge fully erected. The structural models of both situations appear in figure 5.

a) Bridge before completion



b) Fully erected bridge

Figure 5. Structural models

The bridge under construction is subjected to the self weight and two isolated loads at cantilever tip representing half the weight of the remaining bridge deck. The completed bridge is subjected to self weight and three different load cases representing the service load at right, center or left span.

In this problem the objective is to obtain the minimum weight for the deck and cables, in other words

$$\min F = t_d p_d l_d + 2\sum_{i=1}^{80} A_i l_i \tag{1}$$

being t_d, p_d, l_d deck thickness, perimeter and length, A_i and l_i (i =1,...80) the area and length of each cable. Expression (1) takes in account that the bridge is symmetric with regards to a longitudinal plane.

Design variables are constituted by deck thickness and cross area of cables, namely 81 design variables are considered.

Design constraints were linked to the behavior of the bridge. It was required that the stress value of cables was lower than 800 MPa, deck deflections during construction and horizontal displacement of tower top was null and for the completed bridge was requested that deck deflection was lower than 1/550 of the span length and the horizontal displacement of tower top was also lower than 1/550 of tower altitude.

The numerical results for each value of β appears in table 1. It can observed that as the value of β increases the amount of material of the deck decreases and so the volume of cables does. This trend could be known in advance but the study carried out allows that such common sense feeling had been quantified at the end of the numerical optimization process.

5 COMPUTATIONAL EVALUATION OF AERODYNAMIC COEFFICIENTS

The flow around the simplified deck cross-section has been modeled considering a 2D unsteady flow (see figure 6 where *B* is the deck width and the cross-section is not scaled). The URANS κ-ω SST turbulence model has been used considering a turbulence intensity of 1% and length scale of 0.1B. Dirichlet conditions have been set at the inlet and outlet boundaries of the flow domain.

With the aim of validating the CFD approach for computing the aerodynamic coefficients of the simplified deck the numerical results at Re= 1E+05 have been compared with the experimental ones published by Novak and Tanaka [8] at Re= 9E+04 for a corner angle β=90º. Two different meshes have been considered: 2.24E+05 cells and 3.35E+05 cells. The results obtained are reported in table 2 and it has been found that the 2.24E+05 mesh with a nondimensional time step of 0.01 for advancement in time provides accurate results with lower computational cost. In figure 7 a general view of that is presented. The definition of the aerodynamic coefficients is as follows and the sign criteria is shown in figure 8.

$$C_D = \frac{D}{\frac{1}{2}\rho U^2 B};\quad C_L = \frac{L}{\frac{1}{2}\rho U^2 B};\quad C_M = \frac{M}{\frac{1}{2}\rho U^2 B^2} \tag{2}$$

6 EVALUATION OF FLUTTER SPEED OF STRUCTURAL OPTIMA

For each optimum design obtained considering exclusively structural constraints the flutter speed can be calculated. It is done by using the Scalan theory [9] defining the aeroelastic forces and establishing the dynamic equilibrium of the structure under such set of forces.

$$\mathbf{M}\ddot{\mathbf{u}} + \mathbf{C}\dot{\mathbf{u}} + \mathbf{K}\mathbf{u} = \mathbf{f}_a = \mathbf{C}_a\dot{\mathbf{u}} + \mathbf{K}_a\mathbf{u} \tag{3}$$

Where $\mathbf{M}$,$\mathbf{C}$,$\mathbf{K}$ are the mass, damping and stiffness matrices of the structure, $\ddot{\mathbf{u}}, \dot{\mathbf{u}}, \mathbf{u}$ the vectors of accelerations, velocities and displacements of the degrees of freedom of the structure and $\mathbf{f}_a$ the vector of aeroelastic forces than depends on the velocities and displacements of the structure according with the following expression and the conventions shown in figure 9.

$$\mathbf{f}_a = \begin{Bmatrix} F_y \\ F_z \\ M_x \end{Bmatrix} = \frac{1}{2}\rho VKB \begin{pmatrix} P_1^* & -P_5^* & -BP_2^* \\ -H_5^* & H_1^* & BH_2^* \\ -BA_5^* & BA_1^* & B^2A_2^* \end{pmatrix} \begin{Bmatrix} \dot{v} \\ \dot{w} \\ \dot{\varphi}_x \end{Bmatrix} + \frac{1}{2}\rho V^2K^2 \begin{pmatrix} P_4^* & -P_6^* & -BP_3^* \\ -H_6^* & H_4^* & BH_3^* \\ -BA_6^* & BA_4^* & B^2A_3^* \end{pmatrix} \begin{Bmatrix} v \\ w \\ \varphi_x \end{Bmatrix} \tag{4}$$

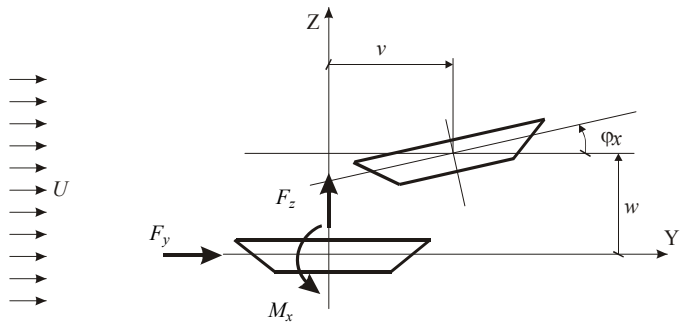

Figure 9. Convention for aeroelastic forces.

Where ρ is air density, V is wind speed, B is bridge width, K is the reduced frequency $K=B\omega/V$, ω is the vibration frequency and $A_i^*, H_i^*, P_i^* \quad (i=1,...,6)$ are the flutter derivatives.
In absence of a proper identification of flutter derivatives the evaluation of flutter speed can be done by using the quasi-steady theory which represents a simplification of the problem. Formulation of the quasi-steady approach can be found in Salvatori and Spinelli [10] or Lazzari [11]. The approximations of the flutter derivatives are presented in equation (5), where μ, that represents the distance between the elastic centre and the geometric centre of the cross section, can be estimated as A_1^*/H_1^* or A_3^*/H_3^* according to Febo and D'Asdia [12].

$$P_1^* = -\frac{2C_{D0}}{K} \qquad P_2^* = \frac{C'_{D0} - C_{L0}}{K}\mu \qquad P_3^* = \frac{C'_{D0}}{K^2} \qquad P_5^* = -\frac{C'_{D0} - C_{L0}}{K}$$
$$H_1^* = -\frac{C'_{L0} + C_{D0}}{K} \qquad H_2^* = -\frac{C'_{L0} + C_{D0}}{K}\mu \qquad H_3^* = -\frac{C'_{L0}}{K^2} \qquad H_5^* = \frac{2C_{L0}}{K} \qquad (5)$$
$$A_1^* = \frac{C'_{M0}}{K} \qquad A_2^* = \frac{C'_{M0}}{K}\mu \qquad A_3^* = \frac{C'_{M0}}{K^2} \qquad A_5^* = \frac{2C_{M0}}{K}$$

The numerical values of μ and the results for the flutter speed corresponding to each optimum design from the structural point of view are presented in table 4 and the latter appear in figure 10.

Table 4. Values of μ and flutter speed

Angle (°)	20	25	30	35	40	45	50	55	60
μ	-0.248	-0.257	-0.272	-0.265	-0.244	-0.201	-0.160	-0.087	-0.048
Flutter speed (m/s)	59.1	83.4	102.5	116.9	124.7	118.6	107.9	82.7	97.3

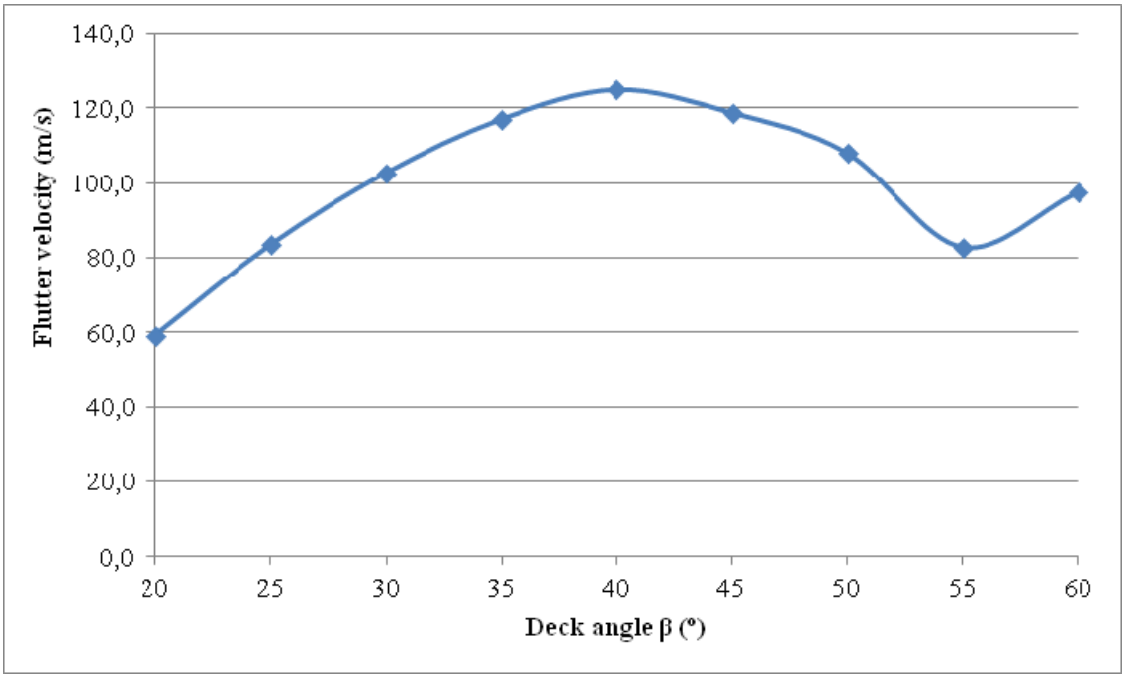

Figure 10. Flutter speed for optimal solutions from the structural point of view.

It can be observed that flutter speed does not evolve monotonically with respect to angle β. For instance for small β values flutter speed increases, then a maximum around $\beta = 40º$ appears. For higher β values the flutter speed decreases and afterwards there is also a local minimum. These numerical results show that if a defined flutter speed is requested, for instance V=100 m/s it can be obtained with two different designs, namely $\beta = 30º$ and $\beta = 52º$; but recalling table 1 it can be concluded that $\beta = 52º$ should be preferred as the amount of material is lower. There is also another conclusion: from the structural perspective, in other words for stresses and displacements considerations, the higher the value of β the better the behavior of the bridge,. But from the aeroelastic point of view the bridge response is different and increasing β, for instance, from $\beta = 35º$ to $\beta = 50º$ the flutter response is worsened. Although this consideration can be known for an experienced designer this research allows to identify such behavior in a quantitative way.

7 COMBINED STRUCTURAL AND AEROELASTIC OPTIMIZATION OF BRIDGE DECK

In the previous paragraphs the design of the bridge deck has been made considering independently structural constraints and aeroelastic constraints. This was done because this is the usual way to do it. Nevertheless in this research the structural part of the design provided the minimum value of the material volume which cannot be obtained by conventional trial and error techniques. Proceeding along this way a value of the flutter speed in obtained by each optimum for a given value of angle β. As mentioned before such value corresponded to two different values of β and the one with less material volume is to be chosen. Therefore this is not the best solution.

The best way to proceed is to consider jointly the constraints related to stresses and displacements and also the value of flutter speed. In other words the limits for the stresses in the material and the displacements of the structure need to be defined and also a value of the flutter speed needs to be established. In that case in the evaluation of the optimum solution the angle β that defines the geometry of the simplified deck needs to be considered as a design variable in addition to the thickness of the deck and the cross area of stays. The output of that optimization problem will lead to a design that is able to have the requested flutter speed with the minimum amount of material. In other words the value of β will be the one producing the maximum flutter speed similarly to the situation shown in the figure 10, in which that maximum will be exactly the required wind velocity.

8 CONCLUSIONS

The following conclusions can be extracted from this research:

1. Design of long span bridges produces a set of intermediate prototypes which usually delays the definition of the final design.
2. Design of long span bridges is a multidisciplinary problem that requires taking advantage of the more cutting edge technologies.
3. In this regards application of numerical optimization techniques can be very helpful for identifying the optimal shape of bridge deck.
4. A procedure working independently with structural constraints and aeroelastic constraints has been formulated.
5. Such procedure has been applied to a cable stayed bridge of 658 m of main span length.

6. Such methodology allows to quantify the relevance of both, the structural and aeroelastic considerations and demonstrate that a joint formulation of the problem is necessary and the optimum design only can be obtained with that combined approach.

ABSTRACT: In this paper, the experimental results for twin box girder of the Kwnagyang Bridge are presented in order to investigate the sensitivity of the Reynolds numbers on aerostatic force coefficient. High speed wind tunnel testing on 1:30 scale sectional model were carried out at the aeronautical wind tunnel in Korea Air Force Academy. The drag and lift coefficients revealed significant decrease of nearby 23% at supercritical region. The safety rail prevented the Reynolds number dependency of aerostatic force coefficients at negative angles of attack. In similar way, the boundary layer trip strip attached at bottom surface of girder reduced the Reynolds number dependency of aerostatic forces by fixing the location of flow transition. The pressure coefficients at girder surface near the gap significantly changed as the Reynolds number increase because of variation of the locations of flow separation and transition. The unbalanced burden of the drag force and lift forces at each box girder appeared in subcritical region was gradually resolved, and both boxes were almost equally loaded the forces at supercritical region.

KEYWORDS: Reynolds number, wind tunnel, suspension bridge, twin box girder.

1 INTRODUCTION

It is generally known that the flow around bluff and sharp edged bodies is independent of the Reynolds number, and the aerostatic forces measured at low speed wind tunnel testing may be directly applicable to the prototype bridge. The modern bridge girders are no longer sharp bluff body and are more likely streamlined section. The Reynolds number at ordinary wind tunnel tests of bridge girder has been generally 10^2 to 10^3 times smaller than that at actual bridges. Accordingly the aerostatic forces, especially drag force, of streamlined bridge sections seem to be no longer free from the Reynolds number.

Drag coefficients of some bridge girder sections were reported remarkably dependency of Reynolds number [1, 2]. In case of the Stonecutter Bridge girder, the drag force coefficient varied 30% according to wind speeds [3]. Considering the flexibility of long span bridges, those variations may significantly affect on structural and economical aspects of bridge design although the drag coefficients obtained at the low Reynolds number appear generally conservative for bridge design. Consequently there is some possibility of Reynolds number effects on girder of the Kwangyang Bridge that is extremely streamlined.

The Kwangyang Bridge, alternatively called as Yi Sun-sin Bridge, is located in south seashore of Korean peninsula which is frequently exposed to the typhoon at summer. During the Typhoon Maemi in 2003 passing nearby the bridge site, maximum instantaneous wind velocity was recorded 49.2 m/s at Yeosu Weather Station which is about 18km away from bridge site. Moreover the bridge superstructure locates 81m above sea level, and accordingly high wind is expected at the deck. Therefore the aerodynamic stability of the bridge is main concern of the design.

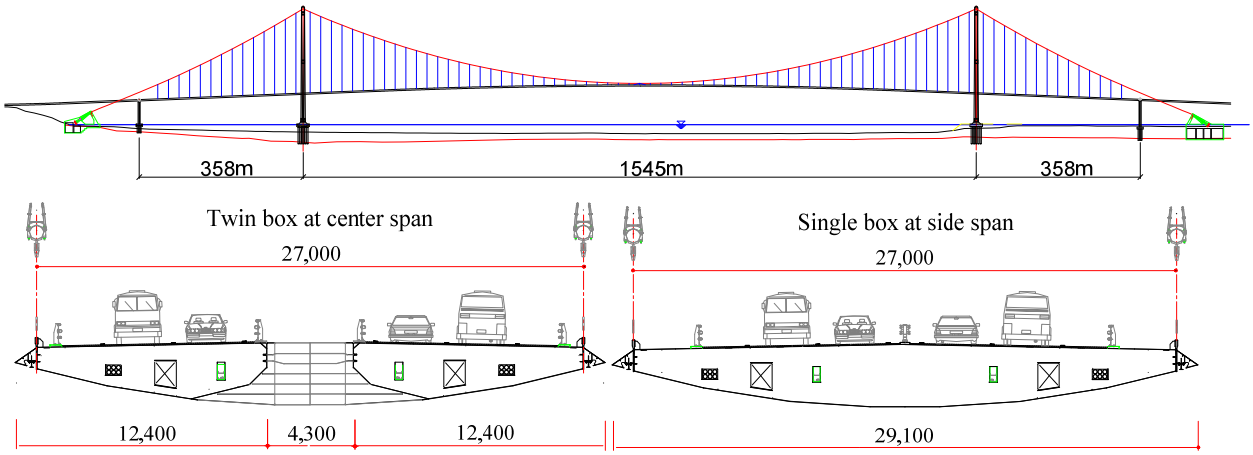

Figure 1. The Kwangyang Bridge.

The objective of present study is to investigate the sensitivity of aerostatic force coefficients of twin box girder of the Kwangyang Bridge according to the Reynolds numbers. This paper presents the 1:30 scale sectional model testing conducted at aeronautical wind tunnel in Korea Air Force Academy. Comparison with the results at low Reynolds number obtained in KOCED Wind Tunnel Center in Chonbuk National University is also provided.

2 TEST SETUP

The ordinary section model tests with scale of 1:70 were performed at the KOCED Wind Tunnel Center in Chonbuk National University during the design of the Kwangyang Bridge. The general results for aerodynamic design of main span girder can be found at Ref [5]. Those were, however, tested at low Reynolds number which was less than 4.8×10^5 (based on total girder width). Moreover smooth ventilation of air flow through narrow gap of 4.3m needs to be confirmed from the high speed wind tunnel tests, because different flow structure around guide vane according to wind speeds was observed at the Stonecutter Bridge.

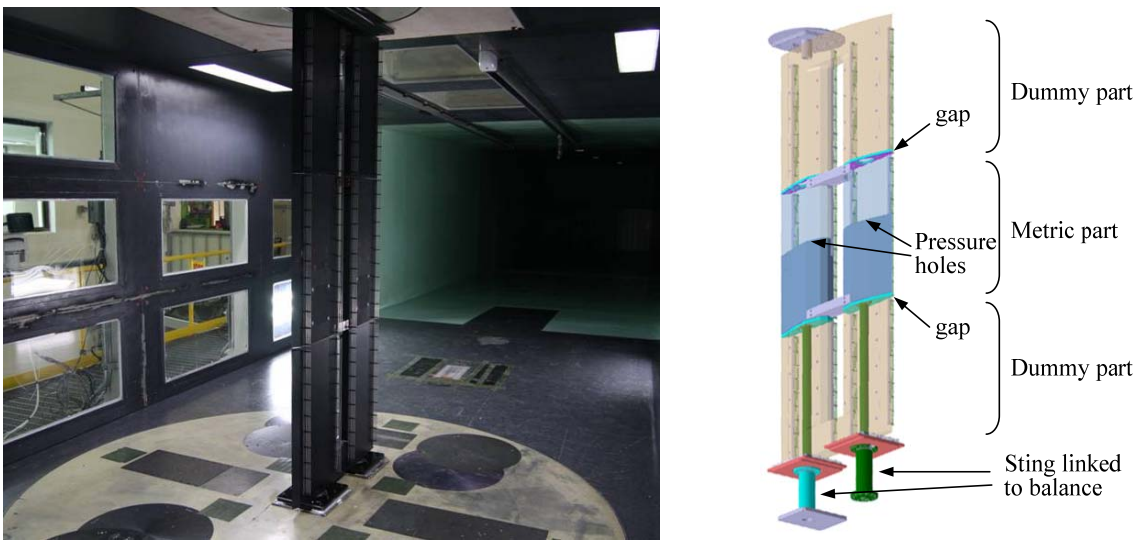

Figure 2. 1/30 scale model at wind tunnel in Korea Air Force Academy

The mid-size aeronautical wind tunnel at Korea Air Force Academy was used in present investigation in order to test at high wind speeds (high Reynolds numbers). Size of the test section was 3.5m(W)×2.45m(H). Contraction ratio was 7.3:1, maximum wind speed was 92m/s, and turbulent intensity was less than 0.038% at 74m/s. This closed circuit wind tunnel equipped boundary layer removal system and external pyramidal balance.

A 1:30 scale section model weighed over 250kg was made by aluminum and steel to resist high wind speed. Length and width of the model were respectively 1.94m and 1.0m which represented 72m of actual bridge girder. As shown in Figure 2, the model consists of three parts, one metric part and two dummy parts. Aerodynamic forces acting on metric part were measured by external pyramidal balance through two stings penetrating dummy part. Electric line sensors were attached at the gaps to warn the contact between metric part and dummy parts. Wind pressures were measured from 92 pressure holes in metric part. The pressure tubes were connected to pressure measurement system (PSI-8400).

Table 1 shows the experimental cases: girder without safety railing (case1), girder with safety railing (case2), girder with safety railing and boundary layer trip strip (case3). Case1 simulated the girder at construction stage where safety rails were generally not installed. Case2 and Case3 represented the girder at completion stage. The boundary layer trip strip is an artificial roughness added to the wind tunnel model in order to fix the location of transition from a laminar to turbulent boundary on the model [6]. The thickness of trip strip used in present investigation was 0.29mm. The trip strip was added on the bottom surface at 1.1m (at prototype) away from leading edge of the girder.

Table 1. Experimental Cases

Test case	Stage	Installation		Wind speed (m/s)	Angle of attack (deg)
		Safety rail	Trip strip		
Case1	Construction	×	×	10~45	+3 ~ -3
Case2	Completion	○	×	10~70	+5 ~ -5
Case3	Completion	○	○	10~45	+5 ~ -5

3 TEST RESULTS

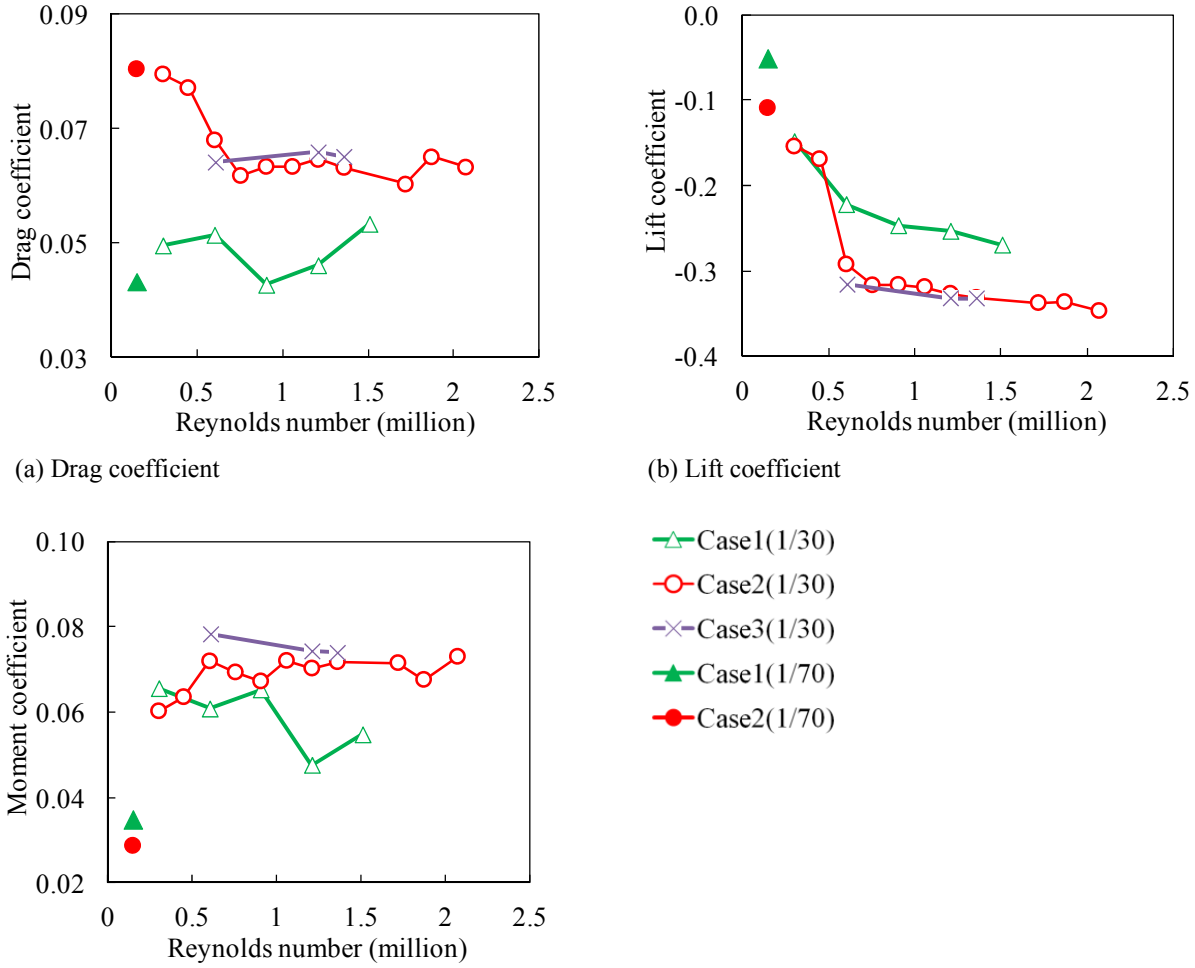
3.1 *Aerostatic force coefficients*

Figure 3 shows the aerostatic force coefficients of the girder normalized by full girder width. As can be seen in the figure, the aerostatic force coefficients obtained from the 1:70 scale model well correspond with those measured from the 1:30 scale model at low Reynolds number. As Reynolds number (Re) increase gradually, the drag and lift coefficients revealed significant decrease of nearby 23%, while pitching moment coefficients were relatively consistent. The drag coefficient at $Re=1.5\times10^5$ (based on full girder width) was 0.083 but dropped to around 0.064 at $Re=7\times10^5$ and kept consistent. The lift coefficient also dropped from -0.096 to -0.347. The critical Reynolds number in present girder was found to be 2×10^5~7×10^5 that is near the range of wind speeds at ordinary section model tests.

It is noticeable that the safety rail significantly influences to the drag and lift coefficients regardless of the Reynolds number. The drag coefficient without safety rail (Case1) was almost half of that with safety rail (Case2 & 3). These represent that any obstacles attached at leading edge of the girder strongly change the drag and lift coefficients.

Higher pressure drag as compared to skin friction drag at low Reynolds number region introduces additional drag. As Reynolds number increases, the transition point has moved forward and drag has reduced accordingly. Two distinct features depending on Reynolds number are the

location of boundary layer transition and the location of separation. A boundary layer trip strip is a tool used for making transition to occur earlier than it is [6]. Unfortunately the girder with the boundary layer trip strip (Case2) was not tested at the critical Reynolds number region. The effect of the trip strip on the Reynolds number independency is not identified in the range of the tested Reynolds number.



(a) Drag coefficient

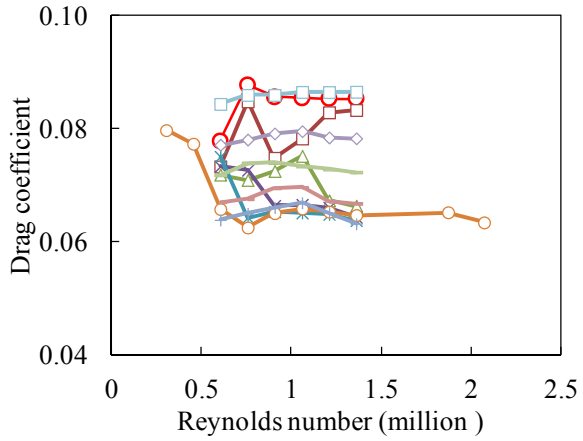
(b) Lift coefficient

(c) Pitching moment coefficient

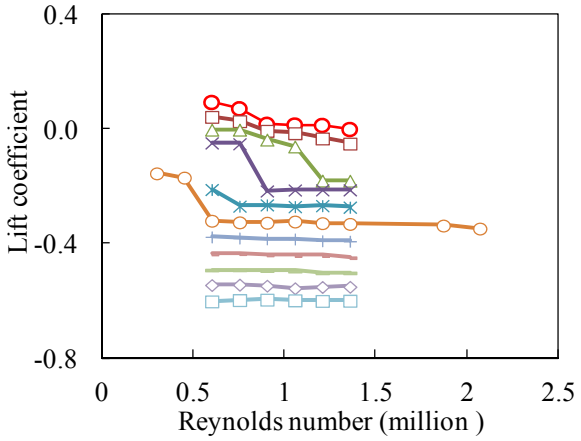
Figure 3. Aerostatic force coefficients at 0º angle of attack

The girder without safety rail definitely revealed the Reynolds number dependency on its aerostatic force coefficients. The tendency is, however, slightly different at the girder with safety rail. Figure 4 shows the aerostatic force coefficients of the girder with safety rail (Case2) according to angle of attack and the Reynolds number. The Reynolds number dependency was observed at zero and positive angles of attack (nose up), yet was not observed at negative angles of attack (nose down). In negative angles of attack, the location of separation on the bottom surface of the girder might be dependent on the Reynolds number. The location of separation did not, however, change because of the safety rail equipped at leading edge when the girder was inclined to negative angles of attack. The safety rail might fix the location of boundary layer transition and the location of separation.

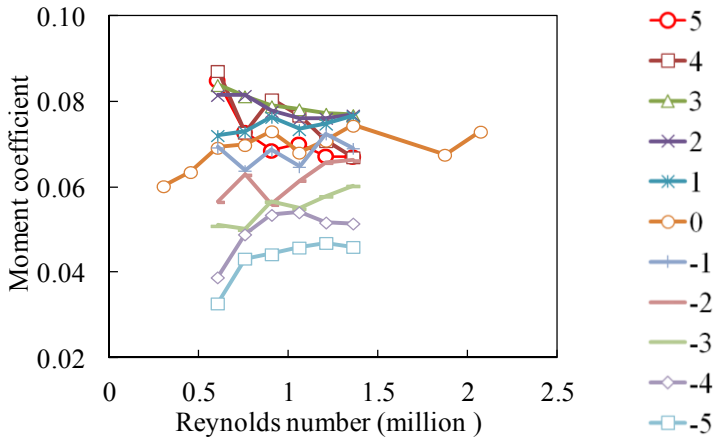
When carefully watching the drag and lift coefficients shown in Figure 4(a) and (b), sudden drops of the coefficients are observed at certain angles of attack, e.g. 2º and 3º. Those drops already occurred at 0º angle of attack moved forward to higher Reynolds number in positive angles of attack. These represent that the critical Reynolds number changes according to angles of attack generally moved to higher value at high positive angle of attack.



(a) Drag coefficient



(b) Lift coefficient



(c) Pitching moment coefficient

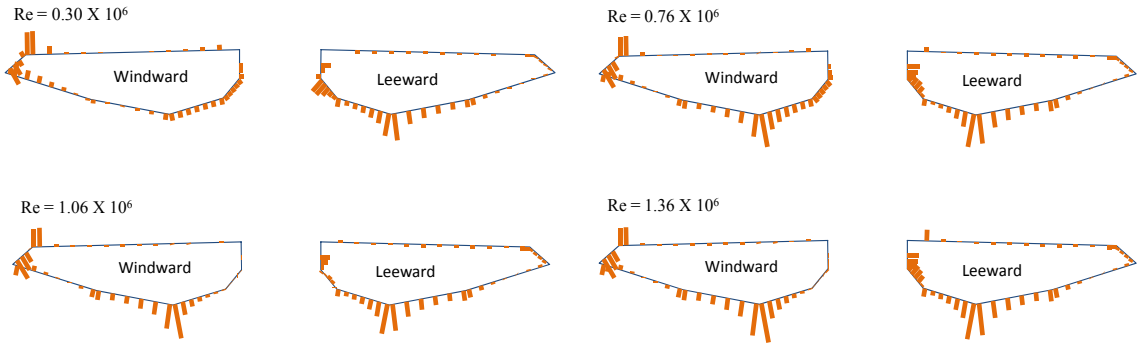
Figure 4. Aerostatic force coefficients of girder with safety rail according to angle of attack

As mentioned earlier, the effectiveness of the boundary layer trip strip which was not clearly identified because the tests were carried out at super critical Reynolds number. This effectiveness can be observed in the delayed critical Reynolds number at high positive angle of attack. The sudden drop of the drag and lift coefficients at the critical region occurred at the girder was eliminated at the girder by patching the boundary layer trip strip at its bottom surface. This removal of critical region from the test ranges represent that the trip strip effectively fix the location of transition from a laminar to turbulent boundary on the model, and can be used for simulating the high Reynolds number effect at low wind speed.

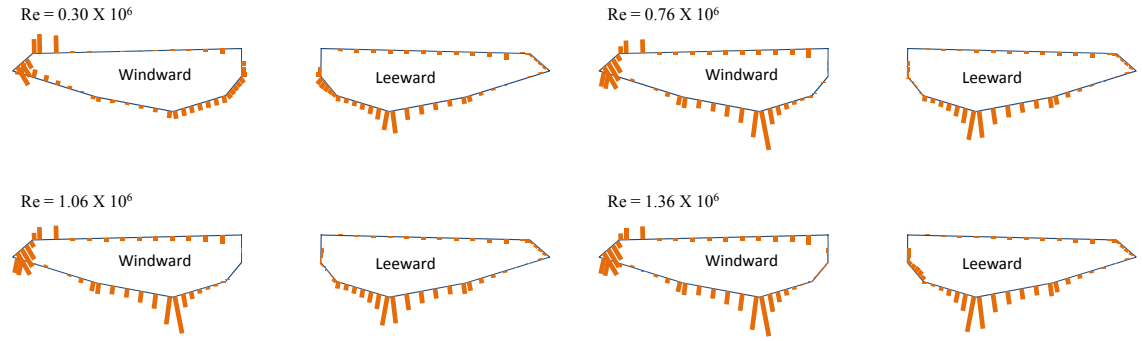
3.2 *Pressure distributions*

Figure 5 shows pressure coefficients along girder section. Pressure coefficient heading outside the box represents negative pressure (suction) and inside means positive. As can be seen in Figure 5(a) for girder without safety rail (Case1), the pressure coefficients at front edge of the leeward box change from negative to positive as the Reynolds number increase. This inconsistency of pressure coefficients is probably a result of moved locations of separation and boundary layer transition as wind speed up. These variations of pressure coefficients result in the Reynolds number dependency of the aerostatic force coefficients.

In case of girder with safety rail (Case2) at low Re, the pressure distribution of leeward box did not change much. However, the pressures at rear and mid bottom surface of windward box were changed at critical Re. The uniformly distributed negative pressures were observed at rear bottom surface of windward box in low Re. As wind speed increases, the strong negative pressure peaks were observed at folded edge of bottom surface above the critical Re.



(a) Girder without safety rail (Case1)



(b) Girder with safety rail (Case2)

Figure 5. Mean pressure coefficients at 0° angle of attack

3.3 *Aerostatic forces acting on each twin boxes*

The aerostatic force sharing ratios between windward box and leeward box are given in Figure 6 as a function of the Reynolds number. The forces were evaluated by integrating the measured pressures along girder sections. At the low Re in subcritical region, the windward box burdened the drag force mostly, yet the leeward box mostly burdened the lift force. It is interesting that the drag force and lift force acting on the leeward box were respectively negative and almost zero at subcritical region.

This unbalanced division of forces was gradually reduced at critical region, and then force ratio was almost equal in both sides of boxes at supercritical region of the Reynolds number. Figure 7 shows the aerostatic force coefficient and division ratio of forces between windward box and leeward box at supercritical region, Re=1.36×10^6. Accordingly it is reasonable to assume in design of twin box girder that the aerostatic forces acting on each boxes can be equally divided into the windward box and leeward box.

4 CONCLUSIONS

The sensitivity of the Reynolds numbers on aerostatic force coefficients of twin box girder were investigated through ordinary section model tests and high speed tests at aeronautical wind tunnel. Main finding obtained from the tests are summarized as follows:

- The Reynolds number dependency of aerostatic force coefficients were observed at present streamlined twin box girder. The drag and lift coefficients revealed significant decrease of nearby 23% at supercritical region. This Reynolds number dependency was only observed at positive angles of attack (nose up) because of the safety rail.
- The boundary layer trip strip was found to reduce the Reynolds number dependency of aerostatic forces by fixing the location of flow transition. The trip strip can be used to simulate the flow structure at supercritical region in low wind speed.
- The pressure coefficients at bottom rear surface of windward box girder and at frontal face of the leeward box girder significantly changed as the Reynolds number increase because of variation of the locations of flow separation and transition.
- The windward and leeward box girders respectively burdened most of the drag force and lift force at subcritical region. This unbalanced division of forces at each box girder was gradually resolved, and both boxes almost equally divided the forces at supercritical region.

Superposability of the unsteady aerodynamic loads on bridge deck sections

Zhitian Zhang
Wind Engineering Research Center, Hunan University, Changsha, 410082, China.

ABSTRACT: The 2-dimensional unsteady aerodynamic forces are investigated from a point of view of whether these forces conform to the principle of linear superposition. It is shown that the basic preconditions, which lead to the linear superposability in cases of thin airfoil sections, are no longer valid for a bluff section. However, theoretical models in bridge aerodynamics, such as the one of flutter-buffeting analysis and those concerning aerodynamic admittance (AA) functions, always necessitate this superposability. The contradiction revealed in this literature may throw light on the perplexing problem of AA functions pertaining to the wind loads on bridge decks. Some theoretical AA models, which were employed rather extensively and derived from flutter derivatives according to interrelations resulted from thin airfoil theories, are demonstrated to a great extent to be illogical. Finally, with understanding of the linear superposability of the unsteady aerodynamic forces, suggestions in connection with experiment-based AA functions are presented in the last section.
KEYWORDS: bridge; unsteady; aerodynamic; superposition; buffeting; flutter

1 INTRODUCTION

Aerodynamic forces acting on bridge decks have generally been classified into steady and unsteady, according to whether or not the loads are time-varying. Unsteady loads in this context are distinguished from those of quasi-steady in whether they are dependent uniquely on the current state of motions (both structure and wind fluctuation) or on the whole motion histories [1]. Strictly speaking, both the motion-related and the turbulence induced aerodynamic forces are, to some extent, unsteady. The determination of aerodynamic response of a long flexible bridge involves the description of the mean wind loads, the motion induced loads (self-excited), and the turbulence induced loads. These three parts of aerodynamic loads are generally described with aerostatic coefficients, flutter derivatives and aerodynamic admittance (AA) functions respectively, and then, are linearly superposed according to the principle of linear superposition. However, it will be shown in the paper that a question arises as to whether these loads can be linearly superposed or, in other words, as to whether there exist a group of AA functions independent neither on the turbulent gust structure nor on the structural motions. That is the main concern of this literature.

2 FUNDAMENTALS OF BRIDGE AERODYNAMICS

The stochastic response of an elongated and flexible bridge structure to turbulent wind flow can be determined roughly by two classes of dynamic loads: (i) those due to wind-structure interactions, namely aeroelastic effects; (ii) those due to the wind speed fluctuations, including those inherent in the oncoming flow and those initiated by the body section itself.

Scanlan and Tomko [2] put forward a method to describe the self-excited loads for bluff sections put in smooth flow, which necessitates six experiment-based flutter-derivatives, functions of a dimensionless frequency. Later, Scanlan and Jones [3] expanded this method and expressed the lift and torque per unit span with eight flutter-derivatives, allowing for inclusion of the displacement terms, as below:

$$L_{ae} = \frac{1}{2}\rho U^2 B[KH_1^* \frac{\dot{h}}{U} + KH_2^* \frac{B\dot{\alpha}}{U} + K^2 H_3^* \alpha + K^2 H_4^* \frac{h}{B}] \quad (1)$$

$$M_{ae} = \frac{1}{2}\rho U^2 B^2 [KA_1^* \frac{\dot{h}}{U} + KA_2^* \frac{B\dot{\alpha}}{U} + K^2 A_3^* \alpha + K^2 A_4^* \frac{h}{B}] \quad (2)$$

where ρ is the air density, U the steady wind velocity, $K=B\omega/U$ the dimensionless frequency, ω the oscillation frequency, B the reference width of the deck section, $H_i^*(i=1\sim4)$ and $A_i^*(i=1\sim4)$ flutter derivatives, h the vertical motion, α the section rotation, $\dot{h}$ and $\dot{\alpha}$ the derivatives of h and α to real time t, respectively.

Though the part of aerodynamic load due to wind fluctuations is, strictly speaking, unsteady both for well-streamlined and bluff body sections, it is always given in quasi-steady form, as

$$D_b(t) = \frac{1}{2}\rho U^2 B\left(2C_D \chi_{Du} \frac{u(t)}{U} + C_D' \chi_{Dw} \frac{w(t)}{U}\right) \quad (3)$$

$$L_b(t) = \frac{1}{2}\rho U^2 B\left(2C_L \chi_{Lu} \frac{u(t)}{U} + (C_L' + C_D) \chi_{Lw} \frac{w(t)}{U}\right) \quad (4)$$

$$M_b(t) = \frac{1}{2}\rho U^2 B^2\left(2C_M \chi_{Mu} \frac{u(t)}{U} + C_M' \chi_{Mw} \frac{w(t)}{U}\right) \quad (5)$$

Where $u(t)$ and $w(t)$ are horizontal and vertical wind fluctuations, respectively; C_D, C_L, C_M are aerostatic drag, lift and torque coefficients; C_D', C_L', C_M' are the derivatives of C_D, C_L, C_M with respect to wind attack angle α; χ_{Du}, χ_{Dw}, χ_{Lu}, χ_{Lw}, χ_{Mu}, χ_{Mw} are the so-called aerodynamic admittances, functions of dimensionless frequency K, playing the role of connecting the wind fluctuations with the buffeting loads.

The most important assumption implied implicitly in Eqs. (3) to (5) is that the AA functions wherein are dependent uniquely upon the reduced frequency and therefore would not be affected by the turbulent gust structures, or, shapes of the curves of wind spectrum.

3 SUPERPOSABILITY OF WAKE EFFECTS

3.1 *Basic theory*

A general form describing the periodic motion of an airfoil with circular frequency ω is [5, 6]

$$w(\theta) = Ue^{i\omega t}\left\{A_0 + 2\sum_{n=1}^{\infty} A_n \cos n\theta\right\}, \quad (6)$$

where w is the vertical velocity distribution relative to the airflow along the chord of the airfoil, and the relationship between x and θ is $x = \cos\theta$.

The multiplier $e^{i\omega t}$ on the right side of Eq. (6) describes the periodic variation of the velocity with respect to time; the infinite series in the bracket expresses the modes of velocity distribution along the chord. The first five modes (x = -1 to 1) are plotted in figure 1. Especially, the term of A_0 denotes the mode of translatory oscillation where a uniform velocity distributed along the whole chord width; the term of A_1 denotes the mode of rotational oscillation where the velocity is proportional to x, the distance aft of the midpoint. The first two terms describe the rigid motion and the other higher-order terms allow the deformative motions.

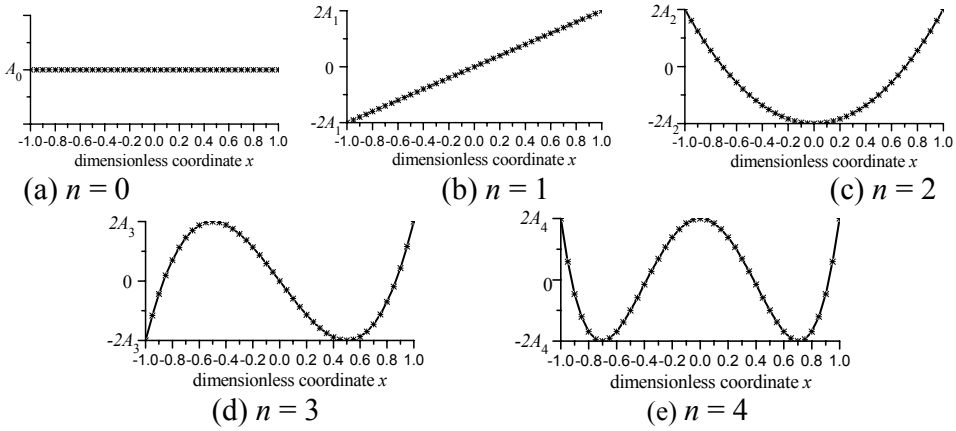

Fig. 1 Fundamental vertical distributions of the first five terms in Eq. (6)

It is worthy of mention that the resulted lift depends only on the first three coefficients in Eq. (6) and the moment on the first four, which means, for any given velocity distributions, the aerodynamic effects are embodied in these four terms. Sears [6] summarized the total lift and moment (about the midpoint) acting on a airfoil with chord length of B, corresponding to the general form of velocity expressed by Eq. (6), as

$$L = \pi\rho BU^2 e^{\mathrm{i}\omega t}\left\{(A_0 + A_1)C(k) + (A_0 - A_2)\cdot \mathrm{i}k/2\right\}, \tag{7}$$

$$M = (\pi/4)\rho B^2 U^2 e^{\mathrm{i}\omega t}\left\{A_0 C(k) - A_1[1 - C(k)] - (A_1 - A_3)\cdot \mathrm{i}k/4 - A_2\right\}. \tag{8}$$

where $k = B\omega/(2U) = K/2$, and $C(k) = K_1(\mathrm{i}k) / [K_0(\mathrm{i}k)+K_1(\mathrm{i}k)]$ is in accord with the Theodorsen circular function that was expressed in the original paper as [10]

$$C(k) = \frac{\displaystyle\int_1^\infty \frac{x_0}{\sqrt{x_0^2 - 1}} e^{-\mathrm{i}kx_0}\,dx_0}{\displaystyle\int_1^\infty \frac{x_0 + 1}{\sqrt{x_0^2 - 1}} e^{-\mathrm{i}kx_0}\,dx_0} = \frac{K_1}{K_0 + K_1}. \tag{9}$$

The Theodorsen circular function is commonly expressed in complex form as

$$C(k) = F_T(k) + \mathrm{i}G_T(k) \tag{10}$$

where $F_T(k)$ and $G_T(k)$ are real functions of the reduced frequency k.

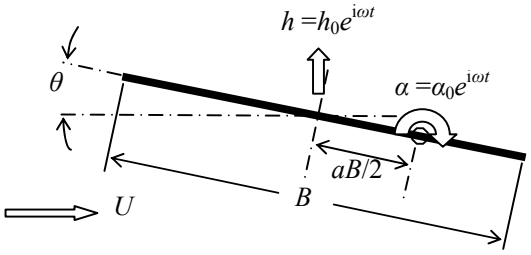

Fig. 2 Diagram show the rigid motion of the airfoil

3.2 *Rigid motion induced loads*

Considering a type of periodic rigid motion shown in figure 2, where the vertical motion is $h = h_0 e^{\mathrm{i}\omega t}$, the torsional motion is $\alpha = \alpha_0 e^{\mathrm{i}\omega t}$, $aB/2$ is the distance from the airfoil mid-chord to the oscillatory rotation point ($a > 0$ denote the location at the right half chord), the relative vertical velocity distribution of the mode shown in Fig. 1(b) in this case is

Reservation of A_0 and A_1 in Eq. (7) and (8) could result in the lift and moment immediately, as

$$L = -\pi\rho UBC(k)\left[U\alpha + \dot{h} + \frac{B}{2}\left(\frac{1}{2} - a\right)\dot{\alpha}\right] - \frac{\pi\rho B^2}{4}\left(U\dot{\alpha} + \ddot{h} - \frac{B}{2}a\ddot{\alpha}\right), \tag{11}$$

$$M_{1/2} = -\frac{\pi\rho UB^2}{4}C(k)\left[U\alpha + \dot{h} + \frac{B}{2}\left(\frac{1}{2} - a\right)\dot{\alpha}\right] + \frac{\pi\rho B^3}{16}\left[\dot{\alpha}U + \frac{B}{8}\ddot{\alpha}\right]. \tag{12}$$

It should be noted that the moment expressed by (12) is about the mid-chord point of the airfoil. The moment about the rotation point may be calculated by

$$\begin{aligned} M_a = M_{1/2} + L\cdot\frac{aB}{2} = &-\frac{\pi\rho UB^2}{2}\left(a + \frac{1}{2}\right)C(k)\left[U\alpha + \dot{h} + \frac{B}{2}\left(\frac{1}{2} - a\right)\dot{\alpha}\right] \\ &-\frac{\pi\rho B^2}{4}\left[\frac{aB}{2}\ddot{h} - \frac{B^2}{4}\left(a^2 + \frac{1}{8}\right)\ddot{\alpha} - \frac{BU}{4}\dot{\alpha} + \frac{BUa}{2}\alpha\right] \end{aligned}. \tag{13}$$

The lift and moment, i.e., Eqs. (11) and (13), are in accord with those reported in other literatures [7,9].

3.3 *Wind gusts induced loads*

A vertical gust that changes harmonically both in time and space could, if the coordinate axes are fixed to the airfoil, be described as a form of relative velocity distribution of the airfoil, as

$$w = We^{\mathrm{i}\omega(t - x/U)} = We^{\mathrm{i}\omega t}e^{-\frac{\mathrm{i}\omega x}{U}}, \tag{14}$$

the expressions of lift and moment can be simplified to

$$L = \pi\rho BUWe^{\mathrm{i}\omega t}\left\{[J_0(k) - \mathrm{i}J_1(k)]C(k) + \mathrm{i}J_1(k)\right\}, \tag{15}$$

$$M_{1/2} = L\cdot\frac{B}{4}, \tag{16}$$

where the Bessel functions $J_0(k)$ and $J_1(k)$ have the forms as bellow

$$J_0(k) = \frac{2}{\pi}\int_1^\infty \frac{\sin kx}{\sqrt{x^2 - 1}}dx, \quad J_1(k) = -\frac{2}{\pi}\int_1^\infty \frac{x\cos kx}{\sqrt{x^2 - 1}}dx. \tag{17}$$

Expression (15) can be rewritten in the notation of complex AA as

$$L = \pi\rho BUWe^{\mathrm{i}\omega t}\chi_s(k), \tag{18}$$

where

$$\chi_s(k) = F_s(k) + \mathrm{i}G_s(k) = [J_0(k) - iJ_1(k)]C(k) + \mathrm{i}J_1(k) \tag{19}$$

is the so-called complex Sears aerodynamic admittance function.

In the case of when the flow turbulence of broad-spectrum and steady stochastic, instead of a gust with a pure circular frequency ω, is encountered, the contributions of each gust component to the unsteady aerodynamic forces could be superposed linearly due to the potential flow around the section induced by gust components fulfill the principle of superposition. Thus, the power spectral density of L in this case can be obtained according to (19), as

$$S_L(k) = \left(\frac{1}{2}\rho UBC_L'\right)^2 |\chi_s|^2 S_w(k), \tag{20}$$

where S_w is the power spectral density of the vertical gust, $C_L' = dC_L/d\alpha = 2\pi$ is the differential of the lift coefficient with respect to wind attack angle α, $|\chi_s|^2 = F_s^2(k) + G_s^2(k)$ is known as the Sears admittance function which serves to link, for an airfoil, the spectrum of vertical gusting

velocity to that of associated lift [4].

In the case of when both the rigid motions and wind fluctuations are involved, the unsteady aerodynamic lift or torque acting on an airfoil section can, theoretically, be determined by the linear superposition of those determined by (11) and (15), or those by (12) and (16), respectively.

3.4 *Applications of superposability via indicial functions*

Another application of the superposability of unsteady aerodynamic loads in 2-D thin airfoil theory is that the resulted aerodynamic forces acting on a section in question due to arbitrary rigid motions or wind gusts could be expressed as convolution integrals over the time histories, resorting to a kind of so-called indicial functions. The general mathematic expression of the indicial function takes the form of

$$\varphi(s) = 1 - \sum_{1}^{i} a_i e^{-d_i s}, \tag{21}$$

Where $s=Ut/(2B)$ is dimensionlesstime, a_i, d_i are constants to be identified and $d_i > 0$.

Applying the following Fourier transform

$$\bar{f}(k) = \int_{-\infty}^{\infty} f(s) e^{-\mathrm{i}ks} ds, \tag{22}$$

to $\varphi'(s)$, the derivative of $\varphi(s)$ with respect to s, and then plus $\varphi(0)$ would yield

$$\varphi(0) + \overline{\varphi}' = 1 - \sum_{1}^{i} a_i + \sum_{1}^{i} \frac{a_i d_i^2}{d_i^2 + k^2} - \mathrm{i}k \sum_{1}^{i} \frac{a_i d_i}{d_i^2 + k^2}, \tag{23}$$

which will be employed for power spectrum analysis later in this paper.

3.4.1 *Wagner function*

One of the typical transient phenomena is, the lift acting on a flat-plate section due to an abrupt step-function change of the attitude of the section relative to the oncoming flow, a_0, would undergo a transient evolution described by

$$L(s) = \frac{1}{2} \rho U^2 B C_L' \alpha_0 \varphi(s), \tag{24}$$

where $C_L' = dC_L / d\alpha$, $\varphi(s)$ is an indicial lift-growth function.

If an arbitrary small rotation $\alpha(s)$ is encountered, the resulted lift would, according to the principle of superposition, be obtained with a convolution integral as

$$L(s) = \frac{1}{2} \rho U^2 B C_L' \int_{-\infty}^{s} \varphi(s-\sigma) \alpha'(\sigma) d\sigma, \tag{25}$$

where $\alpha'(\sigma) = d\alpha / ds$.

A change of variables and integration by parts in Eq. (25) would lead to

$$L(s) = \frac{1}{2} \rho U^2 B C_L' \left[\varphi(0)\alpha(s) + \int_{0}^{\infty} \varphi'(\sigma) \alpha(s-\sigma) d\sigma \right]. \tag{26}$$

3.4.2 *Kössner function*

Another typical transient phenomenon is associated with a flat-plate section entering a sharp-edged vertical gust. The lift evolution in this situation is described by

$$L(s) = \frac{1}{2} \rho U^2 B C_L' \alpha_0 \psi(s) \tag{27}$$

Where $\psi(s)$, different from the Wagner function, is the so-called Küssner function, of which an

excellent approximation was also offered by Jones [8], as

$$\psi(s) = 1 - 0.5e^{-0.13s} - 0.5e^{-s} \tag{28}$$

Now consider the section penetrating a gust of any form $w(s)$ of variable vertical velocity. In a similar way as that leading to equation (26), the lift in this case can be expressed as

$$L(s) = \frac{1}{2}\rho UBC_L'\left[\psi(0)w(s) + \int_0^\infty \psi'(\sigma)w(s-\sigma)d\sigma\right]. \tag{29}$$

4 PRINCIPLES FROM AIRFOIL THEORY TO BRIDGE AERODYNAMICS

4.1 *"Equivalent" indicial function*

Scanlan put forward a method trying to acquire the AA functions for bluff bridge deck sections from tested flutter derivatives [3, 9, 10]. This method is outlined in the following paragraphs.

Taking the lift for an example and considering the part due to vertical motion only, a replacement of α in eq. (26) by $\dot{h}/U$ and φ by φ_{Lh}, may lead to

$$L(s) = \frac{1}{2}\rho U^2 BC_L'\left\{\varphi_{Lh}(0)\frac{h'(s)}{B} + \int_0^\infty \varphi_{Lh}'(\sigma)\frac{h'(s-\sigma)}{B}d\sigma\right\}, \tag{30}$$

where $h' = dh/ds$ and $\varphi' = dh/ds$.

Applying the Fourier transform of (22) to Eq. (1) (Neglecting the terms of α and $\dot{\alpha}$) and to (30) would yield

$$4k(H_1^* - \mathrm{i}H_4^*) = C_L'\,[\varphi_{Lh}(0) + \overline{\varphi}_{Lh}'], \tag{31}$$

Other relations associated with rotation could be obtained in a similar way.

On the other hand, the connection between Küssner function and AA function, for example, the complex Sears AA function, may be resulted from the Fourier transform, as

$$\overline{L}(k) = \frac{1}{2}\rho UBC_L'[\psi(0) + \overline{\psi}']\overline{w} = \frac{1}{2}\rho UBC_L' \cdot \chi_{L'} \cdot \overline{w}, \tag{32}$$

where $\chi_{L'}$ is also a complex aerodynamic admittance function.

Scanlan assumed directly the equivalence between the Küssner function ψ and the Wagner function φ. Thus, according to (31) and (32), one obtain immediately [3]

$$\overline{L}(k) = 2\rho UBk[H_1^* - \mathrm{i}H_4^*]\overline{w} = \frac{1}{2}\rho UBC_L' \cdot \chi_{L'} \cdot \overline{w}. \tag{33}$$

Multiplying (33) by its complex conjugate yields the relation between the auto-PSD of the lift and that of the vertical gust:

$$S_{LL}(k) = (2\rho UBk)^2 \cdot \left[(H_1^*)^2 + (H_4^*)^2\right] \cdot S_{ww} = \left(\frac{1}{2}\rho UBC_L'\right)^2 \cdot |\chi_{L'}|^2 \cdot S_{ww}. \tag{34}$$

This yields immediately a bearing between the aerodynamic admittance and the flutter derivatives, as

$$|\chi_{L'}|^2 = 16k^2\left[(H_1^*)^2 + (H_4^*)^2\right]/(C_L')^2 = 4K^2\left[(H_1^*)^2 + (H_4^*)^2\right]/(C_L')^2. \tag{35}$$

Other AA functions associated with torsional motion or with resulted moment could be derived in a similar way as that of (35).

The vital question in such a methodology is whether or not $\dot{h} = e^{-\mathrm{i}\omega t}$ equals to $w = e^{\mathrm{i}\omega t}e^{-\mathrm{i}\omega x/U}$ as to the resulted aerodynamic effects. The answer is obviously negative.

We can see from what follows that the AA function so obtained would result in incorrect

power spectrum of the associated aerodynamic force component.

Considering only vertical translatory velocity in Eq. (11) and ignoring the apparent mass and quasi-steady terms would result in

$$L = -\pi\rho UBC(k)\dot{h} = -\frac{1}{2}\rho UBC_L' \cdot C(k) \cdot \dot{h} \tag{36}$$

The interrelation between the Theodorsen function and the indicial function can be resulted from a comparison of the Fourier transform of Eq. (36) to that of Eq. (30) for $\alpha = \dot{h}/U$, as [11]

$$C(k) = \varphi(0) + \overline{\varphi'}, \tag{37}$$

Thus, the following relationships could be established according to Eq. (10) and Eq. (23):

$$F_T(k) = 1 - a_1 - a_2 + \frac{a_1 d_1^2}{d_1^2 + k^2} + \frac{a_2 d_2^2}{d_2^2 + k^2} = 0.5 + \frac{0.0003416}{0.00207 + k^2} + \frac{0.03015}{0.09 + k^2}, \tag{38}$$

$$G_T(k) = -k\left[\frac{a_1 d_1}{d_1^2 + k^2} + \frac{a_2 d_2}{d_2^2 + k^2}\right] = -k\left[\frac{0.0075075}{0.00207 + k^2} + \frac{0.1005}{0.09 + k^2}\right], \tag{39}$$

Where $F_T(k)$ and $G_T(k)$ are the real and imaginary parts of the Theodorsen function. These lead immediately to

$$\lim_{k\to\infty}\left|\chi_T\right|^2 = \lim_{k\to\infty}\left[F_T^2(k) + G_T^2(k)\right] = \left(1 - \sum a_i\right)^2 = 0.25. \tag{40}$$

where $\left|\chi_T\right|^2 = F_T^2(k) + G_T^2(k)$ is recognized as Theodorsen aerodynamic admittance function [12].

In a similar way, the limit value of Sears AA function can be obtained as

$$\lim_{k\to\infty}\left|\chi_s\right|^2 = \lim_{k\to\infty}\left[F_s^2(k) + G_s^2(k)\right] = \left(1 - \sum a_i\right)^2 = 0 \tag{41}$$

The comparison of the Theodorsen and Sears AA functions is plotted in figure 3, where it can be seen that the relative discrepancy between the two curves increases rapidly with k.

Thus, the methodology of deriving AA functions by "equivalent" indicial functions would lead to a limit value of the AA functions determined by $(1 - \sum a_i)^2$, which is dependent on the identified parameters and therefore not necessary a zero value.

The essence of this incorrect can be ascribed to the introduction of an assumption that doesn't even hold in aeronautics to bluff sections (the equivalence between Küssner function and Wagner's indicial function). This is logically unacceptable.

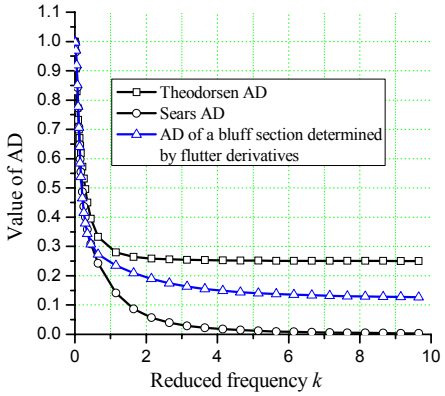

Fig. 3 Thoedorsen and Sears aerodynamic admittance

It is this nonzero limit characteristic of the above AA model that leads to a modification factor

to yield correct limit AA values [9,12], as

$$|\chi_{L'}|^2 = \frac{k^2}{(C_L')^2}\left[\left(H_1^*\right)^2 + \left(H_4^*\right)^2\right]\cdot R(c)\,, \tag{42}$$

Where

$$R(c) = \int_0^B\int_0^B \exp\left[-c_0\frac{\sigma_w}{U}n|x_1 - x_2|\right]dx_1dx_2 \tag{43}$$

is the introduced coefficient determined by the along-wind coherence of vertical gusting over the whole chord width, where B is the chord width, c_0 a constant reflecting the level of coherence, σ_w/U the turbulence intensity and n the frequency of turbulent component. Note that in this situation $R(c) \to 0$ when $n \to \infty$.

While the introduction of $R(c)$ provided the AA function with a correct limit value when k (or n) approaches to an infinite value, there still seems to be no way to provide a quantitative validation for such a model resulted from the combination of an illogical one and a quasi-steady factor based upon the wind coherence.

4.2 *"Equivalent" Theodorsen function*

A number of researchers also tried to determine the AA functions via flutter derivatives, as that proposed by Scanlan but in another point of view of "equivalent" Theodorsen function [13-16]. The main idea of this method is supposing Eq. (19), the bearing between Theodorsen circulation function $C(k)$ and Sears function $\chi_s(k)$, is applicable in bluff deck sections. Thus, according to (31), an "equivalent" indicial function can be identified through the experimentally obtained flutter derivatives, then a "equivalent" $C_{eq}(k)$ may be determined by Garrick's interrelation $C(k) = \varphi(0) + \overline{\varphi'}$, finally the "equivalent" Sears admittance function can be written according to (19) as

$$\chi_{eq,s}(k) = [J_0(k) - \mathrm{i}J_1(k)]C_{eq}(k) + \mathrm{i}J_1(k)\,. \tag{44}$$

This is logically incorrect either. As a matter of fact, according to Theodorsen's original paper [10], one may obtain

$$C(k) = F + \mathrm{i}G = \frac{-J_0(k) + \mathrm{i}Y_1(k)}{-[J_0(k) + Y_0(k)] + \mathrm{i}[Y_1(k) - J_0(k)]}\,, \tag{45}$$

where the integration of J_0 and J_1 are given out in Eq. (17), Y_0 and Y_1 were expressed in the original paper as

$$Y_0(k) = -\frac{2}{\pi}\int_1^\infty \frac{\cos kx}{\sqrt{x^2-1}}dx\,,\quad Y_1(k) = -\frac{2}{\pi}\int_1^\infty \frac{x\sin kx}{\sqrt{x^2-1}}dx\,. \tag{46}$$

Obviously, J_0, J_1, Y_0, Y_1 all are component functions included in the Theodorsen function $C(k)$. Thus, if one tries to use an "equivalent" form of $C(k)$ to describe aerodynamic characteristics of bluff sections, it warrants justification for component functions J_0 and J_1 remaining the original forms applied in aeronautics instead of "equivalent J_{eq0}" and "equivalent J_{eq1}".

5 EXPERIMENT-BASED AA FUNCTIONS

A number of researchers have experienced the method of determining the AA functions of bluff bridge deck sections through model tests in wind tunnel with certain turbulence characteristics [17-20]. This seems to be the only possible approach to date to deal with bluff sections, and the AA functions so-obtained are expected to be applicable to the buffeting assessment of the full

bridge immersed in various turbulent fields, as that of a thin airfoil. Such a methodology entails the AA functions being univariate functions of the reduced frequency k and, particularly being independent on the structural motion and the turbulent gust structure. This is true for an airfoil due to the assumption of potential flow around it always works, and also due to un-stationary aerodynamic forces resulted from rigid translation, rigid rotation, harmonic gusts, or an arbitrary combination of them can be treated separately and superposed linearly.

Thus, for a bluff body section, the critical problem is not whether the linear superposition principle still holds, but, for a given configuration, to what extent this principle can be considered to hold approximately. Some researches indicate that the AA functions of bridge deck do show dependence on the wind field characteristics (Matsuda, et al, 1999; Larose and Mann, 1998). But they failed to provide an explanation. Therefore, if experiments are designed in order to identify AA functions of a bridge deck section, the following two problems should be considered cautiously:

6 CONCLUSIONS

Theoretical investigation presented in this paper indicated that the linear superposability of the unsteady aerodynamic forces acting on a 2-dimensional section, which is applicable for a thin airfoil where wake effects are linear superposable, would not be valid for bluff bridge deck sections due to a series of hypotheses, such as the approximate linear distribution of the wake vortices, incompressible and inviscid flow, as well as potential flow around, etc., are no longer applicable. This directly throws doubt on some basic concepts underlying the current bridge aerodynamics, especially on, for a given deck configuration, the existence of AA functions dependent uniquely on reduced frequency. Some theoretical AA models, which have been obtained in essence according to the linear superposition principle and employed now rather extensively in bridge aerodynamics, are discussed in this literature and turn out to be, to a great extent, illogical. Thus, the superposability of the unsteady aerodynamic forces, or the level of this superposability could arrive at, should probably be a root factor relating to the issue of AA functions as well as to the flutter-buffeting theoretical model in bridge aerodynamics. Future work relating to this subject, the superposability of unsteady aerodynamic forces, will be experiment-based investigations aiming at deck configurations extensively employed in long-span bridges.

The influences of sectional parameters to aerodynamic performances of H-section hangers

M.G. Liu [a]; Z.Q. Chen [b]

[a]*State Key Laboratory of Subtropical Building Science, South China University of Technology, Guangzhou, Guangdong, China*
[b]*Wind Engineering Research Center, Hunan University, Changsha, Hunan, China*

ABSTRACT: An in-depth investigation on the H-section hangers' aerodynamic performances in forms of flutter, galloping and vortex shedding has been conducted through a series of wind tunnel tests. A total of 7 H-section models with different flange perforation ratio and depth-to-width ratio are tested to investigate their effects on aerodynamic behaviors of hangers, respectively. It is found that the flange perforation may enhance the aerodynamic capability against galloping and vortex resonance to some extent but have no obvious effects on flutter instability, at least for the shallow H-section with D/B=0.417 (flange depth D to web width B). The aerodynamic performances of H-sections could be significantly influenced by the increase of depth-to-width ratios. The results indicate the increase of depth-to-width is better than the flange perforation in resisting wind-induced vibrations of H-section hangers.

KEYWORDS: Hangers; H-sections; Wind-induced vibration; Flutter; Galloping; Vortex-induced vibration; Wind tunnel test.

1 INTRODUCTION

In recent years, slender hangers with H-sections are widely adopted in arch bridges built in China. In comparison with hangers with circular section, the H-section hanger is prone to variously wind-induced vibrations due to unfavorably aerodynamic shape. From the early 1970's large-amplitude wind-induced vibrations of H-shape have been observed in several arch bridges worldwide. Ulstrup[1] listed 9 episodes of wind-induced vibrations on slender bridge components. In the 1990's, the H-shaped hangers of Jiujiang Yangtze River Bridge built in China, suffered vortex-induced vibration at moderate wind shortly after completion of the bridge[2]. In August 2006, large-amplitude torsional vibrations of H-section hangers were observed in Dongping Bridge, which were characterized as torsional flutter through wind tunnel studies conducted by Chen and co-workers[3].

Many efforts have been made to study aerodynamic characteristics of H-sections in the past decades. Chi *et al*.[4] conducted wind tunnel tests of three typical H-sections with aspect ratios being approximately 1:1, 3:4 and 1:2, and they determined that the Strouhal numbers for these sections are in the neighborhood of 0.125~0.134. Chi & Vossoughi[5] predicted the vortex-induced response of H-section cylinders by a modified Hartlen-Currie model which needs to be calibrated with wind tunnel data. Maher & Wittig[6] investigated the vibration of H-shaped members of the Commodore Barry Bridge and its possible remedy countermeasures including modifying H sections into box sections and the uses of cable ties and perforated web. They concluded that vortex-excited vibration in heaving modes and torsional modes may build up for the H-sections studied and the vibration in the Commodore Barry Bridge is very likely to a kind of traditional Karman vortex shedding. Kubo *et al*.[7] studied the vortex-excited oscillation and galloping of H-section cylinders of Langer bridge, Japan, in both laminar and turbulent flow. They clarified that both vortex-induced vibrations and galloping may develop in the laminar flow, but

in the turbulent flow the former seldom takes place and the oscillation became mainly a galloping one. Ruscheweyh[8-9] developed a mathematical model for predicting the vortex-excited vibration, formulated taking into account the increasing correlation length of the exciting force with increasing vibration amplitude. Using this model, Ruscheweyh predicted the amplitudes of the vortex-excited bending vibration of several steel stacks and bridge hangers. The predicted amplitudes had been verified with full-scale measurements and the agreement is very good. This model had been included into Eurocode ENV 'Wind Action'. Ma *et al.*[10] studied the characteristics of galloping and vortex-induced vibration of H-section hangers, and they pointed that there were apparent effect on the galloping stability by changing the size/shape of web perforation in hangers.

Although H-sections are aerodynamically unstable, they are convenient in manufacture connection and maintenance and are frequently adopted in practice. It is therefore very important to study aerodynamic characteristics of H-sections from the point of view of its wind resistant design. More systematic studies of H-sections, including four section models with different web perforation ratios and 16 section models with different depth-to-width ratios, web and flange perforation ratios, were conducted to studying the performances of flutter, galloping and vortex-excited vibration by Chen & Liu[3, 11]. As a follow-up study, seven section models are conducted to studying the influence of flange perforation ratios and depth-to-width ratios on the aerodynamic performances of H-sections, respectively.

2 EXPERIMENT SETUP

2.1 *Model construction*

A prototype suspender is selected as a basic section for wind tunnel study of aerodynamic characteristics of H sections. The web is 1.2m wide and the flange is 0.5m deep. The depth-to-width ratio of the H-section is D/B=0.5/1.2=0.417, and the model is denoted as M0. On the basis of the model M0, two groups of models are designed and tested in wind tunnel, respectively. The sectional parameters of the models are provided in Table 1. The first group of section models haves the same depth-to-width ratio as the model M0, but with different flange perforation ratios (the flange perforation is a rectangular hole as shown in Figure 1, and perforation ratio is defined as the ratio of perforation area to the whole flange area before openings). The flange perforation ratios of these models are 11%, 20.1% and 28.6%, and these three models are named as A-1, A-2 and A-3, respectively. Another group with models named as B-1, B-2, B-3, respectively, have the same flange perforation ratios as the model M0, with different depth-to-width ratios of 0.625, 1.0 and 1.333, respectively.

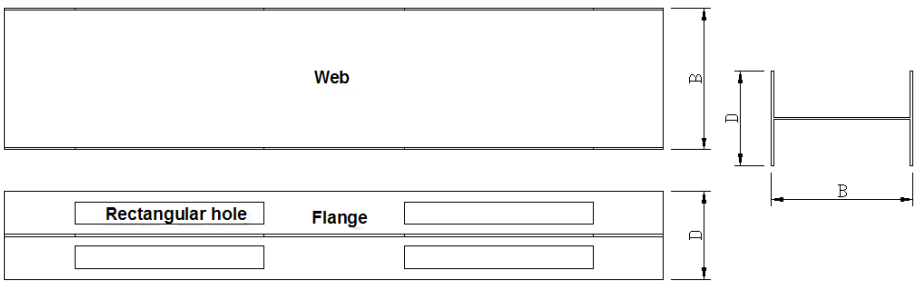

Figure 1 Cross-section parameters for H-section

Table 1 The prototype sectional parameters of the 7 models

Model	Width *B* (cm)	Depth *D* (cm)	Depth-to-width ratio *D*/*B*	Flange perforation ratio (%)
M0	120	50	0.417	0
A-1	120	50	0.417	11
A-2	120	50	0.417	20.1
A-3	120	50	0.417	28.6
B-1	120	75	0.625	0
B-2	120	120	1.0	0
B-3	120	160	1.333	0

2.2 *Experiment procedure*

All the wind tunnel tests are carried out in uniform flow at HD-2 wind tunnel of Hunan University. The section models are manufactured at 1:4 geometrical scale except model B-2 and B-3 with scale of 1:6. The dynamic modes of the hanger are analyzed with a finite element model using shell elements, the axial force applied on the prototype is considered as the initial stress effect, and the axial force for all prototype hangers is the same value. Table 2 summarized the main parameters of the seven prototype H-section hanger. The section models are elastically suspended in wind tunnel with 8 springs in the way that the ratio of torsional frequency to weak-axis-bending frequency is nearly the same ratio of the prototype's, as shown in Figure 2. Each spring is connected to a dynamometer to measure the vibration. The highest prototype wind speed for each section model testing is higher than 70m/, which is calculated as torsional mode. The definition of wind attack angle α is illustrated in Figure 3. The wind direction normal to the flange is defined as α=0°, and the direction perpendicular to the web is defined as α=90°. The tests are carried out for wind attack angles in the range of 0°~90° with an increment of 5°.

Table 2 Parameters of H-section hangers

Prototype parameters		M0	A-1	A-2	A-3	B-1	B-2	B-3
Mass (kg/m)		235.6	219.7	206.4	194.1	307.9	444.6	559.8

3 RESULTS AND DISCUSSIONS

3.1 *Aerodynamic performance of model M0*

The flutter and galloping instabilities develop for the model M0, Figure 4 shows the prototype critical wind velocity of flutter and galloping under different attack angles. It is shown that galloping instability occurs at attack angles close to 0^o and 90^o, the corresponding critical wind speed is around 23.6m/s and 60m/s, respectively. Moreover, the flutter instability develops for wind attack angles from 20^o to 35^o, and the lowest critical wind speed is in the vicinity of 20m/s, a wind velocity being likely to occur in most parts of China. The criterion for flutter instability is taken as the mean square deviation of torsional amplitude being large than 0.5^o; this threshold is based on the Chinese design standard[12].

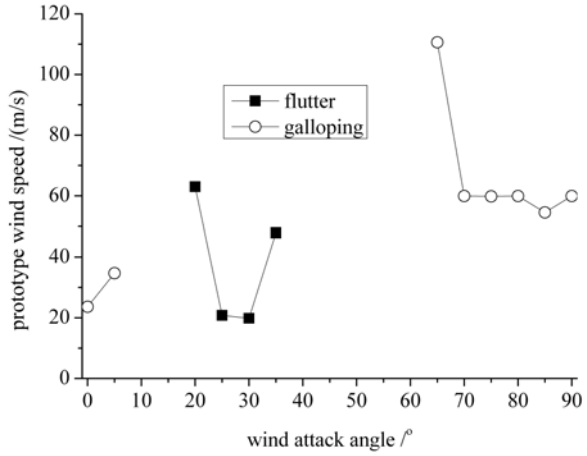

Figure 4 Flutter and galloping characteristics of model M0

Table 3 shows the vortex-induced vibration characteristics for model M0 for the wind attack angles from 0° to 90°. The wind speed and amplitude of vortex shedding response in Table 3 have been converted to full scale values. The permitting amplitude of vortex resonance is determined as[12]:

$$[h_a] = \frac{0.04}{f_b} \tag{1a}$$

$$[\theta_a] = \frac{4.56}{Bf_t} \tag{1b}$$

where $[h_a]$ and $[\theta_a]$ are the permitting amplitude for bending and torsion, respectively; f_b and f_t are the bending frequency and torsion frequency, respectively, and B is the width of H-section. the Strouhal number is calculated as:

$$St = \frac{fL}{V} \tag{2}$$

where f is the frequency of vortex-excited resonance; L is a characteristic dimension of the body projected on a plane normal to the mean flow velocity, defined as $L=D$ for $0^o \le \alpha \le 45^o$ and $L=B$ for $45^o < \alpha \le 90^o$; V is the velocity of the oncoming flow. From table 3, it is shown that: (1) the onset wind speed of vortex resonance at different angels is around 4-10.5m/s for bending and 8.6-21.5m/s for torsion, which is generally low value; (2) the lock-in wind speed of vortex resonance for bending is generally less than 3.3m/s. However, the wind speed of torsional vortex-induced vibration is large and the maximum is around 30m/s observed at attack angle of 20°; (3) the maximum amplitude for bending and torsion at different attack angles is 0.132B and 5.3°, respectively, which are both exceeding the permitting amplitude.

Table 3 Vortex resonance characteristics of model M0

Wind attack angle (°)	Wind speed (m/s)	Vibration type	Maximum amplitude	Permitting amplitude	Strouhal number
0	4.0-6.9	Bending	0.132B	0.018B for weak-axis bending	0.238
	8.6-10.5	Torsion	1.1°		0.126
	19.1-22.2	Torsion	5.1°		0.057
5	4.9-6.9	Bending	0.073B		0.194
	17.5-32.1	Torsion	5.2°	1.8° for torsion	0.062
15	13.4-20.1	Torsion	4.6°		0.081

20	16.8-20.7	Torsion	3.6^{o}	0.065
	21.5-57.4	Torsion	5.3^{o}	0.051
30	10.5-13.8	Bending	0.022*B*	0.091

In order to facilitate comparison the vortex-induced vibration characteristics of H-section with different sectional parameters, a normalized value *R* which is used to evaluate the vortex resonance, considering the influence of onset wind speed, lock-in wind speed and maximum amplitude, is determined using:

$$R = \sum_{i=1}^{n} \frac{\Delta V_i}{V_i} \cdot \frac{A_i}{[\cdot]} \tag{3}$$

where ΔV, A and V are the lock-in wind speed, maximum amplitude and onset wind speed at a certain vortex-induced vibration; [.] is the permitting amplitude calculated using equations (1a) and (1b); n is the total number of the vortex resonance. From the expression (3), it is shown that the greater the index value *R*, the worse the performance of vortex-induced vibration. The normalized *R* for model M0 is 17.5.

3.2 *Effect of flange perforation ratios*

Torsional flutter and galloping instability is observed for all the models under different wind attack angles. Table 4 summarizes the ranges of wind attack angle and the prototype critical wind velocities. Compared with the model M0, the attack angles occurring torsional flutter increase for the three models with flange perforation, and the flange perforation does not visibly promote the flutter critical wind speed of H-sections. These results conclude that flange perforation has little effect on the flutter performance of H-section hangers.

As seen in Table 4, flange perforation has different impact of the galloping instability for weak axis and strong axis. For the model A-1, the galloping instability still appear at 0^{o} and 5^{o} (weak axis) with a little increasing in critical wind speed compared with model M0. For the model A-2 and A-3, no galloping instability occurs at weak axis. It is concluded that the galloping performance for the weak axis of H-sections is much improved by flange perforation. However, the flange perforation only promote the attack angles occurred galloping instability rather than the critical wind speed.

Table 4 Flutter and galloping characteristics of H-section hangers with different flange perforation ratios

Model		Wind attack angle	Lowest prototype wind speed	Reduced wind speed *V/fB*
M0	Flutter	20^{o}-35^{o}	19.8m/s	7.6
	Galloping	0^{o}-5^{o}	23.6m/s	10.3
		65^{o}-90^{o}	54.5m/s	7.5
A-1	Flutter	10^{o}-35^{o}	24.5m/s	9.5
	Galloping	0^{o}-5^{o}	27.0m/s	11.9
		70^{o}-90^{o}	51.7m/s	7.3
A-2	Flutter	0^{o}-25^{o}	14.3m/s	5.6
	Galloping	80^{o}-90^{o}	36.6m/s	5.3
A-3	Flutter	0^{o}-25^{o}	21.0m/s	8.6
	Galloping	80^{o}-90^{o}	46.7m/s	7.0

Table 5 shows the vortex-induced vibration characteristics of the three H-section models for the wind attack angles from 0^{o} to 90^{o}. It is concluded that: (1) for the model A-1 with small flange perforation, the vortex-induced resonance occurs mainly in the weak axis, which is similar to model M0. For the model A-2 and A-3 with large flange perforation, vortex induced vibra-

tion occur both in the weak axis and strong axis; (2) the attack angle interval occurred vortex resonance for model A-3 with flange perforation ratio of 28.6% is less than other models'; (3) the wind velocity of vortex-induced vibrations is less than 10m/s, not improved compared with the model M0; (4) the flange perforation can improve the maximum amplitude in the weak axis, but no effect is found to reducing the amplitude in torsion and strong axis; (4) the normalized *R* is declined with the flange perforation gradually increasing, it is shown that flange perforation play a beneficial role in improving the vortex vibration performance of the H-section hangers.

Table 5 Vortex resonance characteristics of H-section hangers with different flange perforation ratios

Model	Wind attack angle (^{o})	Bending vortex resonance				Torsional vortex resonance				*R*
		Wind speed (*m/s*)	Maximum amplitude	Permitting amplitude	Strouhal number	Wind speed (*m/s*)	Maximum amplitude	Permitting amplitude	Strouhal number

	5	4.5-5.0	0.015*B*		0.208	7.3-19.4	5.4^o		0.139	
	70	51.8-56.2	0.004*B*	0.006*B*	0.130	/	/		/	
	75	51.3-69.4	0.007*B*		0.130	/	/		/	

3.3 *Effect of depth-to-width ratios*

Table 6 summarizes the ranges of wind attack angle, the prototype critical wind velocities and the reduced wind speed for flutter and galloping. Compared with the model M0, the critical wind speed of flutter for the three models B-1, B-2 and B-3 is much improved and about one times higher than M0'. However, as seen in Table 6, the critical wind speed is not varied with the depth-to-width ratios changing from 0.625 to 1.333. Additionally, the ranges of wind attack angle for model B-2 and B-3 is much smaller than the model M0 and B-1. It is concluded that the increase of depth-to-width ratios have positive effect in stabilizing the flutter of H-sections.

Form the Table 6, it is shown that increasing the depth-to-width ratios notably improves the galloping performances in strong axis, namely enhancing the critical wind speed and reducing the attack angle intervals occurred galloping instability. Nevertheless, the increase of depth-to-width ratios can promote the critical wind speed while enlarging the attack angle intervals in the weak axis.

Table 6 Flutter and galloping characteristics of H-section hangers with different depth-to-width ratios

Model		Wind attack angle	Lowest prototype wind speed	Reduced wind speed *V/fB*
M0	Flutter	20^o-35^o	19.8m/s	7.6

	Gallop-	0^o-5^o	23.6m/s	10.3
	ing	65^o-90^o	54.5m/s	7.5
	Flutter	15^o-40^o	39.2m/s	12.2
B-1	Gallop-	0^o-10^o	22.4m/s	7.6
	ing	75^o-90^o	59.5m/s	8.0
	Flutter	15^o; 75^o	38.8m/s	8.9
B-2	Gallop-	0^o-10^o	39.4m/s	8.7
	ing	80^o-90^o	69.6m/s	9.4
	Flutter	75^o-80^o	44.5m/s	9.1
B-3	Gallop-	0^o-20^o	57.6m/s	9.4
	ing	85^o-90^o	80.1m/s	10.9

Table 7 shows the vortex-induced vibration characteristics of the three H-section models for the wind attack angles from 0^o to 90^o. These results concluded that: (1) the ranges of attack angle is significantly more than the model M0. For the model B-1, vortex induced vibration develop for 12 of the 19 wind attack angles; (2) bending motions of vortex-induced vibrations dominate for the models with $H/B \geq 0.625$, and the three models develop torsional motions at a certain wind attack angle; (3) most of the onset wind speed of vortex-induced vibrations for model B-1 is less than 10m/s. For the models B-2 and B-3, the lowest wind velocity is around 30m/s; (4) most of the maximum amplitude of vortex resonance for model B-1 are below the permitting amplitude, which is notably improvement compared with the model M0. However, for the model B-2 and B-3, the maximum amplitude appear to deteriorate with the depth-to-width ratios increasing; (5) the normalized R of model B-1 is only 1.7, but for the model B-2 and B-3, the values are 8.4 and 12.8, respectively. It is concluded that the modest depth-to-width have positive effect in stabilizing the vortex resonance of H-sections.

Table 7 Vortex resonance characteristics of H-section hangers with different depth-to-width ratios

4 CONCLUSIONS

A series of experimental study of wind-induced vibrations of vertical flexible hangers with H-sections for different flange perforation ratios and depth-to-width ratios is carried out using section models. The main conclusions from this study are as follows:

(i) flange perforation can enhance the aerodynamic capability against galloping and vortex induced vibration;

(ii) the increase of depth-to-width ratios significantly improves the aerodynamic performances except the vortex resonance, which gives a best vortex shedding capability with depth-to-width ratio D/B=0.625;

(iii) the increase of depth-to-width is better than the flange perforation in resisting wind-induced vibrations.

Messina strait bridge - confirmatory wind tunnel testing of the bridge towers

1. Introduction: As a part of Messina Strait Bridge design, a confirmatory wind tunnel test was undertaken by RWDI on a 1:100 scale aeroelastic mode. The model was designed based on drawings provided by COWI and structural dynamic information analyzed by Parsons Transportation Group (PTG), the Project Management Consultants for the Stretto di Messina Project. This large model (4 m tall) allowed physical modeling of tuned mass dampers and simulations of a wide range of additional damping. Tested Re range was 1×10^5-3.5×10^5 in smooth flow. The aeroelastic model test was supplemented with a sectional model test in scale 1:100 at Re 2×10^4-2×10^5.

The aeroelastic model test focused on "Free-Standing" and "In-Service" towers configuration. Being confirmatory, the tests were limited in scope compared to the breadth of the original tests carried out by the Project Contractors Eurolink (EIK) The confirmatory tests found various wind induced instabilities that will need to be mitigated both "In-Service" tower configuration and during construction.

2. Aeroelastic Model Tests

The objective of the wind tunnel investigation was to verify the fundamental aerodynamic stability of the structure in smooth flow and to compare against the results obtained by EIK. A 1:100 scale multi-degree-of-freedom (Figure 1) aeroelastic model of the standalone tower was designed and built to simulate the aerodynamically important tower modes as computed by Parsons. The results of the aeroelastic model test were converted to full scale response predictions by application of appropriate scaling factors.

The aeroelastic model was composed of a spine and shell system, to provide the required structural stiffness, the inertial properties, and the geometric shape. For the legs, the spine consisted of a hollow rectangular steel tube over the first 2/3 of height where a splice system connects it to an aluminum rectangular

Figure 1: Tower 1:100 aeroelastic model, In-Service configuration.

tube extending to the tower top. The two lower crossbeam spines consisted of machined steel H-beams whereas the upper crossbeam spine was a machined H-beam made from aluminum. The upper portion of the leg spine was required to be made of aluminum for the selected damping mechanism and due to mass requirements. The exterior geometry of the shell was hand- built using a strong foam core with smooth finish, thin wood diaphragms and robust plywood seats (Figure 2). The top shell of each leg was built utilizing the stereo lithography modeling technique which uses an epoxy resin. The shell was separated into multiple segments, with small air gaps in between of about 2 mm. All gaps were taped with a soft, elastic tape to ensure air tightness of the model without influencing its mechanical properties. The shell segments were painted, sanded and polished to ensure a very smooth finish with the least possible imperfections which possibly could trigger an early transition into critical Re regime.

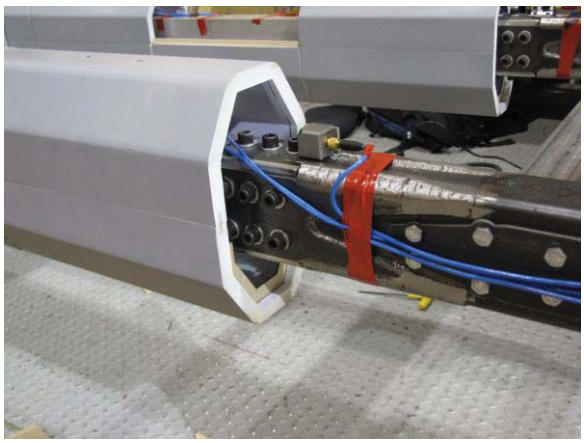

Figure 2: Model details – spine & shell, 3-axial accelerometer

The mass and its distribution on the model were designed to meet the similarity requirements for the generalized mass based on the provided full scale mass information. This was achieved by augmenting the mass of the spine and shell system with lumped masses where required.

To represent the tower in its In-Service condition, a system consisting of an aluminum spine extension and tensioned steel cables mounted at the top of the Free-Standing tower was designed to simulate the first longitudinal and torsional modes. This design was also verified by carrying out a finite element dynamic analysis on the overall structure. The measured mode shapes were in good agreement with the targets (Figures 3). Note that the In-Service model did include the necessary additional stiffness to replicate the targeted mode shapes for the longitudinal direction. The In-Service condition transverse modes were not simulated in terms of generalized mass since they would entail significant additional mass from the main cable and deck motions. The intent of replicating this given configuration was to study the across-wind vortex shedding vibrations (stability) alone, considering the transverse modes not being a problem for the bridge in service.

Figure 3: Mode Shapes - Analytical vs. Model (1st mode comparisons)

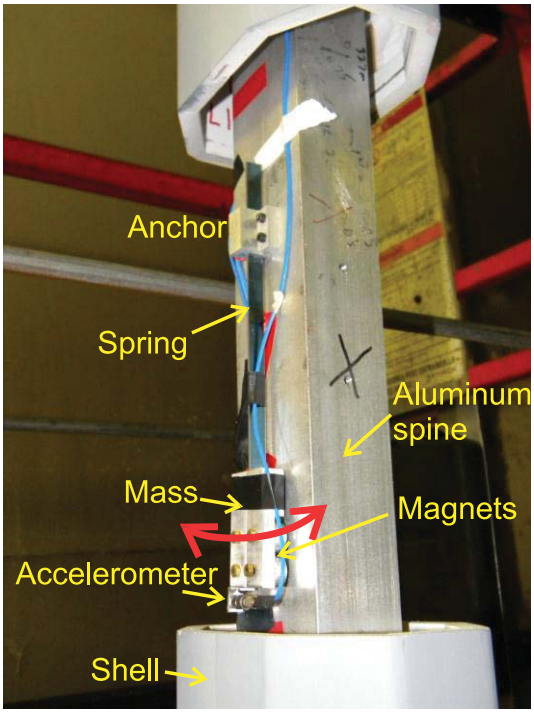

Figure 4: Tune Mass Damper installed on model spine.

To allow for damping variation in the fundamental modes of vibration being studied, tuned-mass dampers (TMD) were designed and built based on the Eddy current mechanism where the relative motion of a magnetic field in a conductor dissipates energy (Figure 4). By introducing an aluminum spine over the upper portion of the tower legs, the spine itself became the conductor able to dissipate energy. Multiple TMDs were attached to the spine representative of the behavior of general inherent structural damping, in the range from about 0.5% to 3.3% of critical. The model without dampers had very low inherited damping in the range of about 0.1% being close to linear over a wide range of amplitudes. Each TMD was made from spring steel flexures supporting an aluminum block where 4 magnets were fixed. Due to internal modeling constraints, the dampers were located at 3 discrete heights, corresponding to full scale elevations of approximately 280m, 310m and 340m. At each of these heights, up to 4 TMDs were installed and tuned to the desired frequencies. The dampers were also constrained by the internal void space in the shells, requiring the selection of an over-damped type system to limit the TMD motions. Based on the above considerations, the dampers were designed with an active mass of 94.5

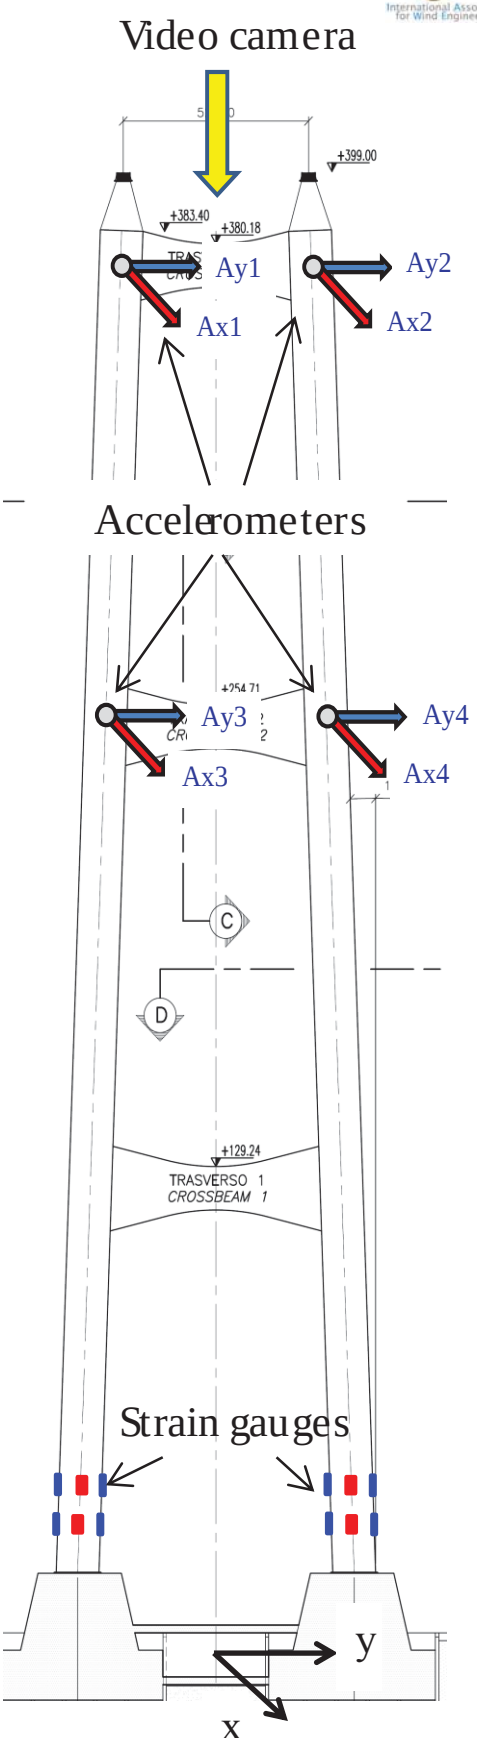

Figure 5: Instrumentation package

grams each. For the Free-Standing tower configuration, the TMD frequency was set to be equal to the fundamental longitudinal model frequency (4.45 Hz), and the TMD damping ratio was set to approximately 17% of critical. By selecting 1 to 4 TMDs located at the available mounting positions, variation in damping levels was achieved. The same devices were applied on the In-Service tower where the TMD damping ratio was approximately 6%. Note that in this case, TMDs were used to increase simultaneously the damping for the longitudinal and torsional modes (16.3 Hz and 19.4 Hz). The damping of the various modes of vibration was measured in off-wind conditions, using the free vibration decay method, and was found to be linear over a wide range of amplitudes for most of the tested cases; slightly un-tuned TMDs resulted in beating effects which were observed in the free decay signals. Even in this case, where both the model and the dampers exhibited damping linear to the amplitude, fitting the response envelope was possible to reliably estimate the actual damping of the system. The model was instrumented with four tri-axial accelerometers mounted on the tower leg spines above the middle cross beam (elevation 259.9 m) and at the top cross beam (elevation 372.2 m), to measure accelerations in the horizontal plane in x and y directions. Strain gauges were installed on the leg spines, at elevations of 33.7 m and 64.2 m, to measure bending moments about axes x and y. Figure 5 shows the selected coordinate system and the instrumentation locations.

The wind tunnel test took place at the 3 m x 6 m Propulsion and Icing Wind Tunnel of the NRC-IAR Aerodynamics Laboratory. This wind-tunnel has an open-circuit layout with a test section of 3.1 m x 6.1 m cross section with a 12.2 m length. The fan is normally driven electrically (750 kW) but high-speed operation (up to 70 m/sec) can be accommodated by a gas turbine drive system (6,000 kW). The minimum wind speed is about 4 m/sec when outside atmospheric winds are calm whereas the maximum speed that can be reached is around 35 m/sec on the electrically driven fan alone.

The model was mounted at the centre of a 25 mm thick steel turning disc to allow variation of the wind direction. For all tested stability runs, uniform and smooth flow was simulated. Under this uniform, smooth-flow like conditions, the background turbulence level in the wind tunnel is approximately 0.5% to 1.0%. The signals from the accelerometers, strain gauges and propeller anemometers, were collected at 250 Hz for 90 seconds at each measurement point and the data was low pass filtered at 80 Hz prior to A/D conversion. The data acquisition system also acquired the ambient temperature, pressure, and relative humidity, as well as the reference pitot-static wind-speed. The primary intent of the study was to identify any fundamental aerodynamic phenomenon in the range from about 10 m/sec up to about 75 to 80 m/sec at full scale. The following scaling principles have been used for this study:

$[\text{Dimension}]_m = [\text{Dimension}]_p \times 100^{-1}$	(geometry)
$[m]_m = [m]_p \times 100^{-3}$	(lumped mass)
$[m_L]_m = [m_L]_p \times 100^{-2}$	(mass per unit length)
$[\zeta]_m = [\zeta]_p$	(structural damping ratio)
$[V]_m = [V]_p \times [f]_m \times [f]_p^{-1} \times 100^{-1}$	(wind speed)
$[\delta]_m = [\delta]_p \times 100^{-1}$	(displacement)
$[A]_m = [A]_p \times [f]_m^2 \times [f]_p^{-2} \times 100^{-1}$	(acceleration)
$[F]_m = [F]_p \times [f]_m^2 \times [f]_p^{-2} \times 100^{-4}$	(force)
$[M]_m = [M]_p \times [f]_m^2 \times [f]_p^{-2} \times 100^{-5}$	(moment)

where "p" designates the prototype (i.e., full scale) and "m" the model. Since it is not critical to follow Froude scaling for vertical structures such as the current stand alone bridge tower (except for the secondary P-Delta effects) the Froude number scaling was not applied for optimal model design. The stiffness of each element (tower legs and crossbeams) was adjusted to achieve target frequencies

and mode shapes which combined with the operational speed range of the wind tunnel, could convert to the required full-scale wind speed range. At the beginning of the test campaign, a speed sweep test was carried out, measuring base moments and forces to ensure the test would remain in the subcritical Re range. In the tested range 1×10^5-3.5×10^5, measured base loads normalized by pressure remained similar without a drop which would be an indication of a transition into the critical Re range. Wind direction 0° designates winds normal to bridge span.

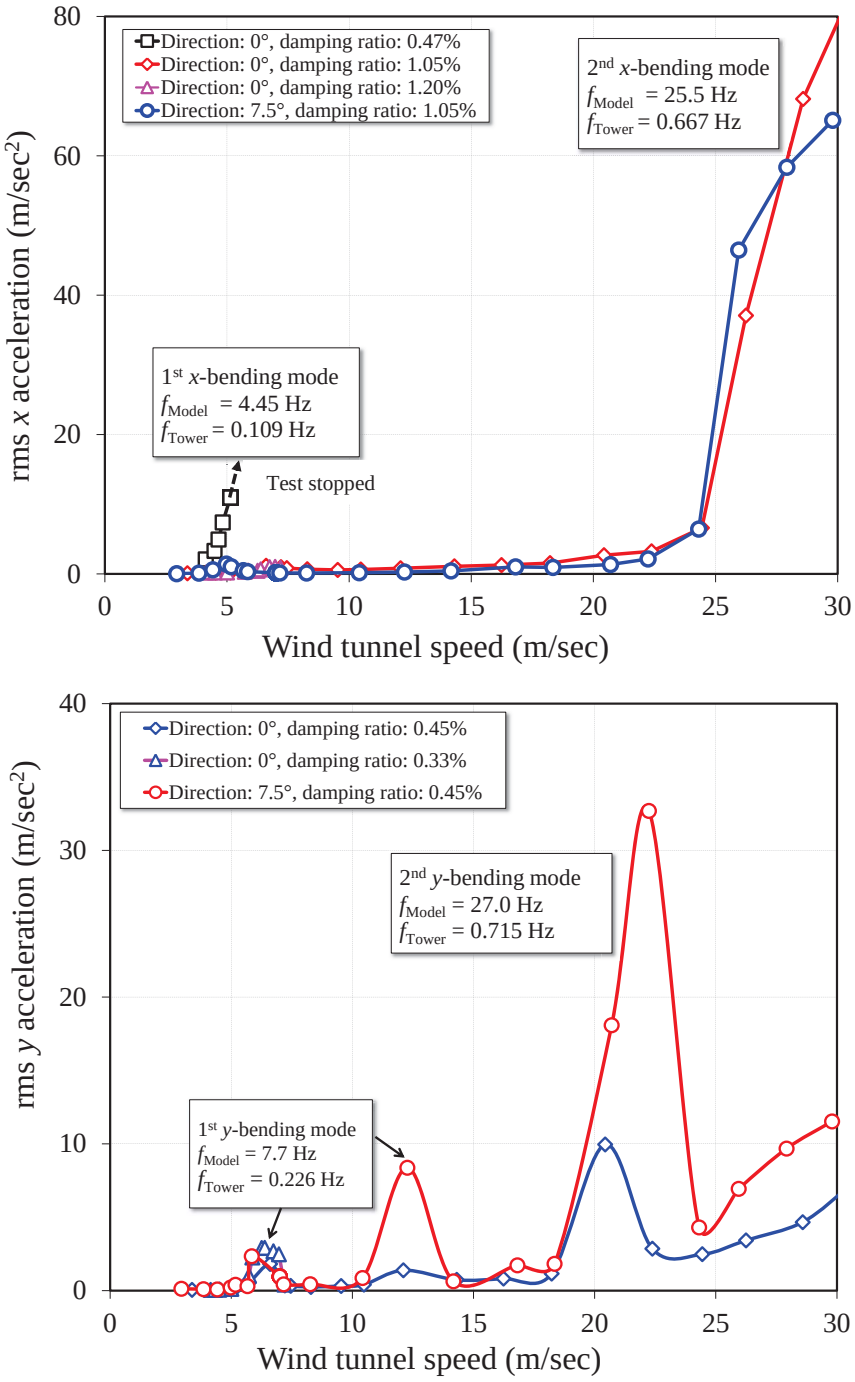

Figure 6: Free-Standing tower response in smooth flow, wind directions 0 & 7.5 deg. rms x/y accelerations vs. wind tunnel speed at top cross-beam

2.1 The Free-Standing Tower

The Free-Standing tower is often identified as a critical stage during bridge construction due to aerodynamic instability problems. In this test multiple vortex shedding excitations were found involving many modes of vibrations. The top of Figure 6 summarizes x longitudinal accelerations at the elevation 3.78 m (upper cross-beam). Vortex shedding responses were observed in the first longitudinal mode for directions 0° and 7.5° and for speeds from 4 to 7 m/sec, corresponding to full scale speeds of 9.5 to 16.7 m/sec. The actual test was stopped during the low damping test to avoid damaging the model when maximum root-mean-square (rms) accelerations of about 11 m/sec^2 (0.62 m/sec^2 full scale) were recorded at speed 5.1 m/sec (12.2 m/sec full scale) for damping ratio 0.47%. Note, the project acceleration limit is 0.5 m/sec^2. All other tests were carried with increased by TMDs damping of at least about 1.0% thus the vortex shedding responses did not reach more than 1.5 m/sec^2 which corresponds to a full scale rms acceleration of 0.09 m/sec^2.

Vortex shedding responses were observed in the 2nd longitudinal mode of vibration at wind directions 0° and 7.5° where the onset speed was about 25 m/sec (full scale speed of 62.3 m/sec). Just before the tests were stopped, the model scale rms accelerations obtained were beyond 60 m/sec^2 (3.7 m/sec^2 full scale). This level of accelerations corresponds to a damping value of about 0.5% of the critical, value which was assumed to be reasonable for second-order modes.

Transvers y-accelerations are also shown in the lower Figure 6. Vortex shedding responses were identified for the first transverse mode of vibration, at directions 0° and 7.5°, for speeds from 5.4 m/sec to 7 m/sec, corresponding to full scale speed from 15.4 m/sec to 20 m/sec. The maximum acceleration was in the range of 3 m/sec^2 (corresponding to a full scale value of 0.24 m/sec^2) where the damping ratio was 0.33% of the critical. A stronger vortex shedding response, again associated with the first transverse mode of vibration, was identified for 7.5° at about 12.3 m/sec (33.5 m/sec full scale). The acceleration was about 8.4 m/sec^2 (corresponding to a full scale value of 0.62 m/sec^2) and for a level of damping 0.45%. For the same wind speed at direction 0°, it seems that the tower was also excited by vortex shedding but at lower amplitudes.

A third vortex shedding response peak was found for 0° at 20.4 m/sec (50.8 m/sec full scale) and for 7.5° at 22.2 m/sec (55.3 m/sec full scale) , where the second transverse mode of vibration was excited. Measured accelerations were in the range of 10 m/sec2 (corresponding to a full scale value of 0.6 m/sec2) and 32.7 m/sec2 (full scale value of 2.0 m/sec2), respectively. These accelerations were measured with damping value of 0.5%. Note all damping levels refer are in off-wind conditions.

The first torsional mode (not shown here) was excited by vortex shedding for both directions 0° and 7.5°, at 20.4 m/sec (53.5 m/sec full scale) and 16.8 m/sec (44.1 m/sec full scale), respectively. At 0°, an acceleration of 17.3 m/sec^2 (corresponding to a full scale value of 1.19 m/sec2) was measured whereas a value of 11.8 m/sec^2 (full scale value of 0.81 m/sec^2) was found for 7.5°. These accelerations were measured with a damping ratio of 0.5%.

2.2 The In-Service Tower

In-Service tower was modeled by tying the top of the tower to the tunnel walls. It should be noted that stiffness effects of the main cable were modeled by offsetting up the attachment point. Added

mass effects were not modeled but these were considered small for most of the x-modes of interest where the tower would pivot about the main cable saddle points.

Figure 7 presents accelerations measured from different runs where the model scale accelerations are shown as a function of the tunnel speed for different wind directions and levels of damping. Presented x-accelerations were measured at the model elevation of 2.60 m corresponding to the middle cross beam elevation, 259.9 m.

The level of damping was varied for the first longitudinal mode of vibration (16.3 Hz) and first torsional (19.4 Hz) mode, and was not adjusted for the first transverse (8.4 Hz). Using again the same set of TMDs tuned to the required frequencies, the obtained damping levels for the first longitudinal mode were from about 0.3% to 3.2% and 0.27% to 2.9% for the first torsional mode. The inherent damping of the first transverse mode was in the range of 0.48% to 0.75% for all test runs. The test results obtained for the In-Service tower showed multiple vortex shedding excitations. Vortex shedding x-responses were observed in the first longitudinal mode of vibration for all directions (0°, 7.5° and 20°), for 15 m/sec to 19 m/sec, corresponding to full scale speed speeds of 40 m/sec to 50.7 m/sec. Before the test was stopped (because the model was damaged), a maximum acceleration of about 20.7 m/sec^2 (1.58 m/sec2 full scale) was recorded at 17.3 m/sec (45.4 m/sec full scale) for to a damping ratio of 0.3%. By increasing the damping ratio to approximately 1.0% of the critical, the vortex shedding responses at direction 0° were suppressed. However, the vortex shedding responses remain significant for directions 7.5° and 20°, even with levels of damping in the range of 1.5% to 1.6%. For instance, the measured acceleration for direction 20° reached 7.8 m/sec^2 (0.58 m/sec^2 at full scale).

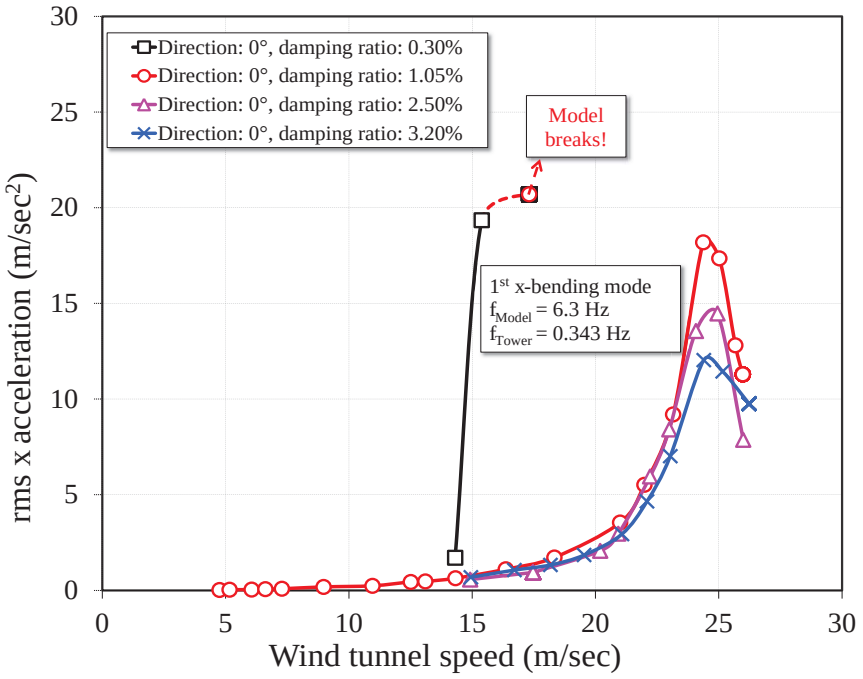

Figure 7: In-Service tower: rms x-accelerations vs. wind tunnel speed at the middle cross-beam

At wind direction 0° only, persistent vibrations were observed in the first longitudinal mode of vibration and for speeds between 22 m/sec (full scale speed of 58.7 m/sec) and 26 m/sec (69.4 m/sec). Peak acceleration of 18.2 m/sec^2 (1.31 m/sec^2 full scale) and 12 m/sec^2 (0.85 m/sec^2 full scale) were measured for damping levels of 1.05% and 3.2%, respectively.

Observed responses in the transverse y-direction (not shown here) cannot be directly applied for full scale predictions due to the expected high added mass and aerodynamic damping by the main cable motions which would likely subdue all tower motions in transverse direction.

The first torsional mode was found to be excited by vortex shedding for direction 0° at 14.3 m/sec (42.7 m/sec full scale) and for the relatively low damping value of 0.27%. The differential peak acceleration estimated was about 14.9 m/sec^2 (corresponding to a full scale value of 1.33 m/sec^2). This instability was suppressed by adjusting the damping level to 1.0%.

As with the along-the-bridge responses, a persistent vortex shedding response was identified at higher wind speeds (> 24 m/sec model scale, corresponding to > 71.9 m/sec at full scale) for directions 0° and 7.5°. The measured accelerations reached 24.2 m/sec^2 (2.17 m/sec^2 full scale) for a damping level of 1.05% of critical at 0°. By increasing the damping to 2.9% of the critical, this value was reduced to 15.0 m/sec^2 (1.35 m/sec^2 full scale). With a level of damping of about 1.9% of the critical and for direction 7.5°, the peak acceleration was in the range of 17.2 m/sec^2 (1.51 m/sec2 full scale) for a speed of 25.4 m/sec (corresponding to a full scale value of 75.2 m/sec).

2.3 Summary of the aeroelastic model test

Free-Standing tower

1. Tests through a range of wind speeds, damping and wind azimuths did capture aerodynamic instabilities where multiple modes of vibration were excited;
2. Some of these excitations exceeded the design criterion of 0.5 m/sec^2;
3. The excitations were identified as: a) vortex shedding at lower speeds and b) wake instabilities at higher speeds in along-, across-flow and torsional motions for directions normal to the bridge span.

In-Service tower

1. The In-Service tower was modeled by installing tensioned cables above the top tower elevation.
2. Tests were carried through a range of wind speeds where the amount of damping was tuned to different quantities for control of vibrating modes involving along the bridge motions only. Vortex shedding instabilities and wake excitation induced motions in several modes.
3. Some results exceed the design criterion at damping levels higher than the design specification.
4. Three excitation mechanisms were identified:
    a) Vortex shedding involving in-phase motions of the tower legs (bending mode) with St=0.2;
    b) Vortex shedding involving out-of-phase motions of the tower legs (torsional mode) characterized by St>0.2;
    c) Vortex shedding and wake induced instability with St=0.135 (combined bending & torsion).

5. Additional verification tests on aeroelastic model in scale 1:200 were also carried out at Politecnico di Milano at similar low Re range which confirmed the main finding of this study.
6. POLIMI & PARSONS tests brought to the conclusion that the wake induced type of excitation (St=0.135) was more difficult to suppress, but also that with 4% non-dimensional damping the design criterion request could be attained. As a final judgment it was recommended that additional tests in the large scale 1:100 should be performed during the Esecutivo Design Phase with TMD devices more closely reflecting the full scale ones, specifically as far as concerns the TMD "stand alone" damping ratio. The correct design of the TMD for Tower Free-Standing conditions was in fact forced to the In-Service conditions (higher frequency and same TMD mass) with a final 6% “stand-alone” TMD damping ratio at the In-Service frequency. So that the TMD Wide-Band design changed in a Narrow-Band design having more critical behavior in terms of tuning.

3. Sectional Mode Tests

The same model shells as of the aeroelastic model were used to produce a sectional model with similar mass & damping properties. This part of the study included: a) measurement of static force and moment coefficients required for wind loads; b) aerodynamic stability; and, c) decay / build-up & limit-cycle data base collection for vortex shedding numerical simulation model parameter identification.

Static force and moment coefficients were measured where one of the two tower legs was mounted on a force and moment balance flexure. An identical "dummy" leg was mounted downwind, initially, from the instrumented model. The entire assembly was installed on a turntable which could be rotated to any angle of interest. The assembly (upper Figure 8) also included large splitter plates to ensure two-dimensional flow. Measured coefficients are shown in Figure 9.

A sectional model test simulating expected mass and damping properties at full scale was carried out. An analytical model was developed to predict the across-wind vortex shedding vibration using the single-degree-of-freedom (Van der Pol oscillator) formulation proposed by Scanlan [1,2,3]. Figure 10 shows a good agreement where the predicted rms amplitudes generated with damping levels 0.85% and 2.0% are in line with the experimental data.

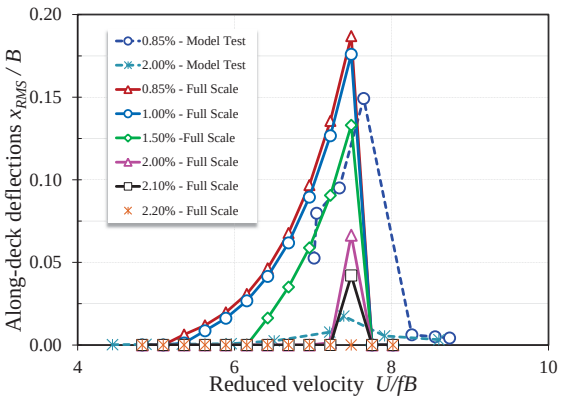

Figure 10: 1:100 sectional model test vs. analytical predictions of x-deflections.

Figure 8: Tower 1:100 sectional model test

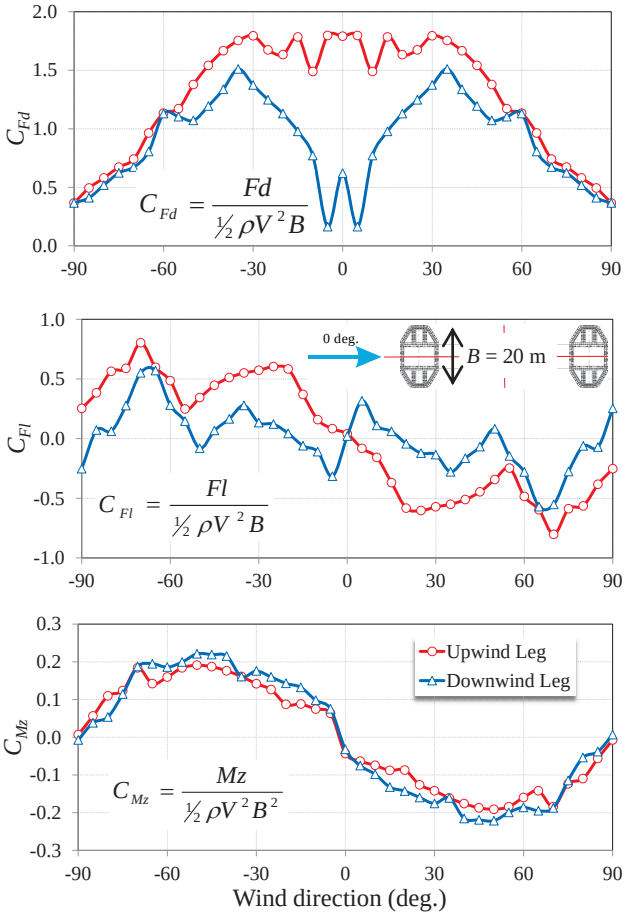

Figure 9: Static force and moment coefficients.

The sectional model test however did not show the St=0.2 mechanism found of the aeroelastic model. It was possible to suppress vortex shedding vibrations in vertical and torsional direction at St=0.12~0.14 with relatively modest level of damping (2~3%). The fact that during the aeroelastic model test, it was not possible to suppress the vibration at St=0.135 even with 3% damping, implies that these are likely different mechanisms where wake and other 3D effects did prevail in the aeroelastic model test. Another torsional motion peak was found at St=0.25, a speed similar to that found in the aeroelastic model test, although at lower lever of excitations.

Compared to the aeroelastic model tests, the observed differences were attributed to: 3D end effects near the tower top; simplifications - inclined legs with variable distance taken as parallel; presence of wide cross-beams at critical locations (tower top, 2/3 elevation); and possible Reynolds number effects. The predictions in terms of amplitudes of the 2D sectional model test were viewed as conservative since they do not include any 3D flow effects which will tend to reduce the uniformity of the vortex wake and the associated fluctuating forces on the tower legs.

4. Conclusions

A unique aeroelastic model test programme was carried out for the Messina Strait Bridge tower. On a comparatively large model in scale of 1:100, damping was controlled by TMD devices which effectively replicated their full scale mechanics in terms of active mass, frequency and viscos damping. Although not fully explored to its capacity, this allowed assessing the effectiveness of the TMD system proposed for the real tower in a manner reflecting the full scale conditions.

The most important result of the test campaign was that the Messina Strait Bridge towers will need auxiliary devices for motions control (dampers) during both construction and In-Service conditions. Whereas the vortex shedding sources of vibrations were relatively straightforward to suppress, requiring likely damping in the order of 2% to control the motions, the wake induced type of excitation proved more difficult, requiring level of damping in the range of over 3 to 4% to attain the required motion criteria.

Acknowledgments

The team of National Research Council of Canada led by Dr. G. Larose who carried out instrumentation, testing and data reduction is highly acknowledged. The authors would like to thank to the specialists of RWDI and Motioneering Inc., for the design and construction of all models and damper system, and wind tunnel testing.

Aerodynamic effects on streamline box girder in active wind tunnel with multiple fans and vibrating airfoils

T.T. Ma, L. Zhao, S.Y. Cao, Y.J. Ge

SLDRCE, Tongji University, Shanghai, China, tingtinghorse@126.com

ABSTRACT: The aerodynamic behavior of a streamline box section model is characterized in an active wind tunnel with multiple fans and vibrating airfoils in Miyazaki University, Japan. A series of single harmonic fluctuating wind with discrete frequencies are generated. The aerodynamic admittance components obtained via cross spectral identification method for different oncoming flows present obvious deviation between each other, which implies the limitation of traditional buffeting theory. More attention is emphasized on the relationship between aerodynamic forces and wind turbulence components, along- and cross-wind, in sinusoidal flow conditions. It is found that the cross-wind turbulence has dominant influence on lift and pitching moment forces. With the strengthening of along-wind turbulence, the lift force increases, while the drag and pitching moment forces vary with different trend in different range of frequency. Moreover, it is found that the contribution of along-wind turbulence to lift and pitching moment forces is neglectable compared with that of the cross-wind turbulence, while for the drag force, the two turbulence components present comparative contributions.

1 INTRODUCTION

Buffeting is a kind of stochastic forced vibration caused by the turbulence existing inherently in natural wind. Buffeting is hence inevitable for any bridges exposed to the natural wind. To ensure the safety of the construction for long-span bridges, the buffeting analysis is necessary to be refined. Many previous studies have made great contribution to the development of buffeting theory [1-4]. For the consideration of the non-stationarity and incompletely spanwise coherence of natural turbulence, the aerodynamic admittance was employed to modify the quasi-steady aerodynamic forces. On buffeting analysis, Sears's function for a vertical wind gust [1] and Devenport's formula for an along wind gust [2] are usually employed. The accuracy of the result depends largely upon the accurate estimation of aerodynamic admittance. Wind tunnel testing is the most popular method to investigate the effects of wind on long-span bridges. Some studies focused on aerodynamic admittance have been conducted in conventional boundary-layer wind tunnels [3-4]. Considering the limits like the adjustment of wind power spectral density and the integral length scale in passive turbulence generation method, a few actively controlled wind tunnels have been proposed [5-8].

Multiple-fan wind tunnel is a relatively fine active generation technique in Japan. In the active wind tunnel in Miyazaki University, 99 fans arranged in a 9 wide by 11 high matrix has been used to generate only along-wind turbulence (*u*-turbulence), which coincide well with the natural turbulent flow [9]. Then in this wind tunnel, a series of single harmonic fluctuating wind were generated to research the relationship between aerodynamic forces induced by sinusoidal fluctuating wind with discrete frequency and broadband turbulence, which verifies the principle of

superposition of aerodynamic forces for sinusoidal flows in some specified frequency range (Fig. 1)[10,11]. However, active wind tunnel with only multiple-fan equipment could not produce sufficient cross-wind turbulence (*w*-turbulence), which may result in significant effects on buffeting forces. In contrast, there is some testing conducted in a wind tunnel equipped with only a series of wings to produce *w*-turbulence, while the *u*-turbulence is neglected [12]. However, the contribution of *u*-turbulence and *w*-turbulence to aerodynamic forces has not been clearly understood. Based on the limits of the existing active wind tunnels, additory active vibrating airfoils are equipped in the wind tunnel of Miyazaki University together with the multiple-fan equipment to produce two-dimensional (*u*- and *w*-) active turbulence. Based on the superposition principle of aerodynamic forces referred above, more attention is emphasized on the relationship between aerodynamic forces and wind turbulence components in sinusoidal flow condition.

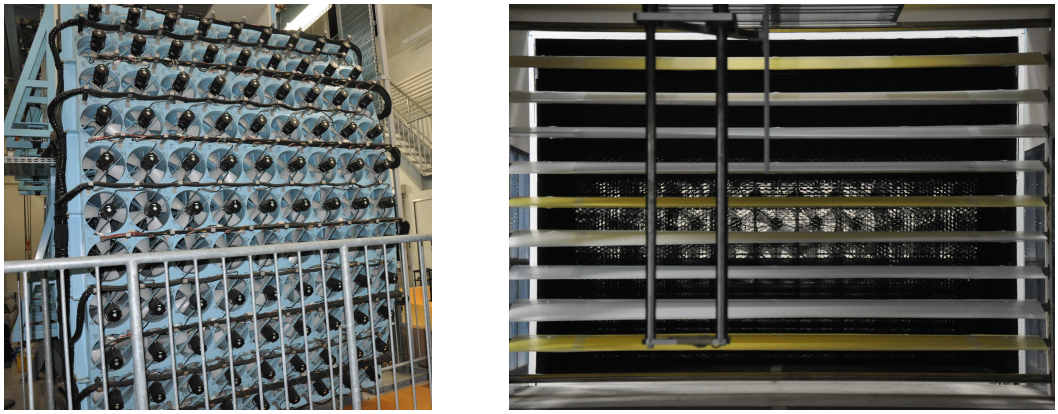
2 EXPERIMENTAL ARRANGEMENT

2.1 *Active turbulence generator*

Fig.1 shows the active wind tunnel with multiple fans and vibrating airfoils in Miyazaki University, Japan. This wind tunnel is an open-circuit one with 99fans of 270mm in diameter at the front. The fans are arranged in a 9 wide by 11 high matrix (Fig. 1(a)). The vibrating airfoils are set to be 1.5m downstream from the honeycomb (Fig. 1(b)). The test section is 15.5m long (maximum), 2.538m wide and 1.804m high. The maximum wind velocity is about 15m/s, while 9m/s for sinusoidal flows with fluctuating amplitude of 3.5m/s. The maximum fluctuating frequency can reach to 5Hz. In this experiment, active fans and vibrating airfoils are combined to produce

sinusoidal turbulent flows of different dominant frequencies and different values of power spectral density (PSD) of *u*- and *w*- turbulence, denoted as S_u and S_w respectively.

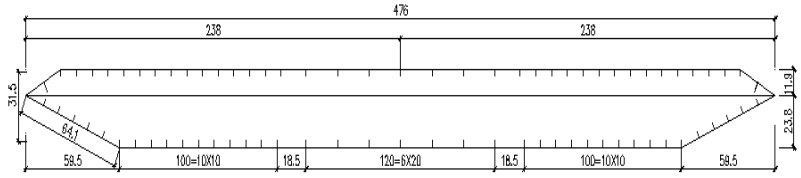


(a) Multiple fans (b) Vibrating airfoils

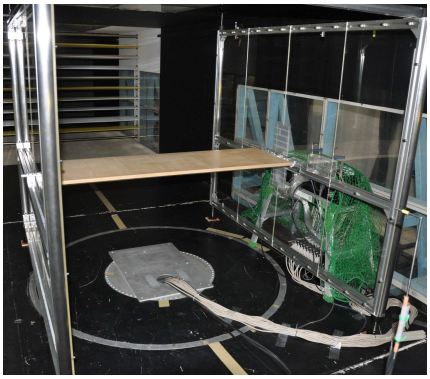
Fig. 2 Active wind tunnel with multiple fans and vibrating airfoils

2.2 *Fixed model tests*

The deck section adopted for tests is a 1:60 scale section model of a streamline box shape. Fig. 3 shows the cross section of the section model and the model in tests. A pressure measurement system was set up for the measurement of aerodynamic forces. There are 80 points around the section under measurement and for each testing process two sections (section 1 and section 2) are simultaneously measured. The static angle of attack of the bridge section is 0°.



(a) Cross section of the section model



(b) Section model in tests

Fig. 3 Streamline box section model

In this experiment, special study about the turbulence statistics along the test section is conducted to identify the relatively steady section for model tests. Fig. 4 shows the variation of PSD,

integral scale, turbulence intensity and average wind velocity of two measure points. It illustrates that when the distance from the honeycomb ranges between 4.1m and 4.6m, the turbulent flows keep relatively steady. The section model is finally fixed 4.4 meters away from the honeycomb.

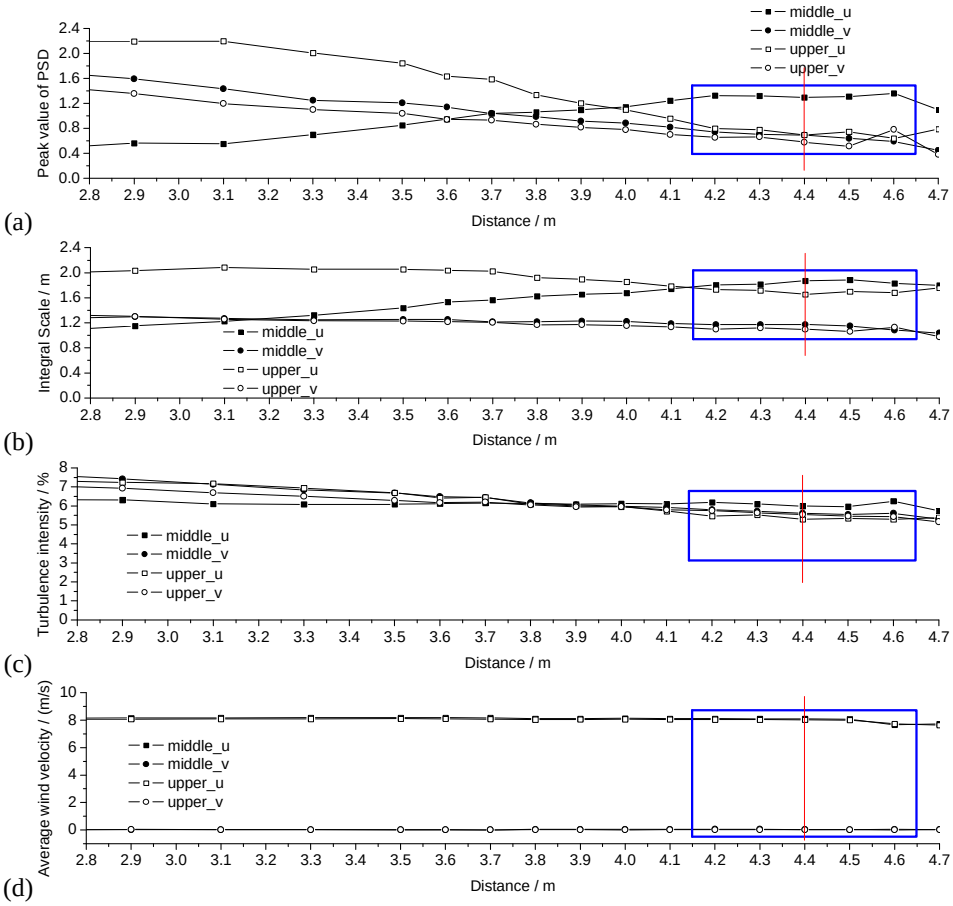


Fig. 4 Variation of (a) PSD, (b) integral scale, (c) turbulence intensity and (d) average wind velocity along test section

In order to study the relationship between aerodynamic forces and wind turbulence components, the active fans and vibrating airfoils are combined to produce a series of sinusoidal fluctuating winds. The detailed testing conditions are listed in Table 1. There are totally three kinds of combination between active fans and vibrating airfoils. In Table 1, f means the dominant frequency of the sinusoidal flow.

Table 1 Different combination of motion for active fans and vibrating airfoils

Testing serial No.	Description of fluctuating flows in entrance section
1	Multiple fans: f=0.2-4.0Hz; $\triangle f$=0.1Hz Average wind velocity U=8m/s ; Amplitude A1=2m/s Airfoils: Vibrating with the same frequency as active fans Amplitude A2=10°
2	Multiple fans: U=8m/s; A1=0 Airfoils: f=0.2-4.0Hz; $\triangle f$=0.2Hz; A2=10°
3	Multiple fans: f=0.2-4.0Hz; $\triangle f$=0.2Hz; U=8m/s; A1=2m/s Airfoils: static

3 EXPERIMENTAL RESULTS

3.1 *Identification of aerodynamic admittance*

Based on the traditional buffeting theory, the aerodynamic admittance functions have been employed to modify the quasi-steady aerodynamic forces. For example, the lift component is expressed as [2]

$$L_b(t) = \rho UB\left(C_L(\alpha)\chi_{Lu} + 1/2\left(C_L'(\alpha) + C_D(\alpha)\right)\chi_{Lw} w(t)\right) \tag{1}$$

where ρ=air density; U=mean wind velocity; B=2b is the bridge deck width; C_L and C_D =mean lift and drag coefficients, respectively; $C_L' = dC_L / d\alpha$;α is the mean static angle of attack of the bridge section; and χ_{Lu}, χ_{Lw} = aerodynamic admittance functions for lift force.

The aerodynamic admittance components here are identified by cross spectral admittance identification method. The aerodynamic admittance for lift force can be expressed by

$$\chi_{Lu}(f) = \frac{S_w(f)S_{Lu}(f) - S_{wu}(f)S_{Lw}(f)}{\rho UBC_L(\alpha)\left[S_u(f)S_w(f) - S_{wu}(f)S_{uw}(f)\right]} \tag{2a}$$

$$\chi_{Lw}(f) = \frac{S_u(f)S_{Lw}(f) - S_{uw}(f)S_{Lu}(f)}{1/2\,\rho UB\left[C_L'(\alpha) + C_D(\alpha)\right]\left[S_u(f)S_w(f) - S_{uw}(f)S_{wu}(f)\right]} \tag{2b}$$

where $S_{Lu}(f)$, $S_{Lw}(f)$ = cross power spectrum between lift force and u- , w- turbulence respectively; $S_{wu}(f)$, $S_{uw}(f)$ = cross power spectrum between u- and w- turbulence; $S_u(f)$, $S_w(f)$ =PSD of u- and w- turbulence.

For the comparison with Sears function, the aerodynamic admittance components shown in Eq. (2) are transformed into equivalent aerodynamic admittance (EAA) with an expression as follows

$$\left|\phi_{LL}(K)\right|^2 = \frac{4C_L^2(\alpha)\left|\chi_{Lu}\right|^2 S_u(K) + \left(C_L'(\alpha) + C_D(\alpha)\right)^2\left|\chi_{Lw}\right|^2 S_w(K)}{\left(4C_L^2(\alpha)S_u(K) + \left(C_L'(\alpha) + C_D(\alpha)\right)^2 S_w(K)\right)} \tag{3}$$

where $\left|\phi_{LL}(K)\right|$ is EAA for lift force; K=2πBf/U. EAA for drag and pitching moment forces, denoted as $\left|\phi_{DD}(K)\right|$ and $\left|\phi_{MM}(K)\right|$, have similar expression as Eq. (3).

3.2 *Aerodynamic admittance of streamline box section*

In this experiment, the time histories of buffeting forces components, i.e. lift, drag, and pitching moment components are obtained by integration of pressure measured around the model section. Three equivalent aerodynamic admittances are identified for each different testing condition listed in Table 1. Fig. 5 shows the comparisons of equivalent aerodynamic admittance (EAA) between different fluctuating flows for section 1. It is clearly shown that the aerodynamic admittance components obtained by cross spectral identification method present obvious deviation between different fluctuating flows. This indicates the limitation of traditional buffeting theory.

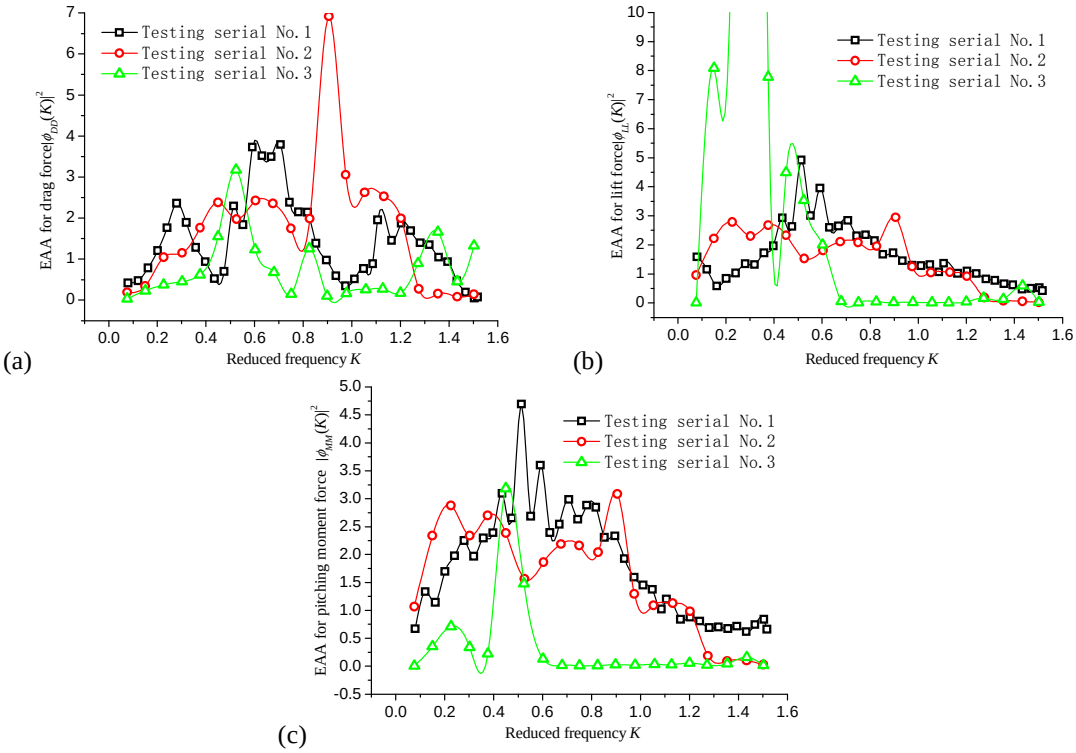

Fig.5 Comparison of equivalent aerodynamic admittance (EAA) for (a) drag force, (b) lift force, and (c) pitching moment force

For further understanding of the effects of turbulence on aerodynamic forces, the testing results for both section 1 and section 2 in a sinusoidal flow with dominant frequency of 2Hz are shown in Fig. 6. Although the PSD of horizontal and vertical turbulence, S_u and S_w, around dominant frequency shows much difference, the aerodynamic forces remain almost the same. This indicates that the aerodynamic admittance is related to the turbulent characteristics, which is different from the traditional buffeting theory.

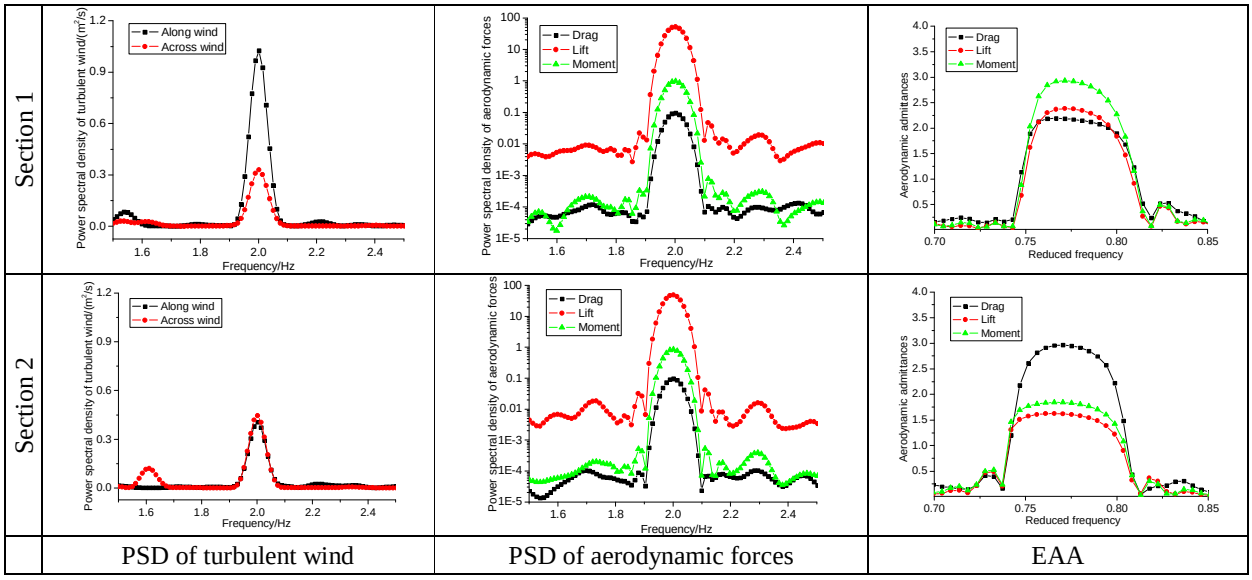

Figure 6 Comparison of the testing results of section 1 and section 2

3.3 *Sensitivity analysis of buffeting forces to turbulence*

For the sake of the limits in traditional buffeting theory, the effects of *u*- and *w*- turbulence (S_u and S_w) on buffeting forces (PSD of buffeting forces: S_L , S_D and S_M) are directly analyzed without the employment of aerodynamic admittance functions. For the purpose of the analysis about the sensitivity of buffeting forces to turbulence, several pairs of results with almost the same values of S_u (or S_w) at the same dominant frequency are selected. In contrast, the values of S_w (or S_u) present relatively obvious differences. The results are listed in Table 2 and Table 3.

Key: ↑= increase of S_F (F= *D*, *L*, *M*); ↓=decrease of S_F (F=*D*, *L*, *M*)

It is shown in Table 2 that all the three aerodynamic forces present increase with the increase of S_w. The contribution of S_w is predominant especially for lift and pitching moment forces. The results indicate the importance of correct simulation of *w*-turbulence in wind tunnels. From Table

3, we can see that the contribution of S_u to buffeting forces is more complex than that of S_w. With the increase of S_u, the lift force increases, while the drag and pitching moment forces present different trend of variation in different ranges of frequency.

Moreover, comparisons about the effects of *u*-turbulence and *w*-turbulence on buffeting forces are conducted. The results with regard to turbulent flows with dominant frequencies of 1.2Hz and 2.0Hz are selected from both Table 2 and Table 3. Here we define an average effects index k_u (or k_w) expressed as

$$k_u(or k_w) = \frac{\delta S_F}{\delta S_u(or \delta S_w)} \quad (F=D, L, M) \tag{4}$$

where δS_u, δS_w=variation of PSD of *u*-turbulence and *w*-turbulence at the dominant frequency and δS_F is the relative variation of PSD of buffeting forces. Fig. 7 shows the average variation of S_F resulted from the unit change of S_u and S_w.

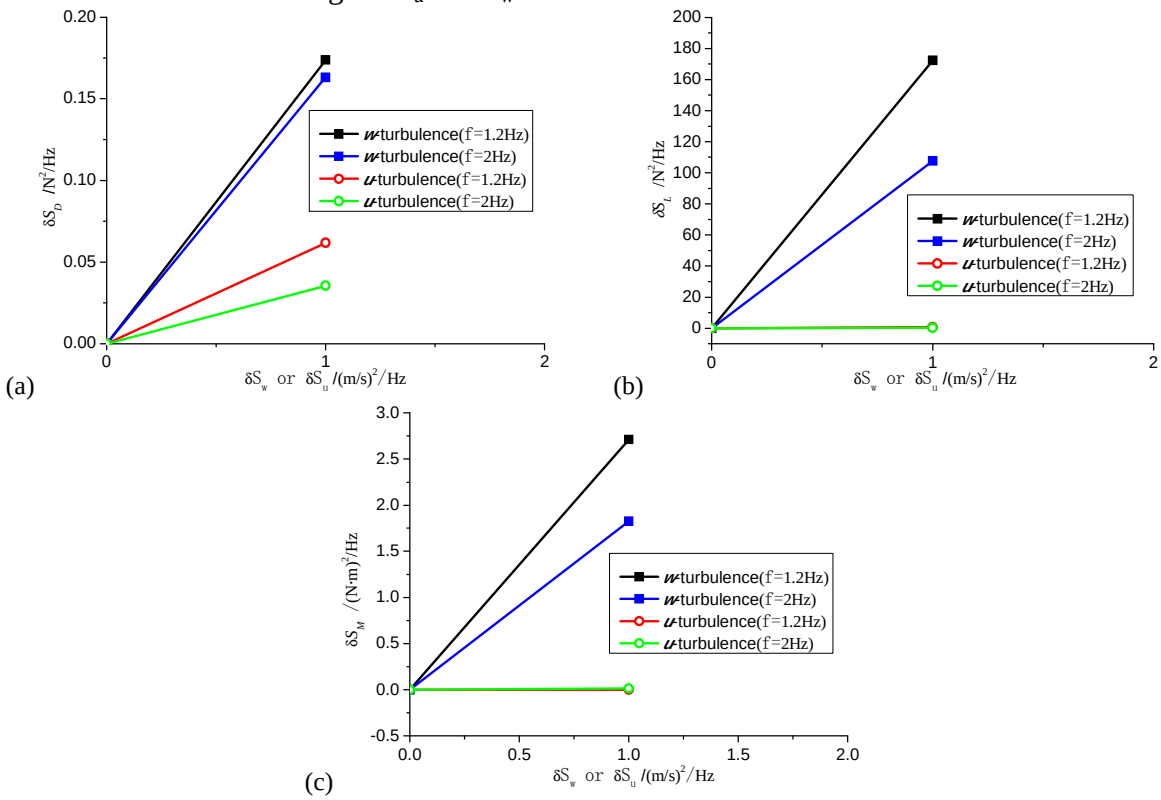

Fig. 7 Average effects of *u*- and *w*- turbulence on (a) drag, (b) lift and (c) pitching moment forces

It is clearly indicated in Fig. 7 that the lift and pitching moment forces are much more sensitive to the *w*- turbulence than *u*- turbulence. It is acceptable to neglect the contribution of *u*- turbulence. For the drag force, the contribution of the *u*- turbulence is less than that of *w*- turbulence. However, they keep the same order of magnitude, i.e. both the *u*- and *w*- turbulence should be corrected simulated for the accurate simulation of drag force.

4 CONCLUSIONS

A series of single harmonic fluctuating winds with different combination of *u*- and *w*- turbulence are generated in an active wind tunnel with multiple fans and vibrating airfoils in Miyazaki University. The experimental results about the relationship between flow turbulence and buffeting forces are analyzed. Conclusions of this study are summarized as follows:

(1) The traditional buffeting theory based on aerodynamic admittances has some limits. The aerodynamic admittance is related to the characteristics of the flow, which is different from the traditional buffeting theory.
(2) The *w*- turbulence has positive contribution to all the three buffeting forces, while the *u*- turbulence presents positive contribution only to lift force. The drag and pitching moment forces present different trend of variation in different ranges of frequency.
(3) The lift and pitching moment forces are much more sensitive to the *w*- turbulence than *u*- turbulence. It is acceptable to neglect the contribution of *u*- turbulence.
(4) Both the *u*- and *w*- turbulence should be corrected simulated for the accurate simulation of drag force, although the contribution of the *u*- turbulence is less than that of *w*- turbulence.

The conclusions above are qualitative ones based on the premise of 0° static angle of attack of the bridge section. More quantitative analyses based on different angle of attack are expected in future.

ABSTRACT ： A pressure measuring experiment on a streamlined bridge deck section model was conducted under simultaneous two-dimensional incident flows in an active-controlled wind tunnel. A commendable wind velocity modification approach based on the stable flow features of the active-controlled wind tunnel was adopted. The correlations of both incident winds and aerodynamic forces were studied, and an obvious impact of integral scales can be seen in this study. The decaying trend of root coherence with large ratios of integral scale to section-interval is a far cry from the conventional exponential expression, thus a new empirical expression is proposed to reflect the spatial coherence features in low frequency region.

KEYWORDS: active-controlled turbulences; aerodynamic loads; correlation coefficients; spatial coherences; empirical expression

1 INTRODUCTION

The existing buffeting theory for bluff body is derived from the airfoil aerodynamics, which is based on a “strip” assumption. The aerodynamic loads on a deck cross section, thus, are only due to the incident flows in the same plane with that section, which gives the aerodynamic loads a two dimensional feature. When these 2D (two-dimensional) forces are applied to a 3D (three-dimensional) structure, the spatial distribution and correlation of these forces along the span-wise have to be sufficiently considered. A criterion for assessing the correlation features of aerodynamic loads or incident flows between two cross-sections is correlation coefficient:

$$\mathrm{Cor}(x_1, x_2) = \frac{\overline{v_1(x_1,t)\cdot v_2(x_2,t)}}{\sigma_{v1}\sigma_{v2}} \quad (1)$$

where the over bar denotes time-averaging; v(x,t) is turbulent wind velocity ; σ_v is standard deviation of the turbulent components.

In the frequency domain, the joint acceptance function is used to represent the distribution and correlation features of aerodynamic loads or incident winds along the span-wise and between different modes:

$$|J(K)|^2 = \iint_0^L \frac{S_{R_1R_2}(K,\Delta x)}{\sqrt{S_{R_1}(K)}\sqrt{S_{R_2}(K)}}\Phi_i(x_1)\Phi_i(x_2)dx_1dx_2 \quad (2)$$

where $S_{R1R2}(K,\Delta x)$ denotes the cross-spectrum of buffeting forces or oncoming flows on different cross-sections at a distance of Δx; S_{Ri} (i=1,2) represents the auto-spectrum of buffeting forces or oncoming flows; $\Phi_i(x)$ is the i^{th} modal shape of the deck; $K=B\omega/U$ is reduced frequency; B is deck width; ω is oscillation frequency; U is average wind speed; L is deck length. In the above function the normalized cross-spectrum is defined as the root coherence function:

$$\mathrm{coh}_{R}^{1/2}(K,\Delta x)=\frac{S_{R_1R_2}(K,\Delta x)}{\sqrt{S_{R_1}(K)}\sqrt{S_{R_2}(K)}} \tag{3}$$

Davenport (1961) proposed one of the first heuristic root-coherence expressions for longitudinal turbulence, which is based on field measurements:

$$\mathrm{coh}_{u}^{1/2}(f,\Delta X)=\exp\left(-c*\frac{f\Delta X}{U}\right) \tag{4}$$

where c is decay factor; fΔx/U is reduced frequency, also used as a collapsing parameter. In early studies, the distribution of buffeting forces along span-wise was considered to be the same as the incident flows, however, a lot of experiments conducted in wind tunnels revealed a larger spatial coherence of the aerodynamic forces. And spatial coherence is not only related to the flow frequency and section-intervals but also has a relation with the integral scale, turbulence intensity, section features like the ratio of deck width to deck thickness, etc (*Matsumoto, 1994; Larose, 1998, 2003; Nagaoa, 2003; el at*).

Nevertheless, all those experiments were carried out in passive atmospheric boundary wind tunnels, some of the key fluid features, such as integral scale, oncoming flow coherence, PSD function of fluctuating wind, etc, cannot be easily reproduced in a passive wind tunnel. Integral scale of stochastic fluctuating wind, however, has a considerable influence on the spatial coherences of the aerodynamic loads, but the integral scale of stochastic fluctuating generated by a passive wind tunnel is always too small, comparing with the model scale. Furthermore, because the incident flow features on the central point of section model cannot be measured directly, the flow features at the up-stream or at the lateral of the section model were just adopted as replacements. As is known, the flow energy decays along the longitudinal direction and the wind velocities are not fully correlated along the lateral direction in a passive wind tunnel, thus the measured wind features cannot represent the real features on the central points of pressure measuring cross-sections, which leaves something to be desired. Moreover, the vertical and longitudinal turbulences cannot be well reproduced simultaneously in a passive wind tunnel, thus the spatial coherence features under simultaneous 2D turbulences have never been fully studied before.

In order to study the spatial correlations of aerodynamic loads under effectively simulated wind features and two-dimensional simultaneous incident flows, an experiment involving a stream-lined cross-section model was conducted in the active-controlled atmospheric boundary wind tunnel in Miyazaki University of Japan. The appellation “streamlined” refers to a closed-box deck designed with emphasis put on aerodynamics, but it is a strictly speaking bluff body with separated shear layers.

2 EXPERIMENTAL ARRANGEMENT

2.1 *Wind tunnel and experimental facilities*

Multiple-fans active wind tunnel in Miyazaki University consists of 99 independent blowers. It can effectively simulate the longitudinal average wind speed, turbulence profiles and different integral scales. Moreover, it can reproduce artificial stochastic wind waves under given controlling parameters (*Nishi et al. 1997; Nishi et al.1999; Cao et al. 2002)*. To generate the vertical turbulent components, an active-vibration grids is adopted which can generate the vertical turbulent wind sufficiently. Altogether 390 pressure tapping points were arranged in 5 parallel sections along span-wise, each section consists of 78 tapping points arranged along

chord-wise. Sampling frequency is 200Hz and sampling time is 100s. 3D hot-wire anemometers (KANOMAX model 1008), high precision electronic pressure scanners and simultaneous acquisition facilities (DASBOX model 2800) were adopted. Deviation of the signal caused by the length and diameter of piezometer tubes was modified.

The following figure illustrates the multi-fans and active-vibration grids in the active wind tunnel as well as the arrangement of tapping points:

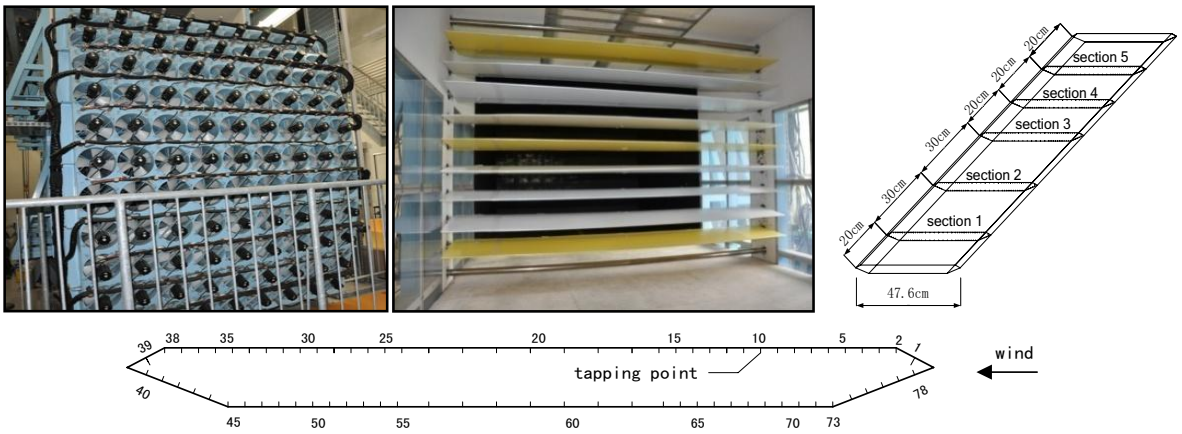

Figure 1. Active wind tunnel facilities and arrangement of tapping points

2.2 *Oncoming flow control and wind velocity modification*

The multiple-fans active wind tunnel can reproduce the target wind features sufficiently under given parameters. The von karman type wind spectrum was chosen as the target longitudinal wind spectrum, which has the following form:

$$S(f) = \frac{4 \cdot I^2 L_x / U}{\left[1+70.8 \cdot \left(\frac{f L_x}{U}\right)^2\right]^{5/6}} \tag{5}$$

where S(f) denotes the wind power spectrum; I, U, Lx and f represent the turbulence intensity, average wind speed, integral scale along the span wise, and wind frequency, respectively. As to the vertical turbulent wind spectrum, the Panofsky spectrum with the following form is adopted:

$$S(f) = \frac{\alpha \cdot u_*^2 / U}{(1+\beta \cdot \frac{f}{U})^2} \tag{6}$$

where α and β are coefficients relating to height. Figure 2 shows the target and measured spectrums of the u and w components:

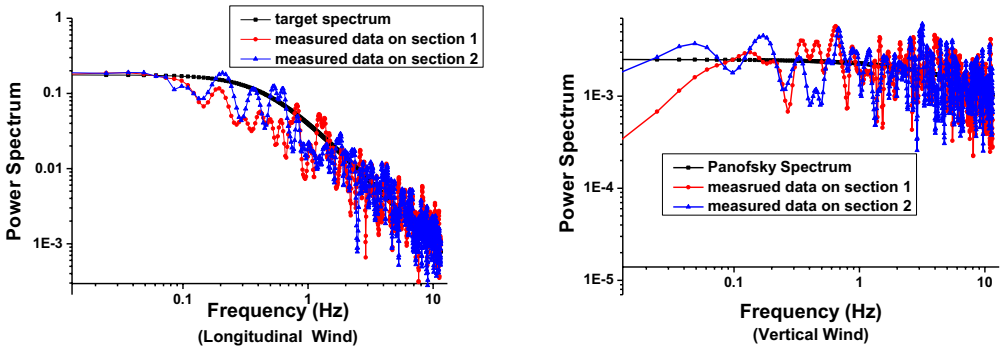

Figure 2. Target and measured power spectrums of longitudinal and vertical components

Aerodynamic forces are caused by the incident flows and are functions of the turbulent wind velocities at the reference point. The 1/4 chord point is often taken as the reference point according to the airfoil theory, and for bridge deck, the central point is always adopted. Because of the existence of section model, wind velocity at the central point of the model cannot be measured directly, thus the flow features are always measured at the up-stream or at the lateral of the deck. The measured wind features, however, are often taken as the flow features at the reference point. Because the wind energy decays along the longitudinal direction, and the wind velocities are not fully correlated between two points along the lateral direction, thus, the measured flow features cannot represent the real flow characters of the reference point.

To reflect the wind features of the reference point, a modification approach was adopted based on the stable flow features in active wind tunnel under given parameters. Firstly, a 3D hot-wire anemometer was fixed at the central point of the pressure-measuring section without installing the section model, then another one was fixed 45cm above it. Secondly, the wind velocities at these two points were measured simultaneously for a while, and the correlations of flow features like magnitude and phase between these two points were studied. A modification algorithm was proposed to reproduce the features of the lower point by using the data measured on the upper point. To examine the efficiency of this algorithm, ten validation tests under different flow conditions were conducted and it came to a commendable result.

Figure 3 illustrates a good modification result. “Target wind velocity” in this figure denotes the measured data by the 3D hot-wire anemometer fixed at the central point of pressure measuring section without the section model being installed, and the “measured data” denotes the wind velocity measured by the 3D hot-wire anemometer 45cm above the former one.

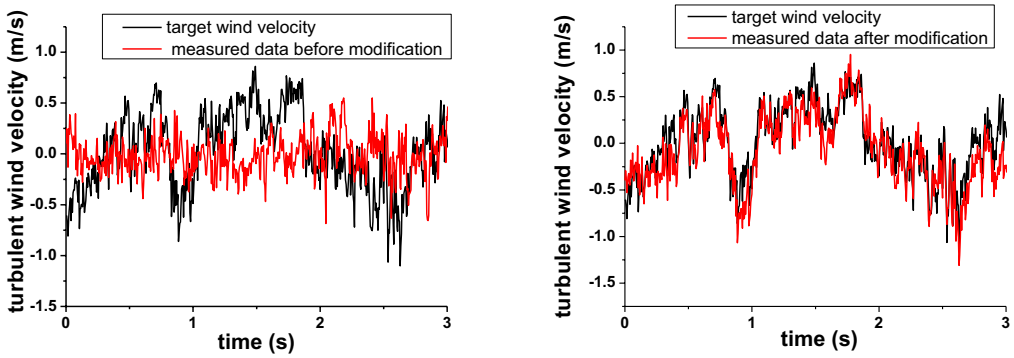

Figure 3. Target wind velocity series and measured data before and after modification

3 EXPERIMENT RESULTS AND DISCUSSION

Altogether 14 oncoming flow conditions with different flow features, like integral scale, turbulence intensity and average wind speed, were reproduced in the multiple-fans wind tunnel. Only the cross-section pressures of section 1, section 2 and section 4 were measured simultaneously with the incident flow velocities, because of the limit on the number of 3D hot-wire anemometers. Thus, the test conditions consist of 3 section-intervals (30cm, 50cm, 80cm) under 14 different flow conditions. The correlation features of aerodynamic forces and incident flows were studies in both time and frequency domains. The schematic diagram of simultaneous measurement of wind velocities and chord-wise pressures is as follows, where the red circles in this figure denote 3D hot-wire anemometers.

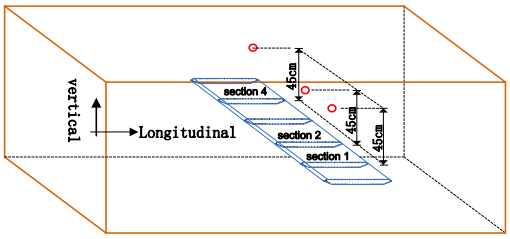

Figure 4. Schematic diagram of simultaneous measurement of wind velocities and chord-wise pressures

3.1 *Correlation coefficients with different section intervals*

In time domain, the correlation coefficients with different section intervals under a given flow condition were calculated, and an obvious phenomenon can be found that the correlation coefficients have a tight relationship with integral scales.

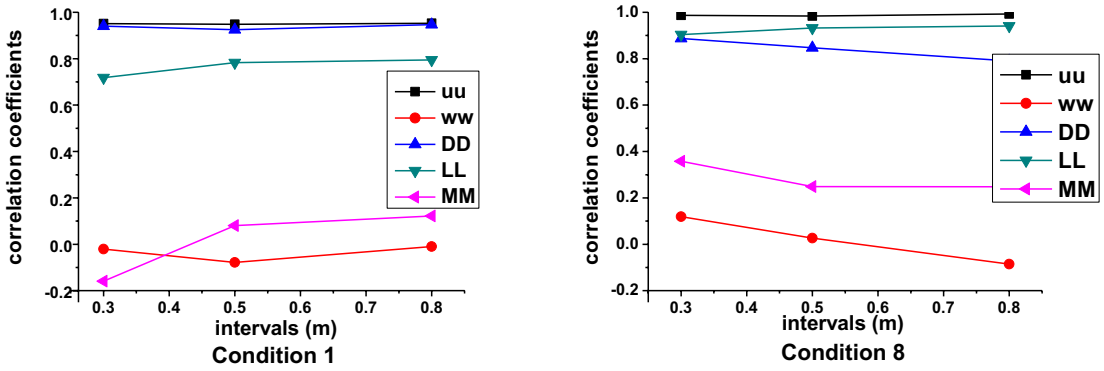

Figure 5. Correlation coefficients of aerodynamic forces and oncoming flows under condition 1 and 8

Figure 5 illustrates the correlation coefficients under condition 1 ($L_u^x = 2.033\text{m}, L_w^x = 0.097\text{m}, U = 4.57\text{m/s}$) and condition 8 ($L_u^x = 3.782\text{m}, L_w^x = 0.166\text{m}, U = 6.54\text{m/s}$). By comparing these two pictures, we can find that the longitudinal turbulent wind and the aerodynamic drag force obey the same trend, and the correlation coefficients primarily dominated by the integral scale of longitudinal turbulent wind. If the integral scale of longitudinal turbulent wind is large enough (much bigger than the section-intervals), the drag forces and longitudinal turbulent winds are almost fully correlated (around 0.95) and do not decay with the increase of section-intervals. Both the aerodynamic lifts and moments show a larger correlation feature than the vertical turbulences.

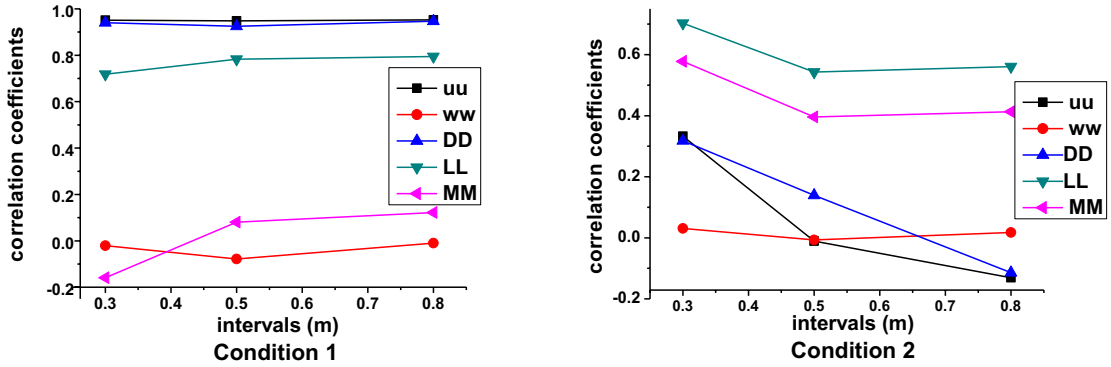

Figure 6. Correlation coefficients of aerodynamic forces and oncoming flows under condition 1 and 2

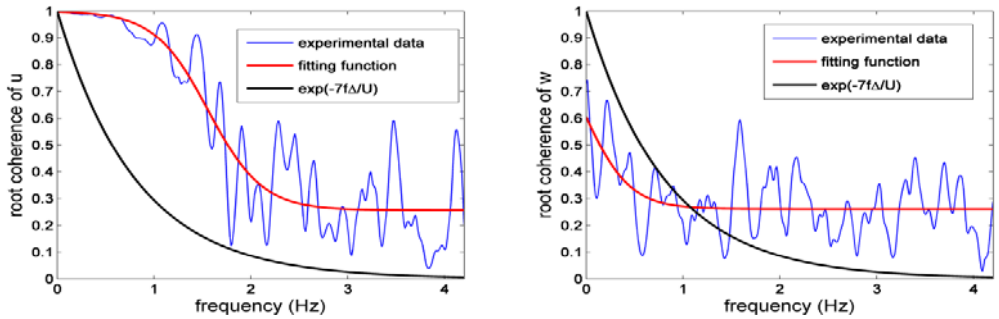
This figure illustrates the correlation coefficients under condition1 ($L_u^x = 2.033\text{m}, L_w^x = 0.097\text{m}, U = 4.57\text{m/s}$), and condition2 ($L_u^x = 0.562\text{m}, L_w^x = 0.2\text{m}, U = 4.61\text{m/s}$). By comparing these two pictures, we can find that the longitudinal turbulent wind and the aerodynamic drag still obey the same trend, although the integral scale changes a lot. With the integral scale of longitudinal wind changing from 2.033m to 0.562m, an obvious decaying trend of the correlation coefficients for both longitudinal wind and aerodynamic drag occurs. With the integral scale of vertical wind changing from 0.097m to 0.2m, an obvious increase of the correlation coefficients of aerodynamic moments can be seen. Both the lifts and moments show a much higher correlation feature than vertical wind.

3.2 *Spatical coherences and a new empirical function*

The root coherences of the three-direction aerodynamic loads have different decaying trends versus frequency. The root coherence of aerodynamic drag is bigger than that of the longitudinal wind at the higher frequency region, which has been observed by other researchers too. The aerodynamic lift has an inconsistent decaying trend with the vertical wind, and is more correlated in the frequency range of interest. The aerodynamic moment shows a similar decaying trend with the vertical turbulence and has a lower correlation feature than both of the drag and lift forces.



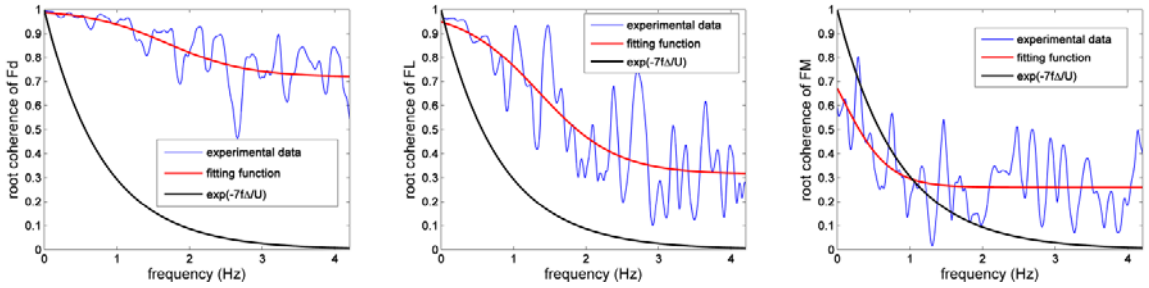


Figure 7. Root coherences of turbulent winds and aerodynamic forces under condition 1

The above figure illustrates the root coherences of the incident flows and aerodynamic forces between two cross sections at an interval of 80cm, under condition 1. The blue solid line in this figure denotes the experimental data, and the red and black solid lines respectively denote the fitting functions using the exponential expression and a new empirical function, which will be discussed later.

In order to detect the impacts of integral scales and turbulence intensities on the coherences of aerodynamic loads, a series of cases with different ratios of integral scale to section-interval were studied.

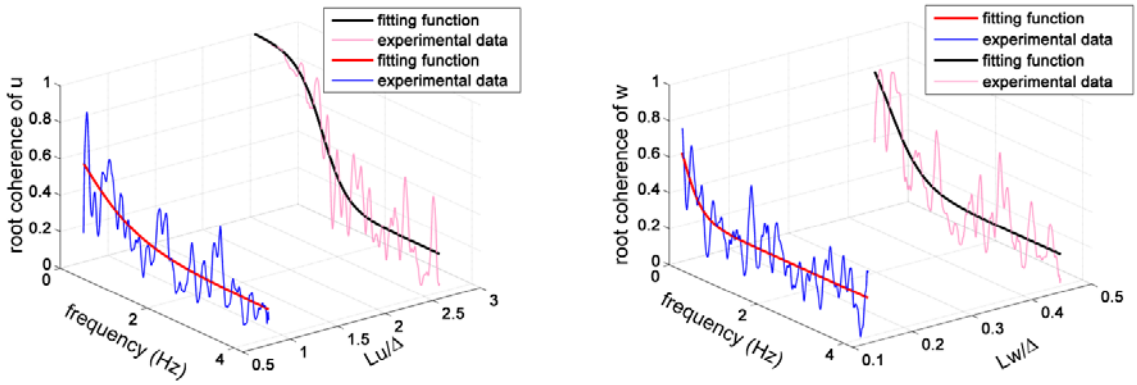

Figure 8. Root coherences of turbulent winds with different integral scales

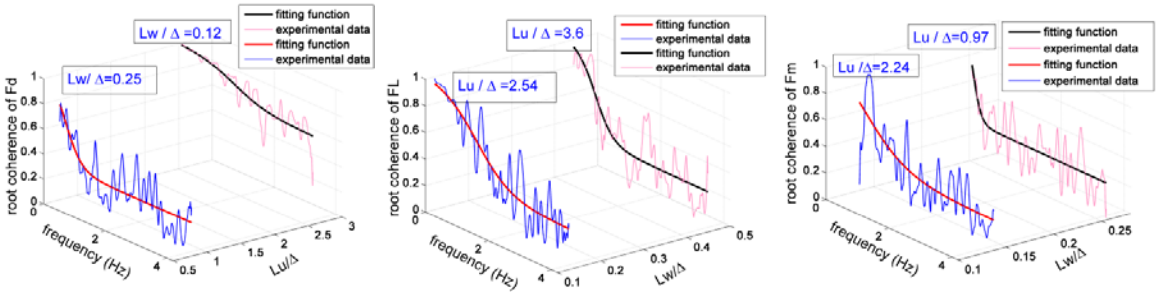
Figure 8 illustrates that the wind correlation feature improves with the increase of integral scale, which is not difficult to understand. It is worth noting that, under a large integral-scale condition, (e. g $L_u/\Delta = 2.5$), the root coherence shows a different decaying trend versus frequency, especially in the low frequency range, where the exponential expression is no longer applicable.



(a) Drag (b) Lift (c) Moment

Figure 9. Root coherences of aerodynamic forces under different flow conditions

Figure 9(a) shows the coherences of aerodynamic drags under different incident flow conditions. As can been seen from that picture, the aerodynamic drag is primarily dominated by the longitudinal wind, since the coherence of the aerodynamic drag decays fiercely with the decrease of longitudinal wind integral scale, though the integral scale of the vertical wind is increased. As to the aerodynamic moment, the coherence is mainly dominated by the vertical wind, on account of the similar decaying trends versus frequency at similar vertical wind integral scales, although the longitudinal components changes violently, which is reflected in Figure 9(c). The aerodynamic lift, however, seems to have a relation with both of the vertical and longitudinal incident flows, as can be seen from Figure 9(b), and its spatial coherence features cannot be simply evaluated by those of the vertical winds. The influence of turbulence intensity was also considered in this approach, and an intuitional sense is that, with the increase of turbulence intensity the value of root coherence trends to become bigger in the higher frequency region. However, because the variation range of turbulence intensities generated in this experiment is small, the detail and respective impacts of I_u and I_w on three aerodynamic forces need further experiments.

As mentioned above, the form of root coherence differs with the changes of integral scale and turbulence intensity, and once the ratio of integral scale to section interval is large enough(>1), the root coherence shows a totally different decaying trend with the exponential expression. Besides, the longitudinal and vertical turbulences have different contributions to different direction aerodynamic forces. In order to reflect the influences of these relevant factors and taking into account the different decaying trend with the exponential expression under large integral scale conditions, a new empirical expression of root coherence is proposed, which is based on the nonlinear least square method and has the following form:

$$\mathrm{Coh}^{1/2}(f,\Delta x)=c_1+\frac{1-c_1}{1+\exp\left(c_2*\left(\frac{f\cdot B}{U}\right)-c_3*\left(\frac{L^x}{\Delta x}\right)^{c4}-c_5*I_t\right)} \tag{7}$$

In this expression, f represents the frequency; Δx denotes the distance between two cross sections; U is average wind speed; B is deck width; $c_1 \sim c_5$ are fitting coefficients. As to L^x and I_t, they denote the integral scale of incident wind along the span-wise and the corresponding turbulence intensity, respectively. For the root coherence of longitudinal or vertical turbulent wind, L^x and I_t signify the flow features of its own. And for the aerodynamic forces, the static coefficients are adopted to measure the contribution ratios of different turbulent winds to different aerodynamic forces. The static coefficients were measured under uniform flow condition in the TJ-1 wind tunnel of Tongji University, Shanghai, China. Table 1 shows the values of static coefficients and their slopes under attack angle of zero:

Table 1. Static Coefficients Measured in TJ-1

C_d	0.039	C_d'	0.115
C_L	-0.012	C_L'	3.678
C_M	0.004	C_M'	1.875

The integral scales and turbulence intensities used in the root coherences of aerodynamic forces can be defined as follows:

$$L^x_{drag}=\frac{C_d*L_u+C_d'*L_w}{C_d} \qquad I_{drag}=\frac{C_d*I_u+C_d'*I_w}{C_d} \tag{8}$$

$$L^x_{lift}=\frac{|C_L|*L_u+C_L'*L_w}{C_L'} \qquad I_{lift}=\frac{|C_L|*I_u+C_L'*I_w}{C_L'} \tag{9}$$

$$L^x_{moment}=\frac{C_M*L_u+C_M'*L_w}{C_M'} \qquad I_{moment}=\frac{C_M*I_u+C_M'*I_w}{C_M'} \tag{10}$$

And the fitting coefficients through the nonlinear least square fit are illustrated below:

Table 2. Fitting Coefficients

C_1	C_2	C_3	C_4	C_5
0.23	15~25	0.85	0.85	3

(The value of C_2 is 20~25 for turbulent winds and 15~20 for aerodynamic forces.)

This expression can reflect the impacts of turbulence intensity and ratio of integral scale to section-interval on spatial coherences, and can account for the different decaying trends between aerodynamic forces and incident winds through their corresponding integral scales and turbulence intensities. But it is worth noting that this expression is derived from the experimental conditions with different integral scales but limited section-intervals. It can reproduce the decaying trend of root coherences of both aerodynamic forces and incident winds in the low frequency region preferably, which is the insufficiency of the exponential expression. However, this expression cannot demonstrate the correlations in high frequency region. The combined use of this expression with the exponential expression or a united expression containing both features of these two expressions needs further experiments and study.

4 CONCLUSION

The root coherences of both incident winds and aerodynamic forces were studied and an obvious impact of integral scale can be seen. The three-direction aerodynamic loads have different correlation features under same incident flow conditions, and the decaying trend of root coherence under large ratios of integral scale to section-interval is a far cry from the exponential expression. A new empirical expression is proposed to reflect the spatial coherence features in low frequency region and taking into account the different contribution ratios of incident winds to different aerodynamic loads. Since it is not applicable for high frequency region, the combined use of this expression with the exponential expression or a united expression containing both features of these two expressions needs further experiments and study.

ABSTRACT: Not only aerodynamic instability such as flutter but also aerostatic instability such as lateral-torsional buckling would be concerns of wind-resistant design of super long-span suspension bridges. Authors' past analytical study on lateral-torsional buckling proved the difficulty of distinction of lateral-torsional buckling from divergence, both of which are divergent response phenomena. This study tried to numerically identify lateral-torsional buckling of a long-span suspension bridge with considering geometric and aerodynamic non-linearity under wind loading.

KEYWORDS: Lateral-torsional buckling, suspension bridge, geometric nonlinearity, aerodynamic nonlinearity

1 INTRODUCTION

As the main span length of a suspension bridge becomes much longer, it was pointed out (Nakamura, et al., 1998) that not only aerodynamic instability such as flutter but also aerostatic instability such as lateral-torsional buckling would be concerns of wind-resistant design. Hirai (1942) of the University of Tokyo of those days firstly proposed a calculation formula of the critical wind speed of lateral-torsional buckling of a suspension bridge. This formula included some simplifications such as only consideration of force equilibrium of a wind-loaded girder and exclusion of geometric nonlinearity. Since then, analytical studies (Nazmy, et al., 1990, Boonyapinyo, et al., 1993) on lateral-torsional buckling including aerodynamic, geometric and material nonlinearity have been conducted.

Recently, owing to the availability of powerful advanced FEM analysis softwares, sophisticated structural analysis including nonlinearities and wind-structure interactions can be possible. Authors have tried to analyze lateral-torsional buckling of suspension bridges (Yamada, et al., 2009). However difficulty of distinguishing lateral-torsional buckling from divergence was encountered. Because they are both aerostatic instability accompanying sudden large wind-induced deflections at a certain high wind speed.

In this study, a Mode Tracing Flutter Analysis method (Nguyen, et al., 1998), which was originally developed to trace modal parameters of pre-selected particular vibration modes in flutter analysis, was used to identify and distinguish lateral-torsional buckling from divergence. The paper presents the analytical methodology and demonstration results for lateral-torsional buckling of a long-span suspension bridge.

2 CLOSED-FORM SOLUTION OF AEROSTATIC INSTABILITY

2.1 *Lateral-torsional buckling*

A girder of a suspension bridge deflects largely in an along-wind direction under wind loading. Not only lateral bending moment due to a drag force but also vertical lift and torsional moment are applied to the bridge girder. This may accelerate the occurrence of lateral-torsional buckling of the girder more than only drag force case.

Hirai (1942) firstly proposed a calculation formula of the critical wind speed of lateral-torsional buckling of a suspension bridge girder. A girder is subjected to a drag force laterally about its strong axis, a lift force vertically about its weak axis and a pitching moment about its rotation center, as shown in Figure 1. Equilibriums of all forces for the girder are written in Equation (1).

$$EI\frac{d^4\eta}{dx^4} - 2H_\omega\frac{d^4\eta}{dx^4} - 2h_1\frac{d^2y}{dx^2} + \frac{d^2}{dx^2}(\mathrm{M}\varphi) - (S + C_d)pb\varphi = 0 \tag{1a}$$

$$M\frac{d^2\eta}{dx^2} - EC_\omega\frac{d^4\eta}{dx^4} - \left(GK + \frac{H_\omega b^2}{2}\right)\frac{d^2\eta}{dx^2} - bh_2\frac{d^2y}{dx^2} - S_t pb^2\varphi = 0 \tag{1b}$$

where η and φ are a vertical and torsional displacement, respectively, and EI, GK and EC_w are a bending, torsional and bending-torsion stiffness, respectively. H_w is a cable tension under self weight, M is lateral bending moment of the girder. C_d, S and S_t are a drag coefficient, slopes of lift and pitching moment coefficients, respectively. In addition, h_1 and h_2 are an increment of a cable horizontal tension by η and φ, respectively.

Secondly, Hirai developed an equation of motion with including an inertia term of the girder. He identified the critical wind speed condition by comparing a critical condition of lateral buckling, as shown in Equation (2).

$$V_k^{\,2} = \frac{142.2}{\mu C_D \rho b l^3}\sqrt{EJ\cdot\overline{GK}} \tag{2}$$

where $EJ = EI + \dfrac{l^2}{2\pi^2}H_\omega$, $\overline{GK} = \dfrac{4\pi^2}{l^2}EC_\omega + GK + \dfrac{b^2}{2}H_\omega$ and $\mu = \sqrt{1 + 0.287\dfrac{S + C_D}{C_D}}$

Equation (2) assumes an asymmetric lateral-torsional buckling mode for a mono span suspension bridge. Therefore, some correction is necessary for a multi span suspension bridge or different boundary conditions such as the transmission of wind load to main cables (JSCE, 1967 & Okauchi, et al., 1967).

2.2 *Divergence*

Divergence is another aerostatic instability which is negative feedback of torsional deflection due to pitching moment. A critical wind speed for divergence is given in Equatin (3) by equilibrium of pitching moment and torsional restoring force. Although divergence is clearly different from lateral-torsional buckling from the viewpoint of occurrence mechanism, it is very difficult to distiguish between two aerostatic instabilities by numerical prediction. Because both two phenomena suddenly occur at a certain wind speed.

$$U_C = \sqrt{\frac{2k_\alpha}{\rho B^2 S_t}} \tag{3}$$

where k_a is torsional stiffness.

3 ANALYTICAL FORMULATION OF LATERAL-TORSIONAL BUCKLING

3.1 *Mode-trace Method*

A mode-trace method, which was developed by Dung (1998), et al, is a flutter analysis method with consideration of large wind-induced deflection of a bridge. It consists of two parts: static and dynamic analyses. The static analysis part solves an equilibrium condition of the bridge structure under wind loading and corresponding large deflection at each analytical wind speed step. The dynamic analysis part uses that equilibrium condition and solves an eigenvalue problem with consideration of aeroelastic wind forces. In particular, the mode-trace method can solve only eigenvalues of interest which are selected in advance. Using this method, particular modes only can be sought with the increase of wind speed.

In this study, the static analysis part is used to find the critical condition of lateral-torsional buckling. In case of a suspension bridge, large wind-induced deflection is caused by wind load. Geometric nonlinearity should be considered. In addition, wind load of a suspension bridge girder is dependent on angle of attack (wind-induced torsional deflection). Wind load should also be updated according to wind-induced torsional deflection obtained at each wind speed.

As described in 2, lateral-torsional buckling and divergence are both static instability that torsional deflection suddenly increases at a certain wind speed. It is difficult to distinguish those two phenomena from wind-induced torsional deflection only. In this study, lateral-torsional buckling is identified by searching a condition that any diagonal term in the stiffness matrix is non positive during conducting the static analysis part of the mode-trace method.

3.2 *Benchmark study*

In order to validate the identification method of lateral-torsional buckling by diagonal terms, a benchmark study was conducted with using a simple beam subjected to uniform distributed loads as shown in Figure 3. The beam has a 10 m I shape cross section with 300 mm wide, 500 mm high, 11 mm flange thickness and 18mm web thickness. Lateral load which is equivalent to 0.1% span length imperfection was applied. Increasing the uniform distributed load, a critical condition that any diagonal term in the stiffness matrix is non positive was sought.

Figure 4 shows vertical, lateral and torsional deflections in the middle of span versus uniform distributed load intensity. Lateral and torsional deflections suddenly increase at the load intensity of 84 kN/m while vertical deflection increases linearly. At this step, diagonal terms of the stiffness matrix became no positive. It turned out that identification of lateral-torsional buckling by non positive diagonal terms in the stiffness matrix is valid.

4 LATERAL-TORSIONAL BUCKLING OF AKASHI KAIKYO BRIDGE

4.1 *Original analysis*

Using the mode-trace method, lateral-torsional buckling of the Akashi Kaikyo Bridge was analyzed. It has a truss-stiffened girder with the center span of 1,991 m and two side spans of 960 m. It was modeled by a 3D frame model with lumped masses as shown in Figure 5. Figure 6 shows three component force coefficients vs. angle of attack.

According to the three component force coefficients and an angle of attack at each wind speed step, drag, lift and pitching moment were applied at shear centers of the girder. In addition, drag and lift were applied at main cables, and drag was applied at towers.

Figure 7 shows wind-induced deflections in the middle of the center span of (1) vertical, (2) Lateral and (3) torsion versus wind speed. Vertical and torsional deflections suddenly increase at a wind speed of 140 m/s where a diagonal term of the stiffness matrix is non positive. Because a diagonal term of the stiffness matrix is non positive, this sudden increase of vertical and torsional deflections at a wind speed of 140 m/s must result from the onset of lateral-torsonal buckling, which is clearly different from divergence.

4.2 *Parameter analysis*

In order to investigate the contribution of each three component force coefficient to lateral-torsional buckling, parameter studies with different combinations of three component force coefficients were carried out.

Firstly, drag forces were only applied (CD only). Figure 8 and Table 1 show comparisons of wind-induced torsional deflection between drag only case and original case (Figure 7). This case exhibited lateral-torsional buckling at a wind speed of 305 m/s, which is much larger than the original case. This shows that a drag force can cause lateral-torsional buckling due to the structural feature of a suspension bridge that the girder is suspended by hungers. In addition, it can be understood that a lift force and pitching moment can enhance the onset of lateral-torsional buckling because those forces act out of the lateral direction.

Secondly, effects of a lift force were investigated. Figure 9 and Tabale 1show comparisons of wind-induced torsional deflection among different lift force coefficient cases. The case that lift force coefficients were decreased to 1/10 exhibited lateral-torsional buckling at a wind speed of 140 m/s. In addition, the 10 times case yielded 125 m/s. From both results, it can be understood that lateral-torsional buckling is not affected much by lift forces.

Finally, effects of a pitching moment were investigated. Figure 10 and Table 1 show comparisons of wind-induced torsional deflection among different pitching moment coefficient cases. From the cases with 10 times and 1/10 pitching moment coefficients, it can be understood that lateral-torsional buckling is largely affected by a pitching moment. Furthermore, only pitching moment cannot case lateral-torsional buckling easily. It can also be understood that lateral-torsional buckling is an instability phenomenon caused by a multiplication effect of a drag, lift and pitching moment.

5 CONCLUSIONS

Numerical estimation of lateral-torsional buckling of a long-span suspension bridge with using a Mode Tracing Flutter Analysis method was carried out. Results obtained in this study are as follows:

Onset of lateral-torsional buckling was identified by a non-positive value of diagonal terms in the stiffness matrix incorporating wind-loading effects. A benchmark study for a simple beam and an application for the Akashi Kaikyo Bridge showed that a deflection process with the increase of wind speed well represented a sudden onset of instability where a non-positive value was detected in a diagonal term of the stiffness matrix. However experimental work to validate the estimation method should be done in future.

ABSTRACT: Five root-mean-square (RMS) pressure models are used in combination with different turbulence models to determine whether it is possible to obtain a conservative estimate of RMS pressures on a high-rise building model from a RANS calculation. When a precursor domain is used for the generation of inlet profiles the turbulent kinetic energy is severely underestimated and, as a result, all RMS models are found to be highly non-conservative, irrespective of the turbulence model which is used. Although the prescription of an ABL profile of the desired shape at the inlet or the prescription of more appropriate wall functions on the bottom of the computational domain might lead to more conservative results it is concluded that new models are needed to enable the calculation of RMS values from RANS calculations for engineering purposes.

KEYWORDS: RMS pressure model, high-rise building, RANS

1 INTRODUCTION

Although much progress has been made in recent years, the prediction of local peak wind pressures on building facades with CFD analysis has proven difficult (Stathopoulos, 1997). Time dependent techniques like DES or LES are required to obtain accurate solutions (Lim (2009)). However, these techniques are currently too expensive and complex for everyday use by construction engineers. Combined with the fact that validation of these techniques for this application is still an ongoing effort, it is unlikely that CFD analysis will be a viable alternative for building codes or wind tunnel testing in the near future. However, the application of CFD could be beneficial in the early design phase of a building, where a cheap, quick, rough estimate of wind loads is desired. A Reynolds Averaged Navier-Stokes (RANS) simulation meets these criteria.

Unfortunately, this type of simulation only provides information on the mean wind pressures. For the calculation of peak pressures, some assessment of the pressure fluctuations such as a root-mean-square (RMS) pressure is needed. A turbulence model contains some information on the fluctuating state of the flow. For example, the RMS values of the fluctuating velocity components are directly related to the square-root of the time-averaged turbulent kinetic energy. Paterson and Holmes (1989), Selvam (1992), Paterson (1993) and Richards and Wanigaratne (1993) derived models for estimating the RMS pressure from the mean turbulence characteristics of the flow. Another option, the generation of a synthetic turbulent velocity field using a stochastic model and subsequently solving the Poisson equation that governs the pressure fluctuations field (Senthooran, 2004) is outside the scope of the current paper.

These models were developed with best agreement between calculation and experiment in mind. While this is a logical approach from a scientific point of view, for a construction engineer the most important question is whether the model will result in a safe prediction of the actual wind loads. For a safe prediction, the model needs to produce a conservative estimate. From this point of view the most appropriate model is therefore not necessarily the most accurate one.

This study investigates five RMS pressure models using three turbulence models (Standard k-ε, Realizable k-ε, and RNG k-ε) for an isolated high-rise building in suburban terrain conditions. The goal of this study is to determine for the 15 combinations of turbulence and root-mean-square models whether:

- The combination of turbulence model and RMS model is conservative;
- If not, in which regions of the high-rise building model the combination is not conservative.

2 MODEL DEFINITION

2.1 *Wind tunnel model*

Wind tunnel experiments have been carried out in the open circuit atmospheric boundary layer wind tunnel of TNO in the Netherlands, depicted in figure 1a. It has a working section of approximately 13.5 m in length, 3 m in width and 2 m in height. The boundary layer used in this study was developed over the length of the test section using 50 mm cubic roughness elements and 6 spires located at the beginning of the test section, resulting in a wind tunnel roughness length of z_0 = 0.0032 m. The roughness elements extended onto the turntable to prevent the development of an internal boundary layer.

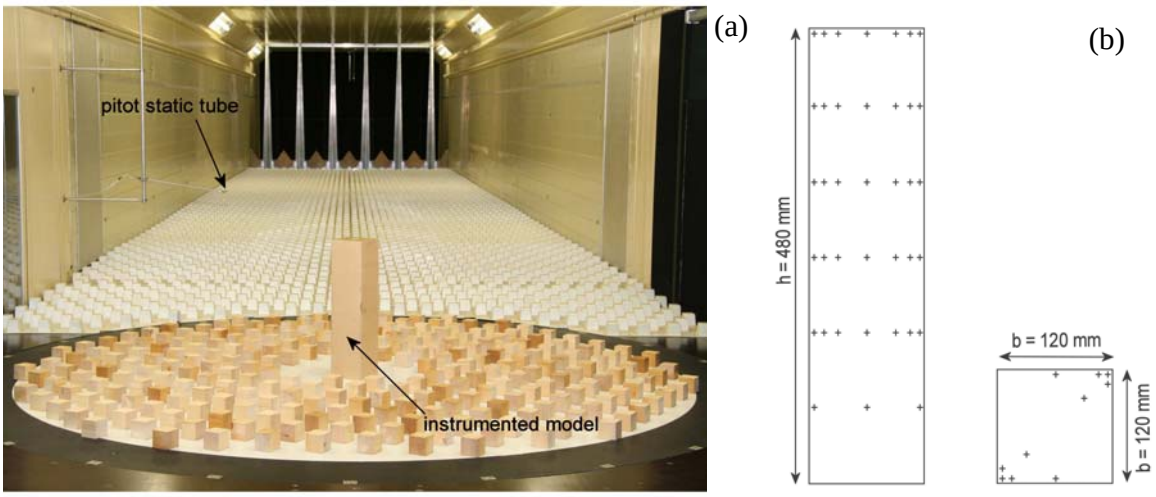

Figure 1. (a) Test configuration in the wind tunnel of TNO, (b) pressure tap distribution on the model faces

Experiments were performed on a geometrical scale of 1:250. The building model was a square cylinder with a height of h = 48 cm and side b = 12 cm. The reference model was instrumented with pressure taps at 86 locations, illustrated in figure 1b, which were sampled simultaneously. After one measurement run the model was rotated 90 degrees and a second run was performed for the same configuration, giving pressure data at 86 new locations. The total number of locations where pressure measurements were performed was therefore 172.

A hot wire anemometer was used to measure both wind speed and turbulence intensity characteristics of the boundary layer flow. Figure 2 illustrates the velocity magnitude and turbulent kinetic energy above the centre of the turntable without model present.

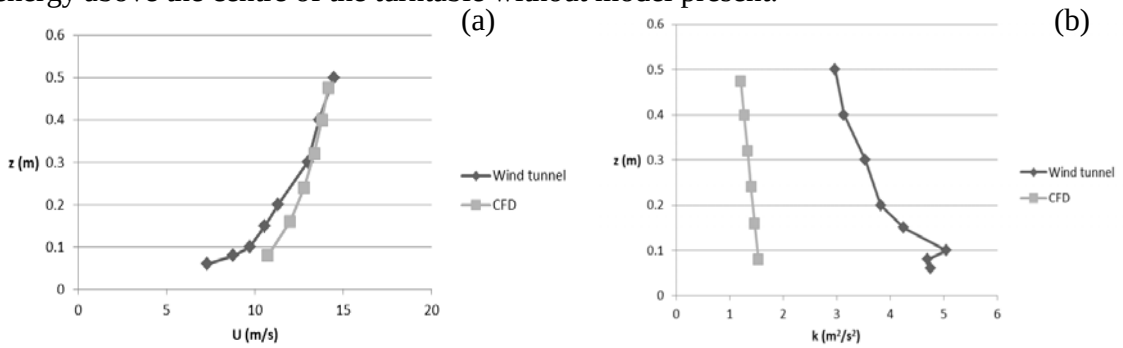

Figure 2 Approach flow profiles of (a) velocity magnitude and (b) turbulent kinetic energy

The wind speed in the wind tunnel in the presence of the model, measured with a pitot static tube, was U_{ref} = 14.2 m/s at model roof height (h_{ref} = 0.48 m). Building pressures were measured with a sampling rate of 400 Hz for a period of approximately 20.5 seconds. The pressures were converted to mean pressure coefficients, defined as

$$C_{\bar{p}} = \frac{\bar{p}}{\frac{1}{2}\rho U_{ref}^2} \tag{2}$$

in which $\bar{p}$ is the time-average of the entire measured pressure signal and ρ the air density.

2.2 *CFD model*

The numerical simulations were performed with the open source flow solver OpenFOAM 2.1.0. The statistically steady flow field was computed by solving the RANS equations using the simpleFoam solver for steady state incompressible flows. Three different turbulence models were employed: the standard *k*-ε model, the realizable *k*-ε model and the RNG *k*-ε model. All calculations were run until the residuals showed no further improvement. For the standard and realizable *k*-ε models residuals of approximately $1.0 \cdot 10^{-6}$ or smaller were achieved. For the RNG *k*-ε model the residuals were much higher, with a maximum of $3.5 \cdot 10^{-3}$ for the lateral velocity component in several calculations. These residuals were much reduced upon mesh refinement (see section 2.3), indicating that this effect is most likely due to a greater mesh sensitivity for this model. Since observed differences in the solution upon refinement were small the results were nevertheless considered adequately converged.

The computational domain corresponded to the wind tunnel model described in the previous paragraph. Velocity, turbulent kinetic energy and turbulent dissipation rate equilibrium profiles were generated by running a precursor computation on a periodic domain and prescribing the resulting profiles at the inlet of the model computational domain. Both the lateral boundaries and top boundaries were modeled as symmetry planes. The building surface was treated as a solid smooth wall. Standard rough wall functions based on the local velocity field (nutURoughWallFunction) were employed at the bottom of the domain.

Gauss linear schemes were used for the calculations of gradients and Gauss linear corrected schemes for the Laplacians. Furthermore linear interpolation and corrected surface normal gradient schemes were selected. For the calculation of divergence the limitedLinear2V scheme was used for the velocity field, in which the calculated face gradient is used to blend in a small amount of the solution in the upwind cell (here a multiplication factor between 0.2 and 0 was used) in order to damp high-frequency oscillations in the solution. Self-filtered central differencing was applied for the calculation of divergences for the k and ε fields. For the last divergence term, involving the effective viscosity, a Gauss linear scheme was applied.

2.3 *Computational grid*

The CFD model of the high-rise building had a length of (L = 10.08 m), a width of (W = 3.00 m) and a height of (H = 2.00 m). The domain measured 4.4 h_{ref} (= 2.1 m) upstream of the building, 16.4 h_{ref} (= 7.86 m) in the downstream direction, 3.0 h_{ref} (= 1.44 m) to each side and 3.2 h_{ref} (= 1.52 m) in the height direction. These values were chosen to enable a fair comparison with the results from the wind tunnel tests and lead to a very low blockage of 0.96 %. They also correspond with most recommendations specified in COST Action 732 (2007).

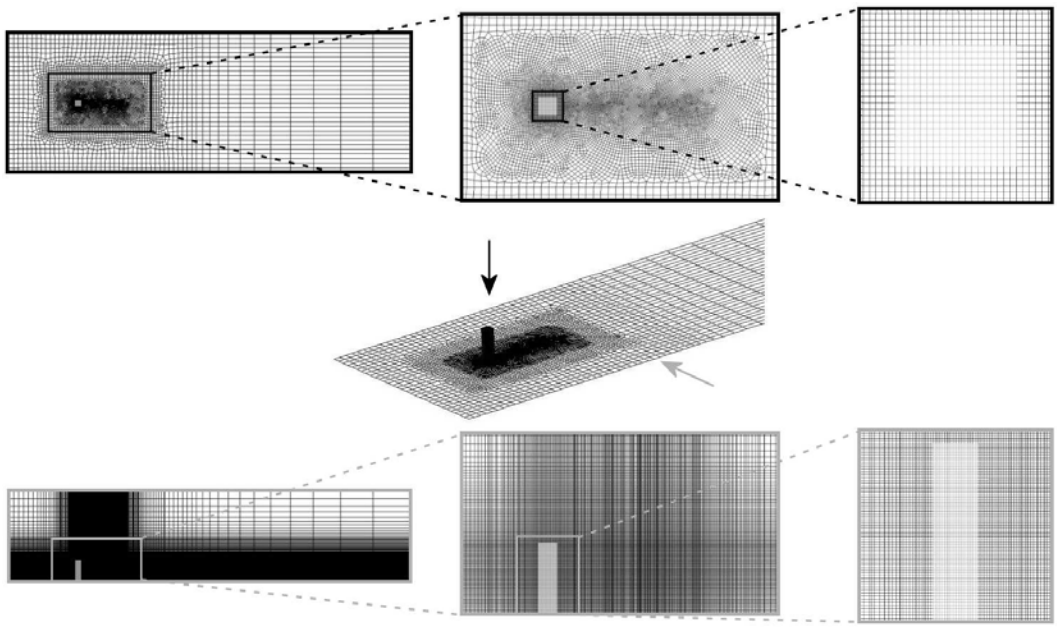

Figure 3 Coarsened mesh (top view in black, side view in grey).

Purely hexahedral meshes were created using Gambit 2.4.6. A coarsened version of the mesh used in the calculation at a zero degree angle of attack is depicted in figure 3. The mesh was successively refined towards the building surfaces and in the wake of the building. This was done by specifying the desired cell size on the building surface and in the wake, meshing the ground plane using a quad pave scheme and extruding the resulting surface mesh in the vertical direction. The smallest cell size at the building surface was approximately 5 mm in each direction, leading to a y^+ range of $1.03 \leq y^+ \leq 310.74$ for all calculations with a mean value of $y^+ = 79.02$. The number of cells over the building surfaces was 24 in the streamwise and spanwise directions and 88 over the building height. The total number of cells used was 2,219,268.

For a mesh refinement study a coarser and a finer mesh with 369,078 and 5,747,816 cells, respectively, were also used. From this study it was concluded that the average difference between $C_{p,mean}$ values calculated for the medium and fine meshes was very small: 0.59 % for the standard k-ε model, 1.14 % for the realizable k-ε model and 0.87 % for the RNG k-ε model. Close to building edges differences up to nearly 100 % were observed owing to the numerical difficulties in modeling sharp corners. Since large near-wall gradients exist for the turbulent kinetic energy the average differences for calculated k values were substantially larger: 6.37 % for the standard k-ε model, 15.41 % for the realizable k-ε model and 23.52 % for the RNG k-ε model. Local differences up to 212 % were observed.

Nine more angles of attack were calculated, ranging from 5 to 45 degrees at 5 degree intervals. Both the resolution near the building as well as the total number of cells in these nine meshes were similar to those for the 0 degree angle of attack medium resolution mesh.

2.4 *RMS pressure models*

Various models have been developed for determining the RMS pressures in a RANS simulation. Paterson and Holmes (1989) published the first formula for prediction of RMS pressure coefficients. Starting from Bernoulli's equation and using experimental results, they obtained:

$$C_{p,RMS} = \frac{2\left[k/3+0.816\cdot\left|C_{p,mean}\right|\cdot U_o\sqrt{k_o}\right]}{{U_h}^2} \tag{2}$$

Here U_o and k_o are the mean velocity and turbulent kinetic energy of the approach flow at the height of interest, $C_{p,mean}$ is the local mean pressure coefficient, k is the local turbulent kinetic energy and U_h is the mean reference velocity at building height. The part proportional to k is associated with small-scale local pressure fluctuations in a flow free of mean velocity gradients, the part containing U_o is a 'quasi-steady' term associated with the amplification of upwind pressure fluctuations by velocity gradients.

Applying a similar procedure as Paterson and Holmes (1989) to derive equation (2), Selvam (1992) deduced an alternate equation for the RMS pressure coefficients:

$$C_{p,RMS} = \frac{2\left|C_{p,mean}\right|\cdot\left[1.414\cdot U_h\sqrt{k_h}+k_h\right]}{{U_h}^2} \tag{3}$$

in which U_h and k_h are the mean velocity and turbulent kinetic energy in the approach flow at building height.

Paterson (1993) derived a second model for large Reynolds numbers from the stream-wise component of the Navier-Stokes equations:

$$C_{p,RMS} = \frac{8{k_o}^2}{{U_o}^4} + \frac{8{C_{p,mean}}^2{U_o}^2 k_o}{\left({U_o}^2+2k_o-2k\right)^2} \tag{4}$$

According to Paterson, results obtained with equation (4) were in better agreement with full-scale and wind tunnel results of the TTU experimental building than results using equation (2). Richards and Wanigaratne (1993) derived a similar equation as Paterson and Holmes' (1989) equation (2), but suggested it should be more of the form

$$C_{p,RMS} = \frac{2\left[Ek_o{}^2 + 0.816^2 \cdot C_{p,mean}{}^2 \cdot U_o{}^2 k_o \right]^{\frac{1}{2}}}{U_h{}^2}, \tag{5}$$

This is a variation on equation (2) where the local turbulent kinetic energy term was replaced with a function of the approach flow turbulence, $Ek_o{}^2$. $E \approx 0.5$, which was determined through investigation of the value of $C_{p,RMS}$ in regions where $C_{p,mean} \approx 0$. Richards and Wanigaratne (1993) developed an additional model through consideration of the flow oriented with respect to the mean stream lines:

$$C_{p,RMS} = 2\left[\begin{array}{l} Ek_o{}^2 + \left(U_o{}^2 \sigma_{uo}{}^2 + Ek_o{}^2 \right) \cdot \left((1-F) + F \dfrac{C_{p,mean} U_h{}^2}{U_o{}^2 + 2k_o} \right)^2 \\ + \left(\dfrac{U_o{}^2 \sigma_{uo}{}^2 + Ek_o{}^2}{\left(U_o{}^2 + 2k_o \right)^2} + 0.25 \right) F^2 \left(\dfrac{\partial C_{p,mean}}{\partial \theta} \right)^2 U_h{}^4 \dfrac{\sigma_{vo}{}^2}{U_o{}^2} \end{array} \right]^{\frac{1}{2}} / U_h{}^2. \tag{6}$$

In which $\sigma_{uo} = \sqrt{\overline{u'_o{}^2}}$, $\sigma_{vo} = \sqrt{\overline{v'_o{}^2}}$. A value $F = 0.64$ was found through investigation of the relationship between $C_{p,RMS}$ and $C_{p,mean}$ for a dataset of wind tunnel measurements.

2.5 *Comparison of wind tunnel measurements and CFD results*

In all locations where a comparison between wind tunnel measurements and CFD results could be made, the five RMS models presented in the previous section were applied to the CFD results for all three turbulence models, leading to a total of 15 combinations. The evaluation of the term $\partial C_{p,mean} / \partial \theta$ in equation 6 was done in a central differencing fashion using the results of the calculations at a ± 5 degree angle of attack with respect to the evaluated angle. In this it was assumed that the units of θ are degrees, as is common in the field of wind engineering, although this was not specified in the original paper. The terms σ_{uo} and σ_{vo} were derived from the calculated Reynolds stresses.

At each pressure tap point the difference between wind tunnel data and the computational result for the mean and RMS pressure coefficients was determined as

$$\Delta C_p = \left| C_{p,CFD} \right| - \left| C_{p,WT} \right| \tag{7}$$

While it is possible to define a quality parameter which is directly related to these difference data, this would lead to a dependence on the choice of measurement locations. In order to overcome this problem the data were interpolated on a regular grid measuring 111 points in the

streamwise and spanwise directions and 396 points in the height. While this approach makes the results dependent on the interpolation method, it reduces the chosen dependence on the pressure tap positions. The interpolation was performed using the Matlab gridfit routine using a triangular interpolation scheme and a smoothness parameter of 1 in the streamwise and spanwise directions and 2 in the height direction. No extrapolation was performed.

To evaluate the performance of different models from a comparison between wind tunnel data and CFD calculations three quality parameters were defined: the fraction of all locations where the evaluated parameter is underpredicted, the average amount of underprediction per underpredicted location and the overall average amount of underprediction. The latter thereby equals the product of the former two.

A comparison of the wind tunnel and computational results is made for four angles of attack (0°, 15°, 30° and 45°). The three quality parameters defined above, derived for each of the wind directions, are averaged to produce an overall quality estimate. Evaluation of the quality parameters is performed on the interpolated grid.

3 RESULTS

In figure 2 the turbulent kinetic energy and velocity magnitude profiles which were measured in the empty wind tunnel are compared with the profiles calculated in the precursor domain of the CFD calculation. The calculated turbulent kinetic energy is lower than the wind tunnel result by a factor of roughly 2.5 to 3. A clear difference between the velocity magnitude profiles can also be observed, especially close to the ground.

The three quality parameters defined in section 2.5, evaluated for every combination of turbulence model and RMS model, are presented in tables 1-3. In these tables the root mean square pressure models are abbreviated as P&H (Paterson and Holmes, equation 2), S (Selvam, equation 3), P (Paterson, equation 4) and R&W 1 and 2 (Richards and Wanigaratne, equations 5 and 6).

Table 1. Fraction of underpredicted locations. For the abbreviations of the RMS pressure models see text.

Turbulence model	$C_{p,mean}$	$C_{p,RMS}$ (P&H)	$C_{p,RMS}$ (S)	$C_{p,RMS}$ (P)	$C_{p,RMS}$ (R&W 1)	$C_{p,RMS}$ (R&W 2)
Standard k-ε	0.3551	0.9880	0.6819	0.9999	0.9987	1.0000
Realizable k-ε	0.4386	0.9988	0.8178	1.0000	0.9995	1.0000
RNG k-ε	0.4251	0.9990	0.8102	1.0000	0.9996	1.0000

Table 2. Average amount of underprediction per underpredicted location. For the abbreviations of the RMS pressure models see text.

Turbulence model	$C_{p,mean}$	$C_{p,RMS}$ (P&H)	$C_{p,RMS}$ (S)	$C_{p,RMS}$ (P)	$C_{p,RMS}$ (R&W 1)	$C_{p,RMS}$ (R&W 2)
Standard k-ε	0.0878	0.0829	0.0732	0.1387	0.0979	0.1226
Realizable k-ε	0.0744	0.0950	0.0686	0.1454	0.1045	0.1259
RNG k-ε	0.0934	0.0970	0.0702	0.1458	0.1046	0.1263

Table 3. Overall average amount of underprediction. For the abbreviations of the RMS pressure models see text.

Turbulence model	$C_{p,mean}$	$C_{p,RMS}$ (P&H)	$C_{p,RMS}$ (S)	$C_{p,RMS}$ (P)	$C_{p,RMS}$ (R&W 1)	$C_{p,RMS}$ (R&W 2)
Standard k-ε	0.0312	0.0819	0.0499	0.1387	0.0978	0.1226
Realizable k-ε	0.0326	0.0949	0.0561	0.1454	0.1045	0.1259
RNG k-ε	0.0397	0.0969	0.0569	0.1458	0.1046	0.1263

As will also be concluded in section 4 it can immediately be seen from table 3 that the best results are obtained when the model of Selvam is used in combination with the standard k-ε model. In order to understand the reason for this, the average amount of underprediction in $C_{p,RMS}$ values for this combination of models is plotted at 0 and 45 degree angles of attack in figure 4 and figure 5, respectively. In these figures bright green represents a conservative estimate (no underprediction).

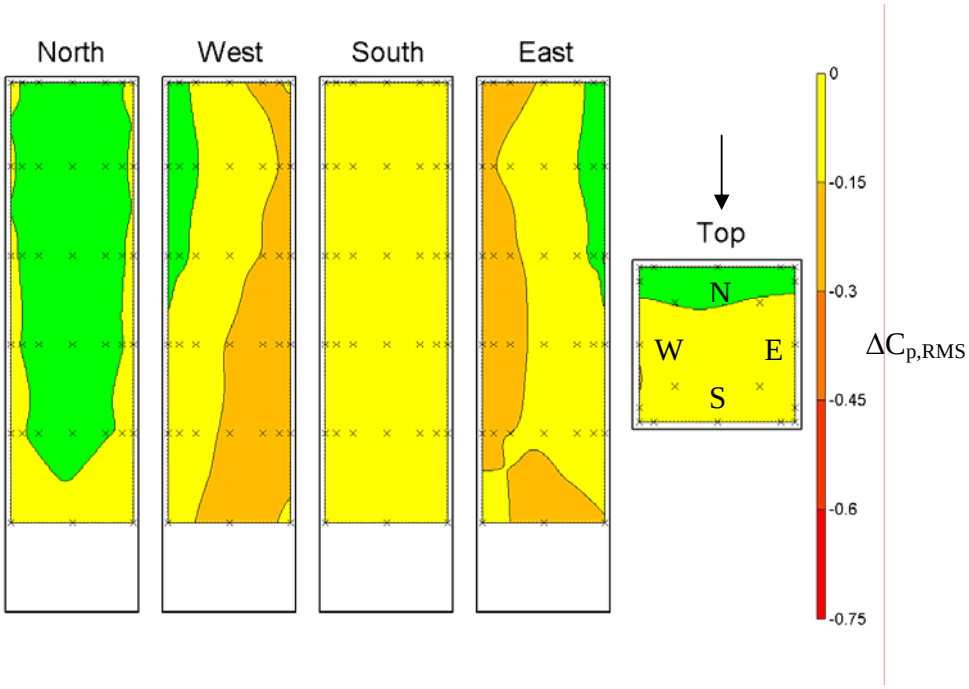

Figure 4 Amount of $C_{p,RMS}$ underprediction as a function of location for the model of Selvam using the standard k-ε turbulence model. 0 Degree angle of attack.

4 DISCUSSION

It can be seen from table 1 that the underprediction fractions for all RMS models are much larger than 0.5, indicating that none of the models are conservative. Both the models of Paterson and Holmes and that of Paterson perform especially poorly in this respect, leading to an underprediction for (almost) every location. Also apparent is the fact that, for the case considered here, the influence of the RMS model which is chosen is much more important than the turbulence model. The differences between the turbulence models show that the standard k-ε model is the most conservative which might be due to the well-known overprediction of turbulent kinetic energy in stagnation areas for this model. All papers where these models were introduced exclusively used the standard k-ε model.

The average amount of underprediction per underpredicted location is given in table 2. Again, although the differences between the results of the three turbulence models are not negligible they are much larger when different RMS models are compared. The least amount of underprediction is found using the model of Selvam whereas that of Paterson again performs poorly.

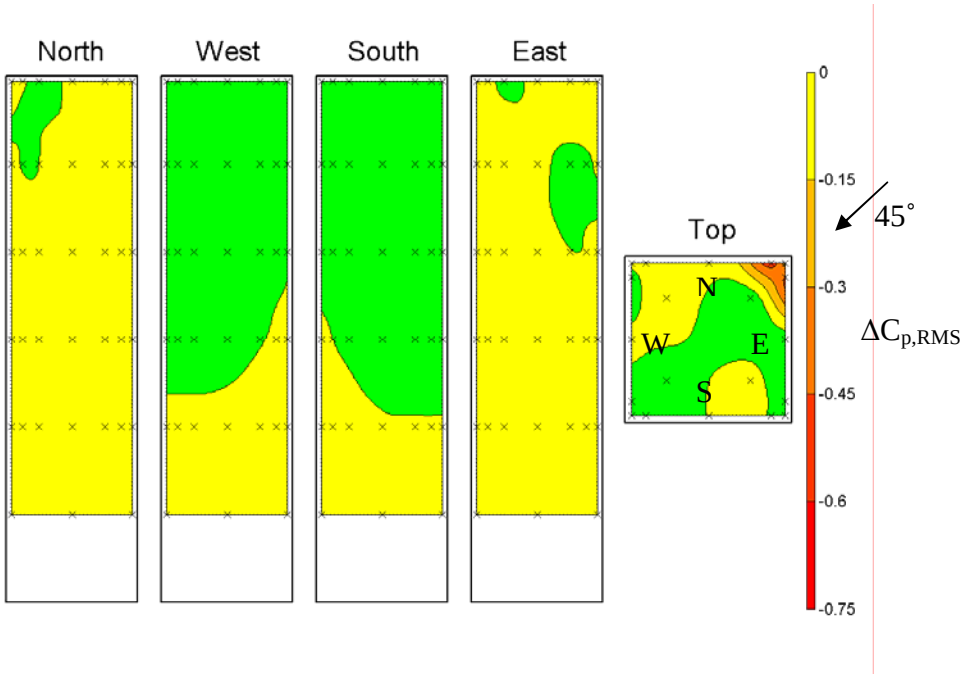

Figure 5 Amount of $C_{p,RMS}$ underprediction as a function of location for the model of Selvam using the standard k-ε turbulence model. 45 Degree angle of attack.

Combining the data in tables 1 and 2 by taking the product of both, the data in table 3 are derived. The values represent an average amount of underprediction for the selected model when overprediction is neglected. The best results are obtained when the model of Selvam is used in combination with the standard k-ε model, leading to an average amount of underprediction of $C_{p,RMS}$ of 0.0499. The worst results are obtained by combining the model of Paterson with the RNG k-ε model in which case the average amount of underprediction is almost three times as high.

The difference between the velocity magnitude and turbulent kinetic energy profiles for the wind tunnel and CFD datasets observed in figure 2 is caused by the wall functions used at the bottom of the CFD computational domain and in the absence of more appropriate wall functions cannot be avoided completely (Blocken, 2007; Kalkman, 2011). The effect of this discrepancy on the quality parameters given in tables 1-3 was therefore estimated through another analysis using the linearly interpolated wind tunnel dataset for the terms U_0, U_h, k_0 and k_h, resulting in a change of 30.5 ± 38.0 %. The most conservative model is again found to be Selvam's. However, although the results of this reanalysis are considerably more conservative even this model still underpredicts RMS pressure values on 32.6 % of the inspected surface area.

5 CONCLUSION

The observation that the RMS pressure models introduced by Paterson and Holmes (1989), Selvam (1992), and Paterson (1993) are generally non-conservative has already been made by the respective authors. Richards and Wanigaratne (1993), however, showed by comparison with data from the Silsoe building that their models performed rather well. In this paper it is shown that

this is no longer the case when they are applied to a high-rise building model. A very likely source of discrepancy is the mismatch between wind tunnel and CFD inflow profiles. As an alternative to the precursor simulation method used in the present investigation one could prescribe an ABL profile of the desired shape, in disregard of the fact that it will not be maintained throughout the computational domain. Another possible explanation for the relatively poor performance of the model derived by Richards and Wanigaratne for the present case is that the factors E and F, which were determined from a fit to the Silsoe building data set, are not universally applicable. Although the mathematical basis for the model introduced by Selvam (1992) is not completely clear it does seem to have a wider range of application. From figure 4 and figure 5 it can be observed that, away from reattachment zones and areas affected by corner vortices, it does not perform too poorly. Nevertheless, it is still non-conservative and therefore not applicable in an engineering context. New models are therefore required.

The effect of the turbulence model on the performance of the RMS model is comparatively minor. Future work should therefore focus on deriving an equation for the RMS pressures from first principles. Closure should be obtained with modelling assumptions also used in the turbulence models. RSM models could be helpful for this.

ABSTRACT: The added mass has significant effect on the vibration of the membrane structures, which depends on the mode shapes and can not be ignored during their vibration analysis. In this paper, the added mass of the circular membrane is investigated by the proposed numerical analysis method. Using the Realizable *k-ε* and RNG *k-ε* model of the FLUENT commercial computational Codes associated with the Dynamic-mesh technique to simulated the air loading on the circular membrane and using FEM to obtain the dynamic matrix equation for the circular membrane, the natural frequencies in consequence of considering the effect of the surrounding air is observed. An existing test result is employed to verify the proposed method. The problem presented herein may be considered as the air-structure coupled problem.

KEYWORDS: added mass, circular membrane, numerical estimation

1 INTRODUCTION

When structures vibrate in a certain kind of fluid, part of the surrounding fluid will be invoked and will vibrate together with structures; this effect is called added mass. Generally, the added mass of building structures vibrating in air, such as steel structures or concrete structures, can be ignored, because their material densities are much greater than that of air. However, the added mass has a significant influence on the vibration of membrane structures due to the light weight of their material.

Actually, the added mass of typical objects, such as cylinders and spheres, moving in fluid with acceleration has been widely investigated. Currently, research on the added mass of membranes is still limited. A study by Minami [1] indicated that the added mass has no relationship to the vibration frequency and amplitude but only to the air density and the dimension of the membrane. The added mass is equivalent to the air uniformly distributed on the membrane with an estimated height equal to 68% of the length of the membrane. Irwin and Wardlaw [2] presented an empirical equation for estimating the added mass of the Montreal Stadium. Li, et al [3] proposed a simplified added mass model which can take into account complicated vibration mode shape of flat membranes, i.e., the added mass above each vibration region is equal to the uniformly distributed air with height of 0.65*l*, in which *l* is the diameter of the inscribed circle of the region. The vibration regions are separated by the boundary lines which are made up of the points at which the displacement in the mode shape is zero.

A numerical method for added masses of the circular membrane vibrating in still air is developed by using the FLUENT commercial computational Codes in this paper with the Realizable k-ε and RNG k-ε model associated with the Dynamic-mesh technique. The vibration of the circular membrane can be simulated and the air loading on the circular membrane can be obtained. Based on the concept of kinetic energy, the added mass of the circular membrane can be derived out. The dynamic matrix equation for the structure is obtained by means of FEM and the natural frequencies in consequence of considering the

effect of the surrounding air is observed. Finally, an existing test result is employed to validate the efficiency of the proposed method.

2 DETERMINATION OF THE ADDED MASS

In the case of an incompressible inviscid stationary fluid, the change rate in time of kinetic energy of any part of the fluid is equal to the work done by the pressures on its surface.

$$\frac{dE}{dt} = -\int_A V_N \Delta p dA \tag{1}$$

where E is the kinetic energy, A is the surface bounding the fluid region and V_N denotes the velocity of the fluid particle in the derection of the normal N. The last integral thus expresses the rate at which the pressure $\triangle p$; exerted from outside an element of the boundary, is doing work. Assuming the fluid-solid interface of the membrane can be expressed as

$$\frac{dE}{dt} = -\int_A \frac{\partial h}{\partial t} \Delta p dA \tag{2}$$

Where $\partial h / \partial t$ is the velocity of the membrane in the normal direction. h is the surface displacement of the circular membrane.

On the other hand, the change rate of kinetic energy in time of the oscillating circular membrane having a mass per unit area equivalent to the added mass, M_a, can be given

$$\frac{dE}{dt} = -M_a \int_A \frac{\partial h}{\partial t} \frac{\partial^2 h}{\partial t^2} dA \tag{3}$$

So an expression for the added mass per unit area can be given in the following form:

$$M_a = \frac{\int_A \frac{\partial h}{\partial t} \Delta p dA}{\int_A \frac{\partial h}{\partial t} \frac{\partial^2 h}{\partial t^2} dA} \tag{4}$$

Eq.(4) indicates the essential dependence of the added mass of the oscillating circular membrane upon the fluid loading, $\triangle p$. The understanding of the properties of added mass will allow the fluid loading to be obtained in the most suitable form.

3 FORMULATIONS OF FLUID STRUCTURE INTERACTION (FSI)

In theoretical considerations, to take into account the fluid effect on the surrounded vibrating structure, the system has to be treated as a fluid structure interaction problem. In that case, the structural dynamics equation has to be coupled with the fluid equations.

It is well known that the discretized structural dynamics equation can be formulated as follows:

$$[K]\{u\} + [C]\{u'\} + [M]\{u''\} = \{P\} \tag{5}$$

In which $[K]$ is the structural stiffness matrix; $[C]$, the structural damping matrix; $[M]$, the structural mass matrix, and $\{u\}$, $\{P\}$ are the displacement and force vector, respectively.

The equation of motion of an undamped dynamic sytem in matrix notation is

$$[K]\{h\} + [\overline{M}]\{\frac{\partial^2 h}{\partial t^2}\} = \{0\} \tag{6}$$

where $[\overline{M}] = [M] + [M_a]$.

The membrane mass matrix is taken as diagonal with the masses corresponding to the collocation points. It can be transformed to the standard eigenvalue problem

$$([K] - \omega^2 [\overline{M}])\{h\} = \{0\} \tag{7}$$

Where ω is the eigenvalue, and the square root of the eigenvalue is the natural frequent considering the effect of the surrounding air.

4 DETERMINATION OF THE FLUID LOADING

4.1 *Mathematical model*

The finite volume method is employed to resolve the fluid governing equations, transforming a continuum domain into a discretized space of small cells where an algebraic system of equations is resolved after linearization and discretization of the original mathematical equations for the mass and momentum conservation. Considering the present vibration of the circular membrane, the following basic characteristics have been implemented in the model:

- Full-scale simulation of the circular membrane over a 3D domain is used segregated solver which solves the equation set sequentially.
- The governing equation of the flow is described by incompressible viscous Navier-Stokes equation.
- Unsteady resolution of the circular membrane using the smoothing techniques and remeshing techniques for dynamic meshes.
- Implementation of a parametric UDF to simulate the vibration of circular membrane can update the position of each node based on the deflection due to fluid-structure interaction.

4.2 *Turbulent model*

Up to know, significant progress in the field of CFD (Computational Fluid Dynamics) has been achieved, and it has been used as an efficient tool for prediction of fluid loads. Generally, the governing equation of the flow is described by incompressible viscous Navier-Stokes equation. Because Reynolds-averaged Navier–Stokes (RANS) modeling can reasonably simulate mean wind characteristics and require less computing time than other CFD methods, it becomes the most widely used method in many industrial applications. For numerical simulation, the governing equations of the incompressible turbulent wind flow around circular membrane are presented by the RANS equations as follows:

$$\frac{\partial}{\partial x_i}(\rho u_i) = 0 \tag{8}$$

$$\frac{\partial}{\partial t}(\rho u_i) + \frac{\partial}{\partial x_j}(\rho u_i u_j) = -\frac{\partial p}{\partial x_i} + \mu \frac{\partial}{\partial x_j}(\frac{\partial u_i}{\partial x_j}) + \frac{\partial}{\partial x_j}(-\rho \overline{u_i' u_j'}) \tag{9}$$

The turbulent kinetic energy, the k equation in Realizable k-ε model is the same as that in the standard k-ε model and the RNG k-ε model. However, the form of the ε equation in Realizable k-ε model is quite different from those in the standard and RNG-based k-ε models. One of the noteworthy features is that the production term in theε equation does not involve the production of k; i.e. It is believed that the present form better represents the spectral energy transfer. It is a mathematical theory which can be used to derive a turbulence model which is similar to the k-ε model. Following improvements compared to standard k-ε model: (1). Additional term in ε equation improves the accuracy when modelling rapidly strained flows. (2). The effect of swirl turbulence is included in the RNG model. (3). The RNG model enables to use Prandtl numbers (turbulent viscosity/turbulent heat conductivity) as variables. (4). Enables to use lower Reynolds numbers than in standard model. The analytical derivation results in a model with constants different from those in the standard k-ε model, and additional terms and functions in the transport equations for k and ε.

4.3 *SIMPLIC algorithm*

The pressure–velocity coupling was resolved using the SIMPLIC algorithm and the under relaxation factors were kept within typical ranges (0.3 for the pressure correction equation and 0.7 for the momentum equation), which helped to speed up the convergence process.

4.4 *Dynamic meshes*

Dynamic and deformable meshes allow the displacement of the domain boundaries in CFD simulations, adjusting the associated mesh to the new locations accordingly. With the dynamic mesh model in FLUENT, it allows an arbitrary motion of fluid boundaries, and the response of the fluid to the prescribed boundary motion can be captured. Meanwhile, the motion control of the circular membrane can be realized by using DEFINE GRID MOTION UDF in FLUENT, and a grid motion UDF can update the position of each node based on the deflection due to fluid-structure interaction.

Different schemes for the mesh reconstruction can be found in the literature, according to the basic characteristics of the moving mesh. In the present study, two fundamental methods have been employed for efficient treatments of the vibration of the circular membrane. One is smoothing techniques: where the initial connectivity of the mesh nodes is remained unchanged. The nodes are repositioned as if they were connected by small springs. Though there is no restriction about the original mesh type, it can be used only in the case of small deformations. The other is remeshing techniques: which is an alternative to the smoothing algorithm when there are excessively large deformations in the model. The mesh has to be locally rebuilt after the changes in the boundaries are completed.

4.5 *Boundary conditions*

It is necessary to impose the boundary condition artificially because the computational domain can not be infinite. The entrance boundary condition is defined by pressure-inlet where the specification of a static (gauge) pressure at the inlet boundary is set to zero. The exit boundary condition is defined by pressure-outlet where the specification of a static (gauge) pressure at the outlet boundary is set to zero. The boundary condition at the top and on both sides of flow field is symmetric boundary which is equivalent to the free-slip wall. The no-slip boundary condition is enforced at wall of the circular membrane surface and the ground.

5 RESULTS AND COMPARISON

Li, et al [3] investigated the vibration of circular membrane vibrating in air and in vacuum. A vacuum chamber was designed to test the vibration of a circular flat membrane in still air with various air pressures. The membrane was clipped by a top circle and a bottom circle. The pressures was imposed uniformly by lifting an inner circle. As Table 1 shown, the vibration of the membrane was measured in 1atm, and 0.6atm. Two membrane materials were used in the tests, including a latex and a rubber membrane, and five prestress levels of the membrane were tested. The natural frequencies of the membrane in 1atm, and 0.6atm were given in Table 2. Using the Realizable k-ε model and the RNG k-ε model of FLUENT commercial computational Codes to derive the aerodynamic pressure, and associating with FEM to derive the natural frequencies in consequence of considering the effect of the surrounding air, the results are shown in Table 3. The fundamental frequency in vacuum was estimated with Finite Element Method (FEM), as listed in Table 4.

Table 1 Test cases

Air pressure	Latex membrane Prestress (MPa)			Rubber membrane Prestress (MPa)	
	σ_1=0.092	σ_2=0.178	σ_3=0.297	σ_4=0.471	σ_5=0.828

Table 4 Natural frequencies of the circular membrane vibrating in vacuum

Prestress (MPa)	Finite Element Analysis				Fitting result of test			
	1st mode	2nd and 3rd mode	4th and 5th mode	6th mode	1st mode	2nd and 3rd mode	4th and 5th mode	6th mode
σ_1=0.092	24.45	39.08	52.48	56.43	24.45	33.38	-	61.96
σ_2=0.178	34.00	54.36	73.00	78.50	34.00	50.97	-	92.92
σ_3=0.297	43.98	70.02	82.50	101.39	43.98	72.18	-	110.18
σ_4=0.471	55.43	88.42	118.75	127.69	55.43	87.13	114.24	-
σ_5=0.828	73.49	117.24	157.45	169.30	73.51	121.13	-	-

Comparing the result of the natural frequencies in Table 2 and Table 3, the FLUENT results have a good agreement with the experimental results and the result of using the Realizable k-ε model and the RNG k-ε model is almost the same. The proposed numerical method is effective and can be used for the analysis of free vibrations of flat membrane. Comparing the result of the natural frequencies vibrating in 1atm and 0.6atm and the result of the natural frequencies vibrating in vacuum, it can find the effect of the air surrounding the membrane structure on the natural frequencies of the structure is very significant.

6 CONCLUSIONS

The numerical method for obtaining added masses of the circular membrane vibrating in still air is proposed in this paper. The aerodynamic pressure associated with the structure deformations is derived by the FLUENT commercial computational Codes and the natural

frequencies in consequence of considering the effect of the surrounding air is observed by FEM. The result based on this method is verified by comparing with the existing test results. Through the numerical example calculated with the use of the air mass, it can find that the effect of the air surrounding the membrane structure on the natural frequencies of the structure is very significant.

ABSTRACT: A numerical movable tornado simulator using Large Eddy Simulation has been constructed to generate the tornado-like vortices and used to evaluate the effects of the translational moving of the vortices on the wind pressure distribution around a cube building. The performance of the simulator has been verified in comparison with the previous experimental results. Although, wind pressure on the surface of the cubic was almost constant in time inside the stationary tornado-like vortices, the pressure was changed significantly when the vortices were translated. The significant changing has also clarified from the wind flow around the cubic with strong whirl vortices and vertical wind components.

KEYWORDS: Tornado-like Vortices, Cubic, Wind Pressure, LES Model, Moving Effect

1 INTRODUCTION

Damages caused by tornado are often due to the destroy or damage on the walls or roofs and tiles of building, those things are then scattered and wrap around a new building or structure to create a new damage. In order to reduce the damages, better understanding of flow field and wind pressure acting on building in tornado needs to be clarified.

Because of the sudden and local occurrence of a tornado, it was found that the measurement of a flow field near the ground in a tornado was difficult[1)]. Some meteorological numerical simulations in the meso-scale tried to elucidate the generation mechanism of a tornado that needed to model a giant cumulonimbus cloud, in which dozens of kilometers wide was in two orders of magnitude of the tornado. The scale of the simulation would become too large to evaluate the flow field near the ground as well as the wind pressure acting on building in detail[2)]. On the other hand, several studies[3,4)] to better understand tornado structure used physical models that simulate tornado-like vortices as a flow field of tornado near the ground below a cumulonimbus cloud. Some experiments[4)] indicated the changing in structure of vortex by Reynolds number and swirl ratio. Recently, Yang et al.[5)] showed the appropriateness of the physical model in modeling the flow field of tornado in comparison with field measurement's results. However, most experiments were carried out in 1/1000 to 1/10,000 of real scale. Because of the constraints of the experimental devices, it was difficult to investigate in detail the structure of the vortices as well as the changing in wind pressure of the building. Numerical simulation using computational fluid dynamic is expected as one of effective method to solve the problem[6,7)].

While those studies made an effort to evaluate the flow field and wind loads on building the in tornado-like vortices, most of them ignored the translational movement of the vortices that could be an important reason of damages caused by tornado. In recent years, some researcher[5,8)] tried to design the prototype of the experimental apparatus that could translate a vortex forcibly. Selvam et al.[9)] proposed a numerical simulator using the Rankine-Combined Vortex Model (RCVM) to simulate the effect of translational movement of the tornado on the forces acting on buildings. Although, this model did not include the vertical velocity, which did occur inside the vortex core of actual tornado, it was found that the forces were higher than the results in the

straight boundary layer wind in the vertical direction. Some new model including the vertical velocity needs to be considered for better understanding.

In this study, a numerical movable tornado simulator using Large Eddy Simulation and dynamic mesh generation has been developed. The performance of the simulator has been verified in comparison with the wind velocity profile and wind pressure distribution of previous experiment. The simulator was then used to evaluate the effects of translational moving of the tornado-like vortex on wind flow field and the wind pressure distribution on a cube building.

2 NUMERICAL MOVABLE SIMULATOR

Schematic of the movable tornado simulator is shown in Fig.1. A Ward-type tornado simulator has been modeled basing on the dimensions of the stationary simulator model of Matsui's experiment[4]. Simulator included a convergent zone of h=20cm height with a shear inflow layer of direction θ, a convection zone with an exhaust outlet and was moved with the translational velocity U_{mov}. Table 1 shows the analysis conditions and those conditions in the actual atmosphere[4,10]. The scale is about 1/1000~1/10000. As the same as previous studies, the swirl ratio($S = d/4h \times tan\theta$) was considered to be the main dimensionless quantity. The ratio of translational velocity and maximum velocity obtained inside the vortex (U_{mov}/U_{max}=0.6/12) is in the range of 0~30/90 in the actual phenomena.

Fig.2 illustrates the mesh of convergent zone in the plan view (a), close-up of the stationary mesh area in the convergent zone (b) and mesh of computational domain. Moving meshes with sliding interfaces were adapted to model the moving of tornado from left to right. In order to minimize the effects of the moving meshes, a stationary mesh zone around the building was modeled. Dynamic layering method was also adapted to split or merge mesh cells to maintain the quality of mesh around the building. Computational model had 779 thousand mesh cells.

Navier-Stokes equations for incompressible flow including the continuous equation and momentum equations were solved using Fluent 6.3 software[12]. LES turbulence model was used in which small eddies were modeled using the standard Smagorinsky model. Governing equations were discretized by the finite volume method. A central difference scheme for convective terms and a second-order implicit scheme for unsteady terms were used.

A cube of width B=0.1h was set up at the center of floor of the simulator. Wind speed U_0=6m/s was kept constant at the outlet boundary, whose outflow's volume was 0.3m^3/s, to generate the upward flow in the convection zone. A same volume of inflow with angle θ=60deg was applied to the inlet boundary to generate a tornado-like vortex with a swirl ratio S=0.65. Walls of simulator were modeled as the moving wall boundaries. Walls of cubic were no-slip boundaries.

In order to clarify the effect of translational movement of the tornado-like vortices, two case studies have been simulated with translational moving velocity U_{mov}=0 and 0.6m/s as the stationary condition and the moving condition, respectively. In case 1, the numerical simulator was not moved (U_{mov}=0m/s), hereinafter referred to the case of the stationary condition. The wind flow field was generated from the analysis conditions to obtain the wind pressure acting on a cubic. In case 2, the numerical simulator was firstly set up in the 0.4m left-hand side of the cube. After 7000 steps of an approach run, which was enough to generate a tornado-like vortex, the simulator was moved to the right hand side with a translational velocity of U_{mov}=0.6m/s, hereinafter referred to the case of the moving condition. Wind pressure acting on the cubic was estimated during the vortex's passing. Each simulation was carried out for 16s at time increment of 0.001s.

Because of time-space changing of wind speed and static pressure in the tornado-like vortices, the method using in straight boundary layer to estimate the wind pressure coefficients cannot be applied. In this study, the pressure coefficient was obtained by the following equation[4].

$$C_p = (P - P_s)/0.5\rho V_0^2 \quad (1)$$

Table 1. Dimensions of the movable simulator and analysis conditions

Parameters	Symbol	Numerical study	Real Scale[4,10]
Upward hole diameter	D	0.3m	1~3km
Convergent zone height	h	0.2m	0.5~2km
Convection zone diameter	D1	1.6m	-
Exhaust outlet diameter	d	0.25m	-
Convection zone diameter	D_2	1.2m	-
Swirl ratio ($d/4h\tan\theta$)	S	0.65	0.05~2
Inflow angle	θ	60deg	-
Outlet volume	Q	0.3m^3/s	10^8~10^9 m^3/s
Outlet velocity	U_0	6m/s	-
Maximum tangential velocity	U_{max}	12m/s	70~90m/s
Translational moving speed	U_{mov}	0, 0.6m/s	0~30m/s
Cubic building width	B	0.02m	20~200m

Where, P is the wind pressure, P_s is the maximum wind pressure far enough away vortex, ρ is the density of air. V_0 is the reference wind speed which was calculated from the difference between the maximum wind pressure of the ground surface and the minimum wind pressure at the center of the vortex that obtained in a stationary condition of the simulator without any cubic. Following the definition, the pressure coefficient at the floor surface is mathematically between -2 to 0 when the vortex is assumed as the Rankine vortex. The pressure coefficient of -1 will also match to the position of the maximum wind speed of the vortex.

Fig.3 illustrates a comparison of tangential velocity and ground surface pressure distributions between experiment and simulation in the stationary condition without any cube. The simulated results showed a good agreement with experimental ones. In addition, the wind pressure coefficient is between -2 to 0, and at the coefficient of 1, the tangential component of wind speed can be seen that nearly becomes the maximum.

3 RESULTS AND DISCUSSIONS

3.1 *Wind Pressure Distributions on a Cube*

Fig. 4 illustrates the wind velocity time series at the 0.75h height, which is on the top of the cube. Comparing to the result in the stationary state, the wind velocity increased in 7.6~8.2s and decreased in 8.2~8.6s as a sudden gust wind occurring when the simulator was passing. Fig. 5 and Fig.6 show the maximum and minimum wind pressure time series acting on each surface of cube in the stationary state and moving state of simulator. A plus (+) mark including A, B, C, D, E letter indicates a developed view of the surfaces of the cube. The rotational direction and translational direction of the tornado-like vortex are also described together. In the stationary condition, wind pressure acting on each surface of the cube becomes almost constant in time. The pressure coefficients on the roof and side surfaces are between 0.0 to -1.0 that is similar to the values obtained by the previous experiment[7]. On the other hand, in the moving condition, a large wind pressure does not occur when the center axis of the simulator is approaching. After the central axis passed the cubic, the pressures change rapidly at 8.2s. The maximum and minimum pressures are up to +3 and -3, simultaneously, whose range is larger than the range of -2 to 0 in assumption of Rankine vortex which has been mentioned above. Incidentally, the position at the time of 8.2 seconds is the same as the position of approximately 0.05m from the vortex center (Fig.3a) that corresponds with the maximum wind speed of the tangential direction of the vortex.

Fig. 7 and 8 shows the vorticity contours and distribution of wind pressure acting on the ground and surfaces of cube at 8.2s. A square in figure (b) is the roof and figure (c) shows the developed view of the surfaces of the cube. In the stationary condition, the vortex axis and minimum pressure distribution are biased in the rotational direction at a position 0.05m away. It can be explained by the effect of the presence of cube. Detail for the effects of cube in dimensions will be discussed in next section. In addition, the wind pressure distribution and vorticity contour in the analysis has been confirmed to be a nearly steady state. On the other hand, in the case of moving, the tornado-like vortex has been almost hit to the cube as shown in Fig-7(a), resulted in a strong negative pressure at the corner ② of the roof as shown in Fig.7(c). A strong positive pressure near the corner① and negative pressures at the other side corners are also found.

In order to clarify the characteristics of wind pressure caused by the translational moving effect of the tornado-like vortex, the flow field in the vicinity of the cube is investigated. Fig.9 (a) and (b) show wind velocity contour and vector in the horizontal plane of z=0.8B at the time of 8.2s. The flow separates and creates one small vortex at the corner ①and one large vortex at the

corner ④ that reattaches to other sides of cubic. The points of separation and reattachment are corresponding with the regions of strong positive and negative pressure in Fig.8(c). Although, these separation vortices are found as similar as the vortices in the boundary layer flow, the generated flow field around the cubic is typically whirled up, as shown in Fig.9(a). Moreover, a sudden changing in wind speed is also found at the separation points, with a strongly rising up flow field at the reattachment points. Fig.9 shows the contour and vector of wind speed in the vertical plane of x=-0.4B. A large upward flow near the corner② has been occurred corresponding to the strong negative pressure obtained in the roof as shown in Fig.8(c). Consequently, it can be found that a complex three-dimensional flow formed by the swirling and strong upward flow caused a strong locally negative pressure in the vicinity of the cube from the tornado-like vortex.

3.2 *Wind vortices around a Cube*

In order to clarify the effect of dimensions of cubic in the tornado-like vortex, a simulation with a cube of *B=0.5h* was also carried in the stationary condition. Vorticity magnitude was estimated from the wind flow of stationary and moving simulators and visualized in 3D volume rendering. Fig.10 illustrates the vortex in the stationary condition with cube of *B=0.1h* and *B=0.5h*. When the width of cube became large, the tornado-like vortex was separated into small vortices. The small vortices were occurred around the corner of the cubic and turn in the tornado direction. In other hand, the moving of the vortex before and after passing the cubic is shown in Fig.10. When the vortex is moving, the core of vortex was bent under effect of ground. Strong vortices are also found around the cubic from the tornado-like vortex.

4 CONCLUSION

A numerical movable tornado simulator using LES has been developed to evaluate the effects of the moving of the tornado-like vortices on the wind pressure distribution and wind flow around a cube. Although, the wind pressure on the surface of the cubic is almost constant in time inside the stationary tornado-like vortices, the pressure is changed significantly under moving of the vortices when the vortices were passing. The significant changing was also clarified from the wind flow around the cubic with strong whirl vortices and vertical wind components.

ABSTRACT: Turbulent wind flows around building structures (bluff bodies) are investigated numerically using Reynolds Averaged Navier-Stokes (RANS) turbulence models. A non-linear viscosity assumption model, which can take into account the anisotropy of turbulence with less numerical cost than LES method, is adopted herein as a turbulence treatment method. Model coefficients of the nonlinear terms are adjusted, aiming to model three-dimensional flows over bluff bodies. Compared with the results of the linear eddy viscosity model and experimental measurements, the nonlinear eddy viscosity model yields more reasonable results, especially for the reattachment length and pressure coefficients. It is also noted that the nonlinear eddy viscosity model performs satisfactorily to reproduce complex turbulent flows around bluff bodies.

KEYWORDS: Nonlinear eddy viscosity model, CFD, Bluff body, Wind flow, RANS models

1 INTRODUCTION

Turbulent wind flows around building structures (bluff bodies) have been studied extensively by wind tunnel tests and field measurements. Rapid developments of computer technology in recent years have made it possible to adopt numerical methods, such as Large Eddy Simulation (LES) or Reynolds Averaged Navier-Stokes (RANS) models, to simulate turbulent flows around bluff bodies. Although LES is an effective tool to calculate turbulent flows around civil structures, RANS turbulence models, such as eddy viscosity models or Reynolds Stress Models, are still valid because they require less computer hardware sources than LES. However, it is imperative to overcome the limitations of RANS models. From the viewpoint of computational efficiency and practical application, nonlinear eddy viscosity models are attractive for simulations of flows influenced by anisotropy of turbulence.

The two-equation turbulence models, for instance, the $k-\varepsilon$ and the $k-\omega$ series models, offer significant simplicity and numerical stability in many cases for predictions of flow fields. The Linear Eddy Viscosity Models (LEVMs) construct eddy flow field using solvable turbulence quantities, such as k, ε and ω (Versteeg & Malalasekra, 2007). The Boussinesq hypothesis, together with the standard $k-\varepsilon$ model (Launder & Spalding, 1974), is generally regarded as the conventional linear eddy viscosity concept. It is found that LEVMs can be successfully applied to two-dimensional boundary layers, three-dimensional flow around simple bodies and thin shear flows which can be treated as approximately equilibrium (Hellsten and Bezard, 2005). This is because the LEVM is only able to provide principle stress component correctly in such flows. Therefore, it is not applicable in flows where anisotropic turbulence eddy fluctuations essentially influence the mean flow. Complex phenomena such as strong three-dimension, separations, recirculations and reattachments are common in wind flows over building structures. It is noted

that the standard LEVMs have severe defects for simulations of complicated flow fields. Consequently, it is required to extend the applicability of the linear eddy viscosity models for capturing anisotropic stress fields.

Recent studies have been mainly focused on the nonlinear relationship between the Reynolds stress and mean flow quantities. The aim of adopting the Nonlinear Eddy Viscosity Model (NLEVM) is to introduce mean flow strain rate (or vorticity) into the Reynolds stress expressions to construct nonlinear stress terms. Quadratic, cubic and fifth order models are commonly used in the NLEVM's, which are different from each another with the degrees of nonlinearity. Craft et al. (1997) and Huang & Rajagopal (1996) developed individual quadratic NLEVM models to simulate two-dimensional turbulent flow over a backward-facing step. Their results showed that the two quadratic NLEVMs successfully predicted the reattachment length of flow over the step. Meanwhile, the quadratic models demonstrated great robustness while CPU cost was not significantly increased. Other quadratic models have been proposed by Speziale (1987) based on the strain rate and by Rubinstein (1990) based on renormalisation-group approach. These models yielded satisfactory results for simple cases.

Jongen et al. (1998) observed that the sensitivity of quadratic models to the rotation is inadequate to predict fully developed channel flow subjected to rapid spanwise rotation. Craft et al. (1995) argued that a cubic Reynolds stress expansion is needed for predicting complex flows with large streamline curvature effects. Craft et al. (1995) adopted a third-order term to sensitize the model to curvature effects to overcome the overestimation of turbulence energy in the impingement area. To capture non-equilibrium flows, Craft et al. (1997) developed a more complicated model, in which the second anisotropy invariant is added in Reynolds stress expansions to form a three-equation of NLEVM. This new model was designed especially for low-Reynolds number transitional and turbulent flows. Apsley & Leschziner (1998) derived a cubic model based on successive iterative approximations to an algebraic Reynolds stress model. They validated the model by considering several flows including a high-lift airfoil flow and separating flow in two-dimensional diffuser. However, they just used the original coefficient-formulas as relationships between the coefficients and recalibrated their values to capture the low-Reynolds number near-wall flow.

Applications of these NLEVMs to complex turbulent flows have displayed inspiring results on flow anisotropy, strong streamline curvature, recirculation and adverse pressure gradient. To evaluate the performance of the NLEVMs in predicting complex turbulent flows fields, this paper presents numerical simulations of wind flow over a bluff body with a quadratic NLEVM in comparison with field measurement data. It should be noted that throughout the numerical simulations, realizability conditions are applied to the NLEVM. It will prove that the NLEVM can be applied to the simulations of turbulent flows with strong anisotropy usually encountered in engineering practices.

2 THE NONLINEAR $k-\varepsilon$ TURBULENCE MODEL

2.1 *Basic equations*

The basic equations of continuity and momentum for steady incompressible flows are:

$$\begin{cases} \dfrac{\partial \rho}{\partial t} + div(\rho \mathbf{u}) = \mathbf{0} \\ u_j \dfrac{\partial u_i}{\partial x_j} = -\dfrac{\partial p}{\partial x_i} - \dfrac{\partial u_i' u_j'}{\partial x_j} + \mu \dfrac{\partial^2 u_i}{\partial x_j^2} \end{cases} \tag{1}$$

Realizable $k-\varepsilon$ model is adopted in this study as follows:

$$\begin{cases} \dfrac{\partial(\rho k u_j)}{\partial x_j} = \dfrac{\partial}{\partial x_j}[\alpha_k \mu_{eff} \dfrac{\partial k}{\partial x_j}] + G_k - \rho\varepsilon, \\ \dfrac{\partial(\rho \varepsilon u_j)}{\partial x_j} = \dfrac{\partial}{\partial x_j}[\alpha_\varepsilon \mu_{eff} \dfrac{\partial \varepsilon}{\partial x_j}] + \rho C_1 S \varepsilon - \rho C_{2\varepsilon} \dfrac{\varepsilon^2}{k + \sqrt{\nu\varepsilon}} + \rho C_{1\varepsilon} \dfrac{\varepsilon}{k} C_{3\varepsilon} G_b. \end{cases} \tag{2}$$

where x_i and x_j are the spatial coordinates; u_i and u_j are the averaged wind velocities; $-u_i' u_j'$ is the Reynolds stress; p is the averaged pressure; ρ is the density of fluid; k is the Turbulent Kinetic Energy (TKE); ε is the turbulent energy dissipation rate; ν_t is the turbulent dynamic eddy viscosity, μ is the molecular viscosity and $\sigma_k = 1.0$, $\sigma_\varepsilon = 1.3$, $C_1 = 1.44$, $C_2 = 1.92$ are the model constants.

For two-equation turbulence model, Reynolds stress tensors τ_{ij} are expressed by the linear constitutive equation:

$$\tau_{ij} = -\rho \overline{u_i' u_j'} = \mu_t \left(\frac{\partial \overline{u_i}}{\partial x_j} + \frac{\partial \overline{u_j}}{\partial x_i} \right) - \frac{2}{3} k \delta_{ij} \quad \mu_t = \rho C_\mu \frac{k^2}{\varepsilon} \tag{3}$$

2.2 *The quadratic eddy viscosity assumption*

Since the standard two-equation model does not take into account the anisotropy of the Reynolds stresses. This shortcoming can be overcome to some extent by introducing a nonlinear constitutive expression as follows:

$$\begin{aligned} \rho u_i' u_j' =& -\mu_t S_{ij} + 2/3 \delta_{ij} k + C_1 \mu_t \frac{k}{\varepsilon}(\Omega_{ik} S_{kj} + \Omega_{jk} S_{ki}) \\ &+ C_2 \mu_t \frac{k}{\varepsilon}(S_{ik} S_{kj} - 1/3 S_{kl} S_{lk} \delta_{ij}) + C_3 \mu_t \frac{k}{\varepsilon}(\Omega_{ik} \Omega_{kj} - 1/3 \Omega_{kl} \Omega_{lk} \delta_{ij}) \end{aligned} \tag{4}$$

where $S_{ij} = \partial u_i / \partial x_j + \partial x_j / \partial x_i$ and $\Omega_{ij} = \partial u_i / \partial x_j - \partial x_j / \partial x_i$

For three-dimensional flows around bluff bodies, the coefficients of Reynolds stress terms are needed to be tuned by consideration of the anisotropy (Champagne, 1970). Firstly, Reynolds stress components are extracted and simplified. According to zero-pressure gradient flow over a smooth plate, wind velocity component can be expressed as follows:

$$\begin{cases} u_1 = u_{y_0} \left(\dfrac{y}{y_0} \right)^\alpha \\ u_2 = u_3 = 0 \end{cases} \tag{5}$$

Then, shear deformation invariant $S = \dfrac{k}{\varepsilon} \sqrt{\dfrac{1}{2} \left(\dfrac{\partial u_i}{\partial x_j} + \dfrac{\partial u_j}{\partial x_i} \right)^2}$ and vorticity deformation invariant $\Omega = \dfrac{k}{\varepsilon} \sqrt{\dfrac{1}{2} \left(\dfrac{\partial u_i}{\partial x_j} - \dfrac{\partial u_j}{\partial x_i} \right)^2}$ can be simplified as:

$$S = \Omega = M = \frac{k}{\varepsilon} \frac{\mathrm{d}u_x}{\mathrm{d}y} \tag{6}$$

where $M = \max(S, \Omega)$ is deformation tensor invariant.

The normal Reynolds stress components are expressed as follows:

$$\begin{cases} \dfrac{u_1'u_1'}{k} = \dfrac{2}{3} + C_\mu \dfrac{2C_1 - C_3}{3} M^2 \\ \dfrac{u_2'u_2'}{k} = \dfrac{2}{3} + C_\mu \dfrac{-C_1 + 2C_3}{3} M^2 \\ \dfrac{u_3'u_3'}{k} = \dfrac{2}{3} + C_\mu \dfrac{-C_1 - C_3}{3} M^2 \end{cases} \tag{7}$$

In two-dimensional boundary flows, constants $C_1 = 0.4$, $C_2 = 0$, $C_3 = -0.13$ and $C_\mu = 0.09$ vary with anisotropic flow characteristics. To satisfy the above mathematical constraints, damping function f_M is introduced into C_1~C_3 as:

$$C_1 = 0.4 f_M(M), \quad C_2 = 0, \quad C_3 = -0.13 f_M(M) \tag{8}$$

It is well-known that the tensor τ_{ij} is positive, the following inequalities are thus satisfied:

$$\begin{cases} \tau_{ii} \geq 0 \\ |\tau_{ij}| \leq (\tau_{ii}\tau_{jj})^{0.5} \\ det(\tau_{ij}) \geq 0 \end{cases} \tag{9}$$

We refer to these three properties as realizability conditions. The normal Reynolds stress components can be concluded based on the first realizability condition in equation (9) as follows:

$$\begin{cases} \dfrac{u_1'u_1'}{k} = \dfrac{2}{3} + C_\mu \dfrac{2C_1 - C_3}{3} M^2 \geq 0 \\ \dfrac{u_2'u_2'}{k} = \dfrac{2}{3} + C_\mu \dfrac{-C_1 + 2C_3}{3} M^2 \geq 0 \\ \dfrac{u_3'u_3'}{k} = \dfrac{2}{3} + C_\mu \dfrac{-C_1 - C_3}{3} M^2 \geq 0 \end{cases} \tag{10}$$

From the second expression of equation (10), constant C_μ satisfies:

$$C_\mu \leq \frac{2}{(C_1 - 2C_3)M^2} = \frac{2}{0.66 f_M(M) M^2} \tag{11}$$

Based on the realizable $k-\varepsilon$ model, turbulent kinetic energy generation G_k, Reynolds shear stress $-u_1'u_2'$ and turbulent viscosity μ_t are expressed below:

$$G_k = -u_1'u_2' \frac{\mathrm{d}u_x}{\mathrm{d}y}, \quad -u_1'u_2' = \nu_t \frac{\mathrm{d}u_x}{\mathrm{d}y}, \quad \nu_t = C_\mu \frac{k^2}{\varepsilon} \tag{12}$$

Reynolds shear stress $-u_1'u_2'$ can be derived by equations (11) and (12):

$$\frac{u_1'u_2'}{k} = -C_\mu M \tag{13}$$

Then another C_μ expression is derived as follows:

$$C_\mu \leq \frac{(C_1 + C_3)S + \sqrt{(C_1 + C_3)^2 S^2 + 4[9 + (2C_1^2 + 2C_3^2 - 5C_1C_3)S^2]}}{9S + (2C_1^2 + 2C_3^2 - 5C_1C_3)S^3} \tag{14}$$

To make sure C_μ satisfies the realizability condition, C_μ expression is given as follows:

$$C_\mu = \min(0.09, 0.3 f_M(M)) \tag{15}$$

Based on the above derivation, the three-dimensional quadratic eddy viscosity model can be expressed as:

$$\begin{cases} \rho u_i' u_j' = -\mu_t S_{ij} + 2/3\delta_{ij}k + C_1\mu_t\dfrac{k}{\varepsilon}(\Omega_{ik}S_{kj} + \Omega_{jk}S_{ki}) \\ \qquad\qquad +C_2\mu_t\dfrac{k}{\varepsilon}(S_{ik}S_{kj} - \dfrac{1}{3}S_{kl}S_{lk}\delta_{ij}) + C_3\mu_t\dfrac{k}{\varepsilon}(\Omega_{ik}\Omega_{kj} - \dfrac{1}{3}\Omega_{kl}\Omega_{lk}\delta_{ij}) \\ C_1 = 0.4f_M(M), \quad C_2 = 0, \quad C_3 = -0.13f_M(M), \\ C_\mu = \min\left(0.09, 0.3f_M(M)\right), \quad f_M(M) = \dfrac{1}{1+0.01M^2} \end{cases} \tag{16}$$

Turbulence modeling, aiming to wind engineering applications, should take the anisotropy of turbulent flow into consideration. It is important to maintain the ease of use and computational stable of the two equation models. Therefore, nonlinear expansions of the Boussinesq hypothesis--the quadratic expressions proposed by Craft et al. (1997)--have been extended in an attempt to account for anisotropic turbulence and curvature related strain effects. Numerical tests of the quadratic model will be carried out in the following section.

3 NUMERICAL DISCRETIZATIONS, MESH SCHEMES AND TEST CASE

3.1 *Numerical Discretizations*

The commercial package FLUENT has been used to solve the governing equations for mean wind velocities and turbulent quantities. The equations are discretized by the finite volume method on structure grids. The second-order upwind differencing scheme and SIMPLEC algorithm are used for convective terms and the pressure-velocity terms individually. The modified quadratic model is incorporated in FLUENT. The turbulent viscosity μ_t is also modified based on the new expressions.

3.2 *Boundary Conditions*

For inlet condition, a fully developed velocity profile is adopted, which is expressed by a power law:

$$u_x = u_{y_0}\left(\frac{y}{y_0}\right)^{\alpha} \tag{17}$$

where u_y (m/s) is the mean wind velocity at height y(m), u_{y_0}(m/s) is the reference velocity at height y_0(m). α is the roughness category coefficient.

Turbulence intensity I is defined in AIJ code (Architectural Institute of Japan, 2004):

$$I = \begin{cases} 0.1\left(\dfrac{y}{Y_G}\right)^{-\alpha-0.05} & , Y_b < y <= Y_G; \\ 0.1\left(\dfrac{Y_b}{Y_G}\right)^{-\alpha-0.05} & , y <= Y_b. \end{cases} \tag{18}$$

where y is the height along the fetch; Y_b, Y_G and α are parameters which can be found in AIJ code. The inlet condition of turbulence kinetic energy (TKE) is defined as a function of turbulence intensity I:

$$k = \frac{3}{2}(u_x \cdot I)^2 \tag{19}$$

Dissipation rate ε can be determined by k and turbulence length scale L, and the relationship is:

$$\varepsilon = C_\mu^{3/4}\frac{k^{3/2}}{L} \tag{20}$$

where C_μ is defined as a constant (0.09).

Turbulence length scale L is defined independently of the terrain conditions of the site as:

$$L = \begin{cases} 100\left(\frac{y}{30}\right)^{0.5}, & 30 < y <= Y_G; \\ 100, & y <= 30m. \end{cases} \tag{21}$$

In summary, the inlet boundary conditions of TKE k and dissipation rate (D) ε are listed below:

$$\begin{cases} k(x) = \frac{3}{2}\left(u_0(\frac{y+y_0}{y_0})^\alpha \cdot I\right)^2 \\ \varepsilon(x) = C_\mu^{3/4}\frac{k^{3/2}}{L} \\ I = \begin{cases} 0.1\left(\frac{y}{Y_G}\right)^{-\alpha-0.05}, & Y_b < y <= Y_G; \\ 0.1\left(\frac{Y_b}{Y_G}\right)^{-\alpha-0.05}, & y <= Y_b. \end{cases} \\ L = \begin{cases} 100\left(\frac{y}{30}\right)^{0.5}, & 30 < y <= Y_G; \\ 100, & y <= 30m. \end{cases} \end{cases} \tag{22}$$

The boundary conditions of the top and bilateral boundaries of the fetch are set as slip boundary conditions, which are expressed as:

$$\begin{cases} u_y = 0, \ \frac{\partial}{\partial x}(u_x, u_z, k, \varepsilon) = 0, \\ u_z = 0, \ \frac{\partial}{\partial x}(u_x, u_y, k, \varepsilon) = 0. \end{cases} \tag{23}$$

The outflow face is assumed as fully developed outflow boundary condition, which can be expressed as:

$$\frac{\partial}{\partial x}(u_x, u_y, u_z, k, \varepsilon) = 0 \tag{24}$$

3.3 *Numerical model and mesh schemes*

To examine the performance of the quadratic eddy viscosity model, numerical simulations of wind flow over a 6m cube are carried out based on the standard realizable $k-\varepsilon$ turbulence model and the quadratic eddy viscosity model. The 6m cube is mounted in atmospheric boundary layer (ABL) at a normal orientation to the incident wind with the computational domain shown in Figure 1. Specific representations of the computational domain and mesh arrangements can be seen in Figure 2.

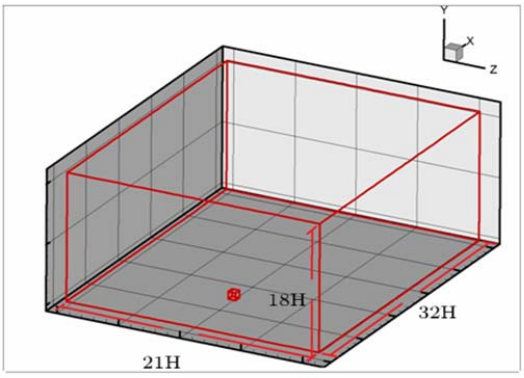

Figure 1. Computational domain around 6m cube.

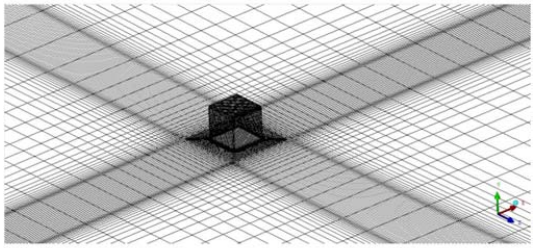

Figure 2. Grids scheme for 6m cube model.

Reynolds number based on the incident wind velocity and the height of the 6m cube model is around 10^7. To resolve the flow field around the bluff body, the first-layer cell near the cube surface is set as $0.015H_c$, which is appropriate for the realizable $k-\varepsilon$ model. The cells are non-uniformly distributed and the stretching ratio is 1.12 along the surfaces. 32 grids are placed on the windward, roof and leeward surfaces of the cube (z-direction). 40 grids are located along the lateral faces of the cube (y-direction). 30 grids with stretching ratio 1.2 are placed in the wake zone of the computational domain.

4 NUMERICAL RESULTS

The computational results are compared with those by the linear eddy viscosity model (the realizable $k-\varepsilon$ model) and the field measurement results (Richards et al., 2001).

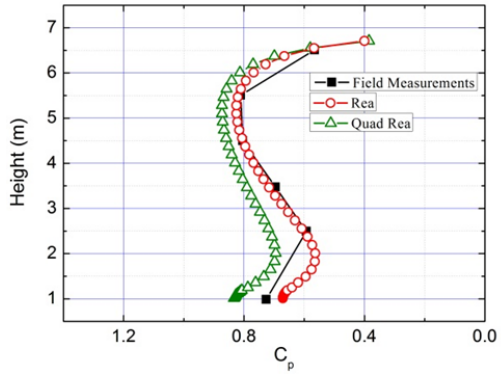

Figure 3. Pressure distributions along the windward face.

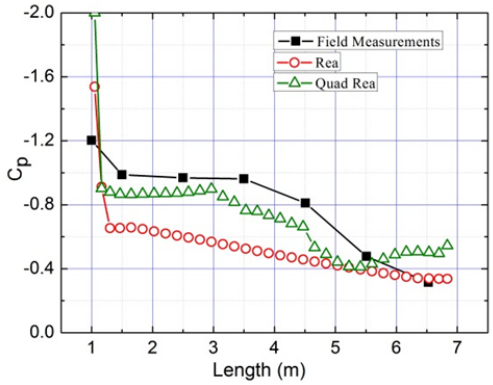

Figure 4. Pressure distributions along the roof face.

Figure 3 shows comparisons of mean pressure coefficient distributions on the windward face. It can be seen that the two turbulence models yield almost same results around the flow stagnation point. The pressure coefficients on the remaining part show relatively similar distribution shapes with differences within approximately 10 percent of the measurement values. It is apparent that the CFD predicted pressure spike position is approximately 0.67m lower than that obtained by measurement results. Figure 4 shows the pressure distributions on the cube roof. The quadratic nonlinear model predicted closer results with the measurements than the linear eddy viscosity model. Both models over predicted the pressure at the front edge of the cube.

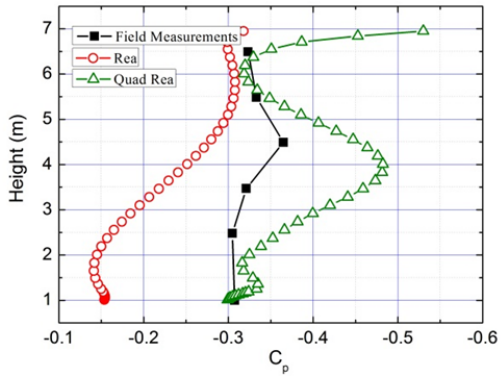

Figure 5. Pressure distributions along the leeward face.

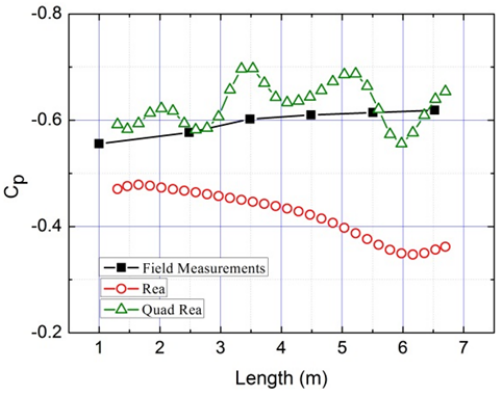

Figure 6. Pressure distributions along the side face.

The pressure distributions on the leeward face are showed in Figure 5. It is apparent that neither of the models could accurately predict the measurement results. The better approximations are obtained by the quadratic model, although the errors are around 45 to 50 percent. The pressure distributions on the side face are displayed in Figures 6. The measurement results on the side face shows a slow increase in negative magnitude as the wind velocity increases with height. The quadratic model predicts more accurate values than the standard linear eddy viscosity model. It has been proved that the size and strength of the roof recirculation zone is reduced as the flow approaching the side walls of the cube. The mass of air flowing over the roof is also reduced. It is therefore clear that the measurement results are affected to a much larger extent by three-dimensional flow phenomenon, due to significant difference between the centre and edge negative pressures. This suggests that the roof recirculation zone in the full-scale measurement contains a much stronger vortex than that predicted by CFD, which causes the pressure difference between the measurements and CFD results.

5 CONCLUSION

The quadratic eddy viscosity model, including new considerations of mathematic constraints, was developed in this paper to predict turbulent flows around bluff bodies. This study shows that adoption of the nonlinear eddy viscosity model yields better results than the standard linear eddy viscosity model, especially for the pressure distributions on the windward, roof and side faces of a 6m cube. Meanwhile, this nonlinear eddy viscosity model has great robustness to calculate turbulence anisotropy and is suitable for numerical simulation of complex flows around building structures. It is indicated that the quadratic NLEVM exhibit its advantages in capturing the pressure variations on a low-rise building, compared with those predicted by the standard two-equation turbulence models.

ABSTRACT: An Embedded LES approach is used to numerically simulate fluctuating surface pressures on a floor-mounted cube in a turbulent boundary layer flow and compared to wind tunnel experiments. The computation were performed with the CFD software ANSYS FLUENT at a Reynolds number at cube height of $Re_h = 1.3x10^5$. The computational mesh exists of 0.77 and 4.7 million hexahedra cells in the RANS and LES domains, respectively. The computed mean values are found to be accurate while the frequency spectrum of the upstream flow is not well captured due to failure of the upstream RANS-LES interface to produce correct velocity scales. However, the body induced turbulence is well captured in the fluctuating pressure coefficients.

KEYWORDS: Embedded LES, Turbulent boundary layer flow, floor-mounted cube.

1 INTRODUCTION

With the advancement in computational performance over the last decade Computational Fluid Dynamics (CFD) has become a powerful and widespread tool and finds increasingly application in the field of Wind Engineering. The here presented study is a part of a research initiative on applying CFD for simulating wind loads on building structures. The reference case is a floor-mounted cube in a turbulent boundary layer (TBL) flow as have been used in numerous other comparative studies. Main focus is on the complex flow field around the cube and the induced surface pressures. Various authors have performed numerical simulations of the flow around a floor-mounted cube. Reynolds-Averaged Navier-Stokes (RANS) models have shown good results when the flow can be described by mean flow quantities, while for predicting unsteady flow patterns and hence peak wind load features Direct Numerical Simulations (DNS) or Large Eddy Simulations (LES) have shown high potential. LES has been used to simulate the flow around floor-mounted cubes in both smooth-walled channels with a high grid resolution (Shah et al., 1997) and with coarser meshes (Krajnovic and Davidson, 2002), and in turbulent boundary layer flows (Nozawa, Tamura, 2002; Lim et al., 2009). Despite the potential of LES shown for the above mentioned studies it is still computationally expensive (in terms of hardware, license and time) to capture the small structures in wall bounded flows. The use is therefore limited for real life wind engineering applications with higher Reynolds number and complex geometries.

The aim of the presented work is to use embedded LES (E-LES) approach trying to combine the advantage of fast time-averaged solution from RANS over the entire domain and apply time resolved solution using LES in the vicinity of the bluff body to get the stochastic loading process. Thus limiting LES to the target flow around the investigated body reducing the overall cost of the simulation compared to a full LES, significantly. For the computations the commercial CFD software ANSYS FLUENT was used. The Shear-Stress Transport (SST) k-ω model (Menter, 1994) and the Wall-Modeled LES (WMLES) SGS model were used in the RANS and LES domains respectively.

2 EXPERIMENTAL AND COMPUTATIONAL TECHNIQUES

2.1 *Simulated Geometry*

The wind tunnel experiments were carried out in the closed-circuit wind tunnel at the department of Civil Engineering at the Technical University of Denmark. Figure 1 shows a longitudinal section of the wind tunnel with the flow processing unit (FPU) and the test section (TS). The wind tunnel test setup is the physical reference in this case and not considered as a scaled model of a building structure in nature. The TBL flow is simulated using spires and roughness elements (Irwin 1981). The cube size, h = 0.1m, leads to a total blockage of 4.5% of the cross section. The roughness elements were restricted to the FPU and not continued into the TS, since they would influence the flow around the cube. They thereby give space for the TBL to develop in front of the cube. The simulations are carried out at a Reynolds number of $Re_h = 1.3x10^5$ based on the velocity, U_h, at cube height. For the numerical simulation the flow is calculated by a RANS domain for the TS (indicated by the dashed line) and in close vicinity to the cube by an embedded LES domain (hatched area) as shown in Figure 1.

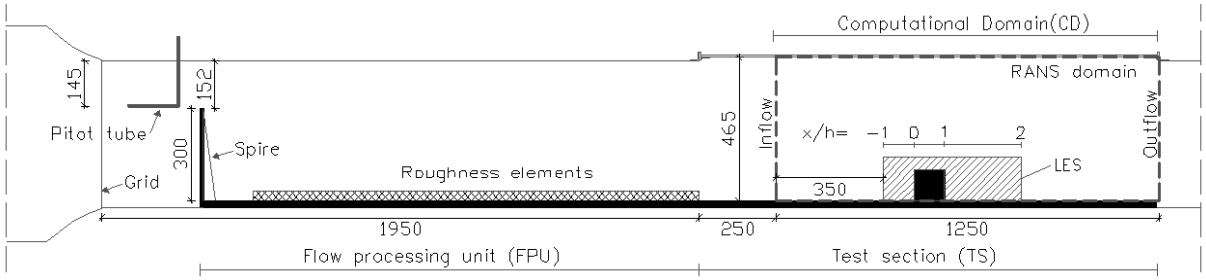

Figure 1. Longitudinal section of the wind tunnel FPU and TS.

2.2 *Velocity and surface pressure measurements*

For the velocity measurements a 4-hole Cobra probe was used providing the fluctuating time series of all three flow components. The surface pressure on the cube was measured using a Kulite piezoresistive pressure transducer (XTL-140M) directly integrated in the cube surface. The sampling frequency for both flow and surface pressure measurements was 2000Hz. Data were acquired by National Instruments LabVIEW software. The reference velocity was sampled with a static Pitot tube upstream of the FPU.

2.3 *Governing equations for LES*

In the LES zone the three-dimensional and unsteady turbulent scales up to a cut-off wave number are directly resolved by the computational mesh, while the effect of the small scale motions is modeled. To separate the time-dependent velocity vector, u_i, into a resolved component, $\overline{u}_i$, and a modeled subgrid-scale (SGS) component, u'_i, the time-dependent basic variables are filtered with a low pass filter in space. Convolution of the velocity field by the filter function $G(x-x')$ is calculated from:

$$\overline{u}_i(x,t) = \int G(x-x')u_i(x',t)dx', \qquad \int G(x')dx' = 1 \tag{1}$$

with the specific box filter function that cuts off values beyond a half filter width, $\Delta = \sqrt[3]{\Delta x \Delta y \Delta z}$:

$$G(x,x') = \begin{cases} 1/\Delta, & |x-x'| \le \Delta/2 \\ 0, & |x-x'| > \Delta/2 \end{cases} \tag{2}$$

Filtering the Navier-Stokes equations for incompressible flow gives the equations used for LES governing the resolved large scales of motion:

$$\frac{\partial \rho}{\partial t} + \frac{\partial}{\partial x_i}(\rho \bar{u}_i) = 0 \tag{3}$$

$$\frac{\partial \bar{u}_i}{\partial t} + \bar{u}_j \frac{\partial \bar{u}_i}{\partial x_j} = -\frac{1}{\rho}\frac{\partial \bar{P}}{\partial x_i} + \frac{\partial}{\partial x_j}\left(\nu \frac{\partial \bar{u}_i}{\partial x_j}\right) - \frac{\partial \tau_{ij}}{\partial x_j} \tag{4}$$

where the SGS stress term, $\tau_{ij} = \overline{u_i u_j} - \bar{u}_i \bar{u}_j$, featuring the effect of the small scales on the resolved ones is unknown and must be modeled. In ANSYS FLUENT the SGS stresses are computed from the SGS turbulent viscosity, μ_t, $\tau_{ij} = -2\mu_t \bar{S}_{ij}$. The modified algebraic WMLES SGS model proposed by Shur et al. (2008) is used to compute the SGS eddy viscosity. The model combines a mixing length model and a modified Smagorinsky model where the eddy viscosity is calculated from:

$$\nu_t = \min\left[(\kappa d_w)^2, (C_{Smag}\Delta)^2\right] \cdot S \cdot \left\{1 - \exp\left[(y^+/25)^3\right]\right\} \tag{5}$$

where d_w is the wall distance, S is the strain rate, $\kappa = 0.41$, $C_{Smag} = 0{,}2$ and y^+ is the normal to the wall inner scaling.

2.4 *Computational configuration*

The computational domain is shown in Figure 1 where a Cartesian coordinate system is placed at the bottom center of the front face of the cube with the x axis aligned with the streamwise, u component, of the flow. The boundaries of the LES domain are chosen quite tight around the cube based on the idea of "economizing" the LES effort to a minimum. LES resolves only the scales larger than 2Δ (twice the mesh elements) and uses the WMLES SGS model to model the influence of the smaller scales on the resolved ones. The high Reynolds number treated in the turbulent boundary layer flow requires high grid resolution near the solid walls and the cube. The WMLES models advantage is that it allows for a coarser near-wall grid resolute than in the classical LES requirements reducing the required near wall mesh density. The WMLES resolution requirements are:

$$\Delta_x = \frac{\delta}{10}, \quad \Delta_y = \frac{\delta}{40} \sim \frac{\delta}{30}, \quad \Delta_z = \frac{\delta}{20}, \tag{6}$$

where δ is the boundary layer thickness. The RANS and the LES domain include 0.77 and 4.7 million structured hexahedra cells respectively. Overall for the entire domain the grid is stretched in normal direction from the domain boundaries and cube walls.

The governing equations were discretised using the cell-centered finite-volume method. A pressure based solver where the governing equations are solved sequentially was used. For deriving the pressure equation from the discrete continuity equation velocity-pressure coupling was

achieved by the SIMPLEC algorithm. The continuity equation (3) and momentum equation (4) were discretised in space using a bounded central difference method and in time using first order implicit time integration.

2.4.1 *Interfaces between RANS and LES domains*

The RANS and LES domains are connected with two dimensional interfaces. As the LES zone requires turbulence quantities at the inlet the upstream modeled turbulent kinetic energy from the RANS domain is converted explicitly to resolved scales at the RANS-LES interface. At the RANS-LES interface a 2D vortex method is used, which generates small-scale turbulent motions by adding random perturbations to the mean flow via a fluctuating vorticity field (Mathey et al. 2006). The method is based on the Lagrangian form of the 2D evolution equation of the vorticity.

$$\frac{\partial \omega}{\partial t} + \left(\vec{u}.\nabla\right)\omega = \nu\nabla^2\omega \tag{7}$$

For solving equation (7) a particle discretisation is used where particles carrying information about the vorticity field represented by the circulation, Γ_i, and the assumed spatial distribution, η, are convected randomly:

$$\Gamma_i(x,y) = 4\sqrt{\frac{\pi A k(x,y)}{3N\left(2\ln(3)-3\ln(2)\right)}} \quad and \quad \eta\left(\vec{x}\right) = \frac{1}{2\pi\sigma^2}\left(2e^{-|x|^2/2\sigma^2}-1\right)2e^{-|x|^2/2\sigma^2} \tag{8}$$

where (x,y) are the coordinates in the plan of the interface, A is the total area of the interface, k the modeled turbulent kinetic energy, N the number of vortex points and σ provides control over the local vortex size. At the LES-RANS interfaces the turbulent quantities from an initial RANS simulation are used.

2.4.2 *Boundary conditions*

At all solid wind tunnel walls and at the cube surface the no-slip boundary conditions for a smooth wall were applied.

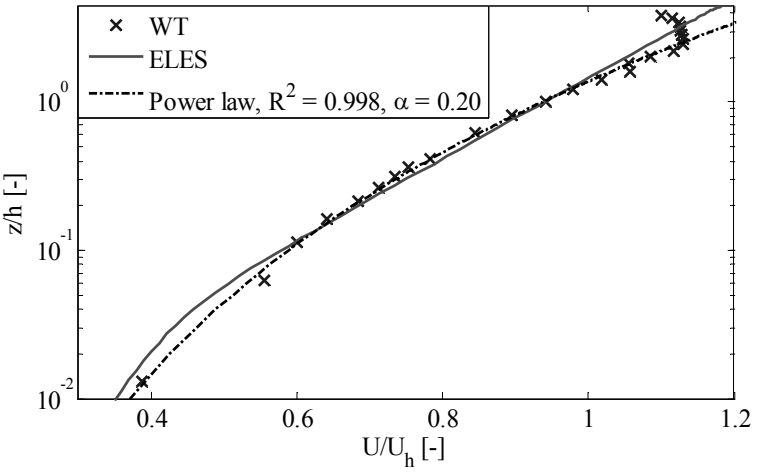

Figure 2. Time-averaged streamwise velocity profiles at the inflow of the computational domain.

At the inflow of the RANS domain a mean wind speed profile comparable to the wind tunnel experiment shown in Figure 2 was imposed. The wind tunnel data follow a power law profile up to z/h = 3:

$$U(z) = U_{10}\left(z/10\right)^{\alpha} \tag{8}$$

with a determination coefficient $R^2 = 0.998$ and a profile exponent $\alpha = 0.20$, which corresponds to terrain class III (Eurocode 1). The turbulence intensity, I_u, at the cube height is around 10%.

3 RESULTS

In the results the computed overall TBL flow around the cube is compared to the experimental data. Furthermore, the cube surface pressure at selected points is compared. Results are presented in form of time-averaged variables, frequency spectra and probability density functions. The numerical data were sampled for 14 flow-through domain times corresponding to 166 large-eddy turnover times (LETOT), $T_b = h/U_h$, which should be sufficient to compute mean field data.

3.1 *Overall flow around the cube*

The mean velocity magnitude vectors around the cube are shown in Figure 3. The center of the horseshoe vortex upstream of the cube is located at around x/h ≈ -0.4, z/h ≈ 0.1. The stagnation point on the cube upstream face is located at z/h ≈ 0.7 and the reattachment point on the cube top surface at around x/h = 0.88. The velocity magnitude plot shows how the flow field is affected by the cube at the position of the RANS-LES inlet interface at x/h = -1. A better choice of the interface placement would therefore be further upstream of the domain in the undisturbed flow field. Thereby allowing the turbulent quantities to get more development before they approaches the cube. Figure 4 shows an instant view of the coherent vortex structure around the cube. The shedding from the front corners of the cube and the body induced turbulence structures are clearly visible. Furthermore the horseshoe vortex in front of the cube can be identified.

3.1.1 *Mean and fluctuating velocities*

Figure 5 (top) shows the mean streamwise and vertical velocity components upstream of the cube at z = h, normalized by the streamwise velocity, U_h. The wind tunnel time histories are filtered with a cut-off high pass frequency corresponding to the maximum frequency resolved in the ELES. The mean flow in the region in front of the cube is well predicted using both RANS and LES models. Figure 5 (bottom) shows that the computed standard deviation for all velocity components is under-predicted in the RANS domain, but increases in the RANS-LES interface to a higher level. The transition between the RANS and LES domain shows some short comings. The streamwise component is captured approximately 0.015m behind the interface; however the spanwise and vertical components are over-predicted. This indicates that the computed turbulent length scale fluctuations are to isotropic compared to the ones found in the wind tunnel.

The computed mean spanwise and vertical flow above the cube shown in Figure 6 (left) and the vertical standard deviation, σ_w, shown in Figure 6 (right) are well predicted. The vortex shedding generated by the front top edge of the cube are generating large part of the turbulence and the transient flow quantities and the influence of the RANS-LES interface are limited in this region. Less agreement is though found in the streamwise standard deviation, σ_u, which can be a result of the horizontal interface above the cube influencing the flow. Further investigations are required to investigate this discrepancy in the streamwise fluctuations.

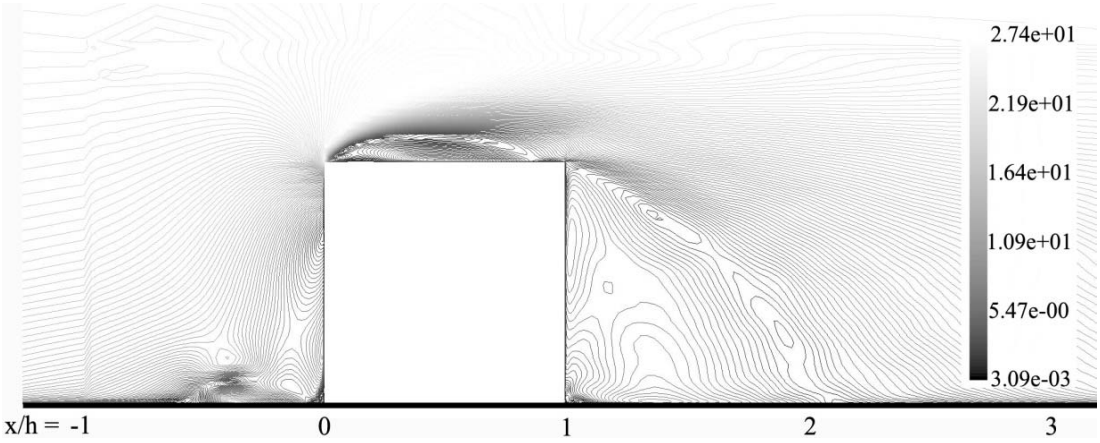

Figure 3. Mean velocity vectors in the x-z plane through the cube.

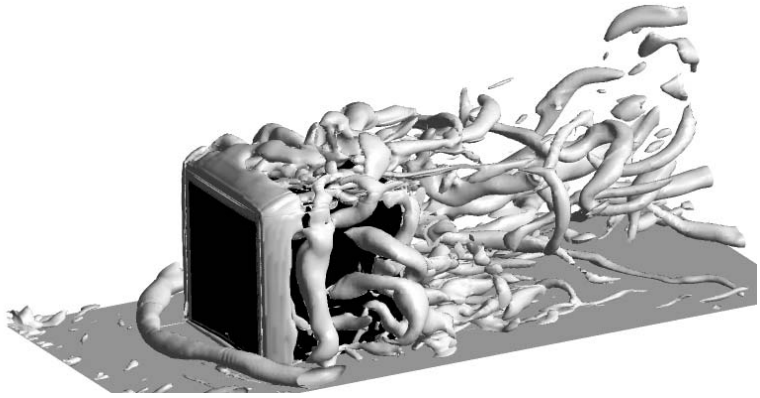

Figure 4. Coherent small scale vortex structure in the LES domain around the cube.

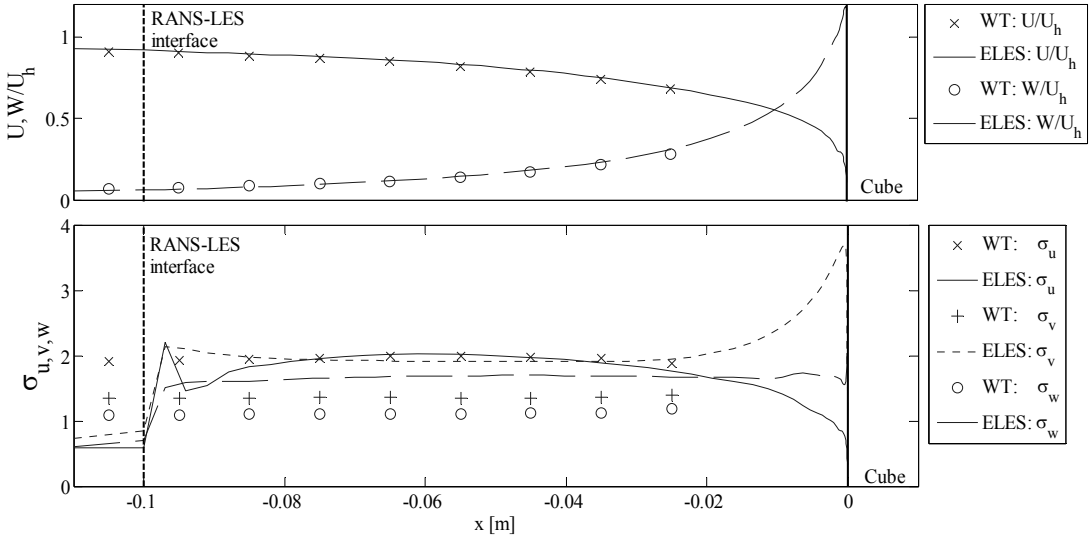

Figure 5. Mean values of u and w (top) and σ of u, v and w (bottom) velocity components in front of the cube.

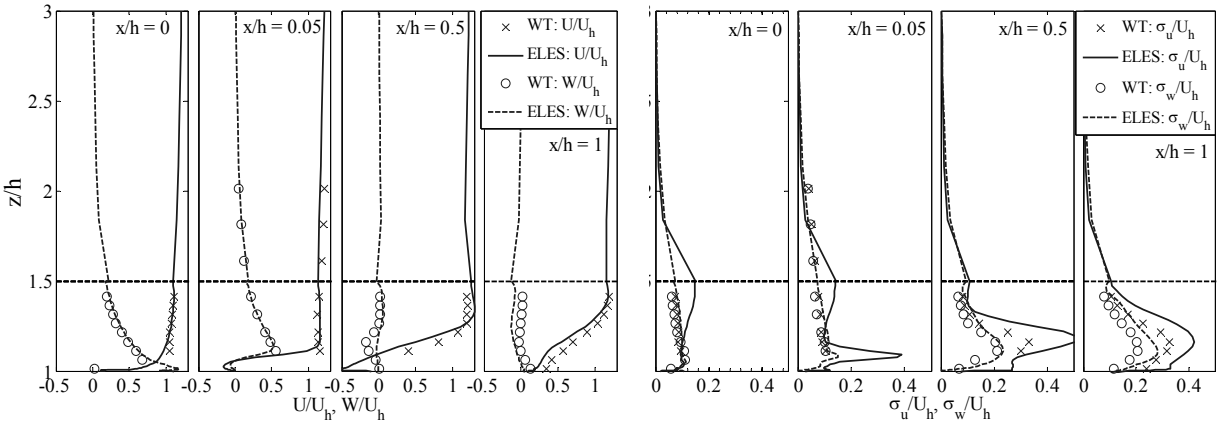

Figure 6. Normalized mean and σ profiles of u and w at four positions at the streamwise centreline on cube top face.

3.1.2 *Spectral density functions*

Figure 7 shows frequency spectra of the streamwise velocity component at z/h = 1 and x/h = -0.75. Even though already in the flow regime affected by the cube this position has been chosen to give the best view on the wind spectrum developed so far in the LES domain. The wind tunnel spectrum was fitted with a von Kármán spectral function which generally can be used to describe the fluctuation of the streamwise component in a free turbulent atmospheric boundary layer flow. The computed spectrum is deformed and does not represent the equilibrium turbulent boundary layer flow in the wind tunnel. The computed time histories do not have the correct stochastic nature resulting in a spectrum consisting of two quite defined peaks. There is no production of large scales and also the small scales supposed to be generated by the interface are missing. This is also apparent from Figure 4 where no small scales are visible in front of the cube. Hence it can be concluded that the RANS-LES interface fails in producing correct scales and is placed too close to the cube for an equilibrium turbulent boundary layer flow to be developed.

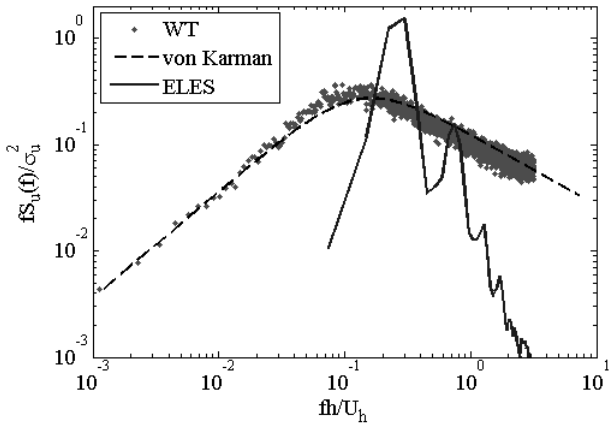

Figure 7. Spectra of the streamwise velocity component at x/h = -0.75 and z = h = 0.1m.

3.2 *Cube surface pressure*

The fluctuating surface pressure was measured in the wind tunnel at five positions along the streamwise centreline of the cube. The measurement points were chosen in the most characteristic body-near flow regions, which are assumed to be equally characteristic for the flow-induced load: 1 - stagnation point on upstream wall (x'/h=0.7). 2 - separation at leading edge on cube top face (x'/h=1.1). 3 - reattachment zone behind separation bubble (x'/h=1.2). 4 - reattached flow on the downstream half of the cube top side (x'/h=1.7). 5 - pressure in wake flow on rear side (x'/h=2.1).

As the energy content of the upstream cube flow is not captured by the ELES deviations in the surface pressure on the cube can be expected. The time-averaged, C_p, and standard deviations, σ_{Cp}, of the fluctuating surface pressure coefficients are shown in Figure 8 where x' denotes the spanwise distance along the centerline of the cube starting at the bottom of the cube upstream face. For further comparison the results from LES computation of turbulent boundary layer flow around a cube at $Re_h = 2x10^4$ by Lim et al. (2009) are also shown in the figure. The experimental and computed values of the mean pressure reflect the characteristic wind load distribution on a floor-mounted bluff body in a turbulent boundary-layer flow: maximum positive mean pressure at the stagnation point on the upstream wall and maximum negative mean pressure inside the separation bubble near the leading edge on the cube top. However, there are deviations in the mean values of up to 30 percent. The experimental and computed σ_{Cp} values are comparable except from a large deviation in point 4 at x'/h = 1.7 at the cube top surface. Furthermore, the distribution of σ_{Cp} is different from what one would expect for a cube in a TBL flow with largest fluctuations at the separation on the top face just after the leading edge. Further research of the cube surface pressure is required to explain the obtained distribution.

Spectra of the pressure coefficients, at points 1, 3, 4 and 5 are shown in Figure 9.The spectra in the stagnation point are most similar to the upstream flow spectrum. Here the computed spectrum is again very deformed. At the other points where the turbulence and length scales generated by the cube are dominant the computed spectra capture well the body-induced turbulence. The lack in fluctuation magnitudes in the computed spectra at the low frequency range is hence largest at the stagnation point but also apparent in points x'/h = 1.7 and 2.1.

3.3 *Probability density functions of Cp*

The variation of C_p is described and compared by using the probability density function (PDF) of the occurring instantaneous values. In Figure 10 PDF's for the fluctuating C_p values at points 1, 3, 4 and 5 are shown and values for the first four moments are given. The short time history for the ELES data results in significant shortage of data point in the computed PDFs.

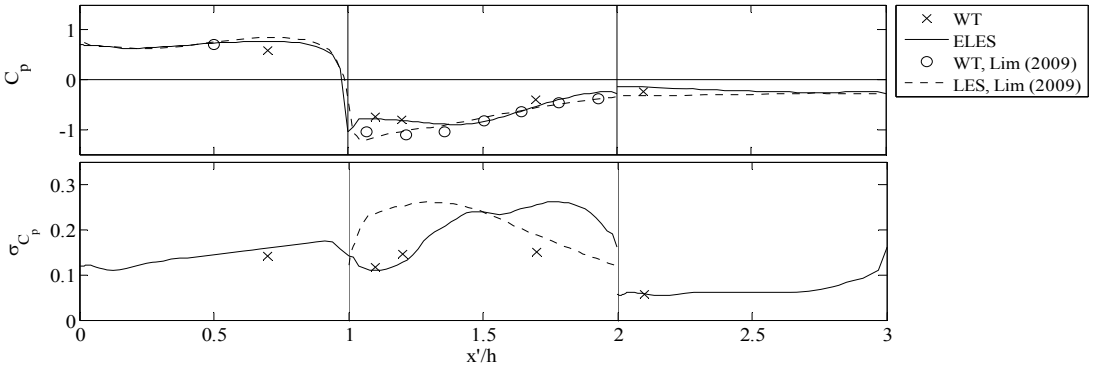

Figure 8. Time-averaged and σ of fluctuating surface pressure coefficients along the axial centerline of the cube.

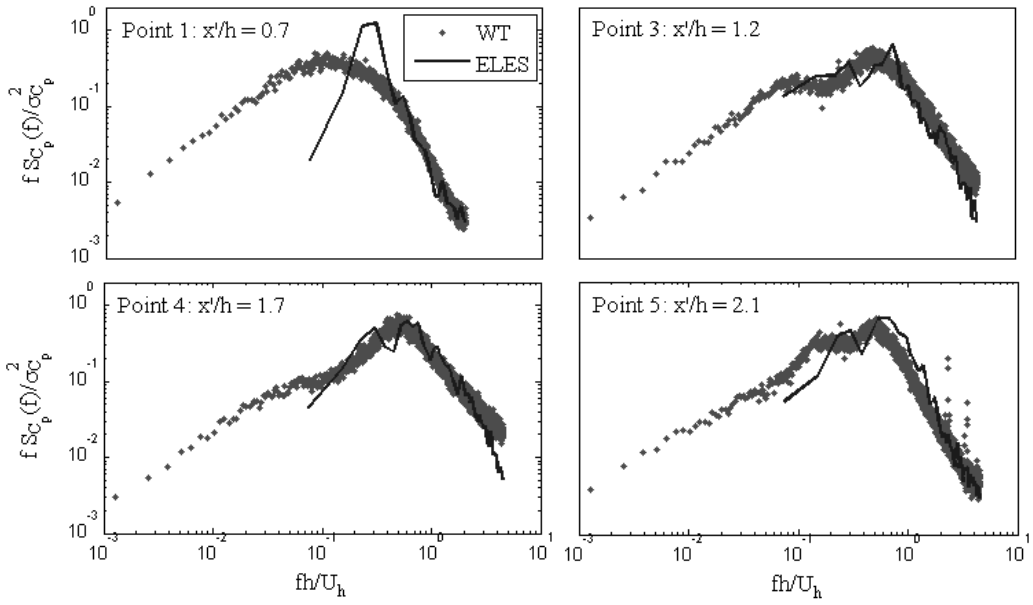

Figure 9. Spectra of the surface pressure coefficients.

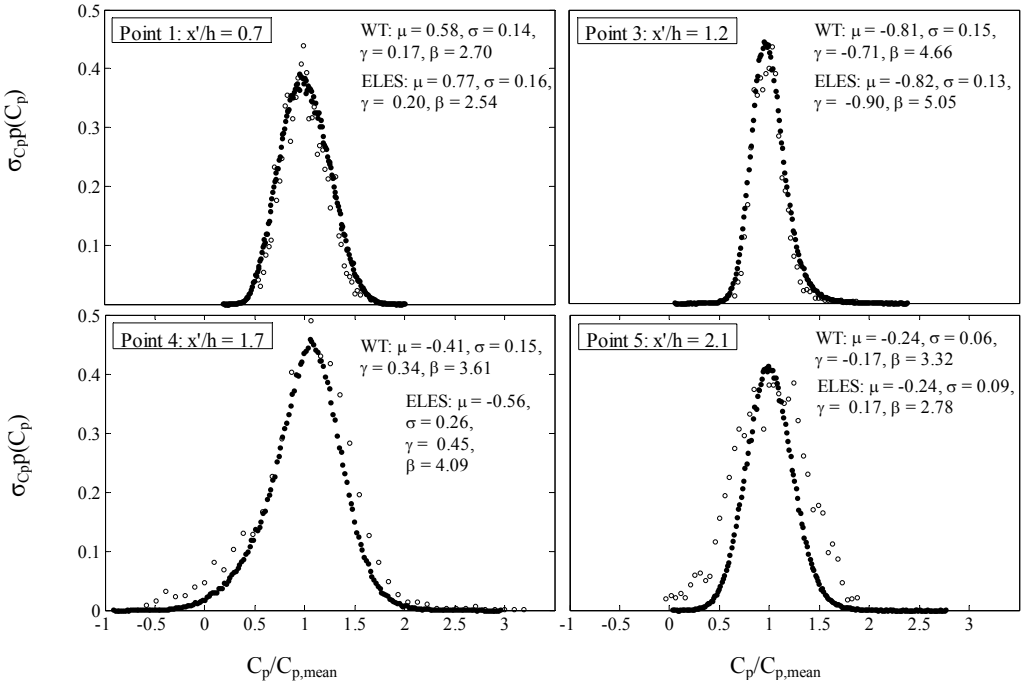

Figure 10. Normalized probability density of the surface pressure coefficients. WT: • and ELES: o.

The PDFs have similar modes and mass distributions. At some positions the outer tail values of the computed data are missing. This can be a result of the peak values not captured due to them not occurring in the limited time computed. Another explanation is the missing low frequency energy magnitude (shown in Figure 9) needed to give the sufficient amplitude for the peak to appear.

4 CONCLUSION

For the purpose of structural design the peak values of the local loading process play a central role and are hence indispensable. As it is known from wind tunnel testing, the flow and load simulation needs to reflect accurately the fluctuation process over the entire frequency range. In case of this study it can be concluded that the development of the upstream turbulent flow within the LES-zone is in this respect insufficient. It is difficult to create correct correlated turbulent inflow boundary conditions by the RANS-LES interface and it is apparent that the interface is not able of producing the correct scales of turbulence. A possible improvement could be achieved by changing the conditions at the interface or achieved by expanding the LES-zone upstream, vertically and horizontally providing longer space for the turbulent flow to develop.

Despite the lower accuracy of the computed turbulent flow the mean and standard deviations of the streamwise flow component are consistent with the experimental data while the vertical and turbulent components are over-predicted. The fluctuating surface pressure coefficients on the cube are also affected by the incorrect upstream flow. However, the body induced turbulence is well captured by the simulation.

ABSTRACT: In this paper, a combined numerical approach on the time-dependent fluid-structure interaction for tension structures with large displacements is presented. The general idea of this approach is to divide the structural response under wind actions into three components: mean response, background response and resonant response. The first component is a static interaction process, which is due to the change of structural geometry under mean wind pressure. The second component can be regard as a steady interaction process, which relates to the motion of large scale eddies. The last component can be called as a transient interaction process, in which the dynamic magnification effect should be considered mainly. Due to the different characteristics of each component, different methods should be adopted respectively. For static and steady interaction, the suitable method is CFD simulation, in which the wind pressure change due to structural deformation will be considered mainly; for transient interaction, the suitable method is nonlinear random vibration analysis in time domain. Base upon the combined procedure, some numerical examples include one-way type roofs and saddle-shaped membrane structures are carried out finally. From the comparison with direct numerical method, which can be seen as a accurate method, it can be concluded that the results obtained from the combined procedure are very close to the direct numerical method; moreover, the combined procedure seems easier for application.

KEYWORDS: membrane structures; wind-structure interaction; CFD numerical simulation; aeroelastic effects; aerodynamic response; geometrical nonlinearity

1 INTRODUCTION

Membrane structures are the most widely used long-span tension structures. As being characterized by lightweight and flexible, they are highly susceptible to the wind action. How to determine the aerostatic and aerodynamic response due to the wind action is a major concerned problem for the design of tension structures. Up to now, comprehensive studies have been performed, but the mechanism of wind-induced vibration of membrane structures has not been recognized in enough detail. The main reasons lie in two aspects: one is the strongly geometrical nonlinearity,

which make the dynamic characteristics of tension structures are obviously different from those of bridges and high-rising buildings, so traditional methods of random vibration analysis in frequency domain can not be used directly. The other reason is the weak local rigidity, which can make membrane structures produce rather large vibration under wind excitation. Sometime, these large vibrations can even affect the surrounding fluid field remarkably; that is to say, the wind-structure interaction or the aeroelastic effects can not be neglected. To solve the previous problem, some nonlinear random vibration analysis methods in time domain have been developed successfully [1]. But all those methods are based on the condition that the inlet flow or the wind pressure process has been determined beforehand, so they can not consider the fluid-structure interaction actually. To determine the actual wind loads on tension structures, especially to reveal the mechanism of wind-structure interaction, some semi-empirical methods have been developed [2], also some wind tunnel tests has been carried out [3]. However, some unavoidable errors will occur when using simplified methods, and wind tunnel tests are too expensive to carry out extensive studies, therefore those methods are only limited to certain special structures.

In recent years, with the development of high speed computer and numerical computational methods, it has been available to integrate computational fluid dynamics (CFD) and computational structure dynamics (CSD) technique to simulate structures and surrounding flow simultaneously, which is called as numerical wind tunnel method. Comparing to those simplified methods and wind tunnel tests, numerical wind tunnel method can solve flowing problems of complex geometrical bodies without disturbing the fluid field, construct computational models whose dimension are same as that of original structures so as to avoid the similarity requirements in wind tunnel test, completely control the properties of fluid and provide great flexibility for selecting flowing parameters to carry out parametric analysis. Because of these superior characteristics, numerical wind tunnel method is highly valued by researches and developed quickly. Now this method has been applied to solve some aeroelastic problems, such as for bridges [4] and also for membrane structures [5]. But due to the tremendous calculate work, this method also can not be used in engineering practice.

In this paper, an overview of the studies on wind-structure interaction of tension structures is provided firstly. Then a combined numerical approach based on CFD simulation method and random vibration analysis method is presented. Finally, Base upon the combined procedure, some numerical examples include one-way type roofs and saddle-shaped membrane structures are carried out.

2 METHODOLOGY

Wind-induced response of tension structures can be theoretically described as a problem of unsteady coupling vibration between incompressible viscous fluid and geometrical nonlinear elastic body. Due to the fluid forces and structure displacements on the interface between fluid and structure are unknown, it is impossible to solve the fluid field and structural field separately, so we have to find some methods that can solve these two fields simultaneously. Undoubtedly, the numerical wind tunnel method provides a good platform for solving this problem.

In Ref. [6], the author had developed a FEM program for calculating two-dimension problem. There were three modules included in this program, each for CFD, CSD and CMD (Computational Mesh Dynamics) calculation, respectively. The flowchart is shown in fig.1. The dynamic fluid-structure interaction was performed by a partitioned solution approach, and the time-dependent simulation process was controlled by an iteration procedure between these three modules until convergence was reached in each time-step. Based on this program, the aeroelastic re-

sponse of one-way type pretensioned membrane roofs has been studied. The effects of several factors, such as height-span ratio, roof slope, roof mass and pretension force et al, were investigated. From these studies, some preliminary but very important conclusions about the mechanism of wind-structure interaction were obtained [7].

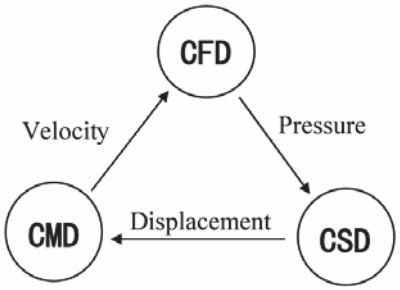

Fig. 1 Flowchart of CFD simulation program

The practical cable/membrane structures are 3-dimensional with complicated surfaces. Using the CFD simulation approach as mentioned above to study the aeroelastic effects of 3-D structures has theoretically possible, but will be very difficult in practice at present. Firstly, the time-consuming of simulating 3-D problem is hundreds times of 2-D problem, which can not be tolerated for systemically studies. Secondly, the increasing computing time will cause lots of numerical dissipation and error cumulation. So if we use the method proposed in Ref. [9] to solve 3-D problem, it means that all the numerical methods in this 2-D program should be improved to get more computing efficiency and precision, however the work is obviously enormous. At the same time, there are two facts: (1) Various CFD commercial software are developing quickly, they have provide more efficient numerical platform to solve fluid problem, however, the problem of fluid-structure interaction can hardly be resolved by these software. (2) From the viewpoint of engineering, engineers usually don't concern about the details of coupling vibration process but some statistic information, such as the mean and peak value, and whether or when will the aeroelastic instability occur. So it is possible to solve the coupling problem by another new method, which is to adopt some simplified analytical methods and numerical methods to get the statistical information of the coupling process, and give up the simulation on wind-structure interaction in detail. The precondition of this method is to give a reasonable explanation about the coupling mechanism of wind-structure interaction.

According to the wind-induced structural vibration theory proposed by Davenport [8], the structural response can be broken into three components: mean response $\bar{r}$, background response $\tilde{r}_B$ and resonant response $\tilde{r}_R$ (Fig.2). The mean response is induced by average wind pressure, and does not change with time. The background responses relates to the motion of large scale eddies, and vary slowly and irregularly with time. It is essentially a quasi-static process and has no dynamic amplificatory effect. The resonant response usually happens at frequencies adjacent with the structural natural frequency, and has obvious dynamic amplificatory effect. If we assume that the wind-induced vibration response of membrane structures has the same characteristics as mentioned above, then different methods can be adopted for different components to get the statistic information separately.

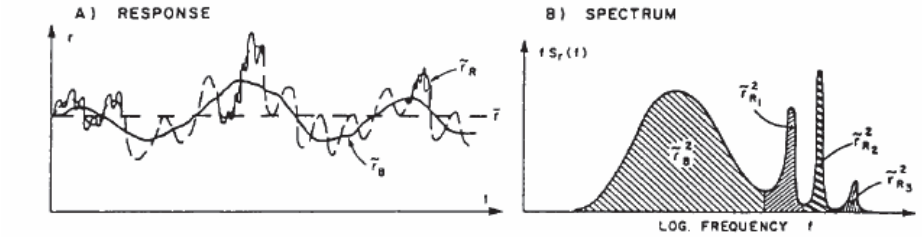

Fig. 2 Response to wind

For the mean response, the coupling effects are mainly induced by the structural average deformation, which will make the mean wind pressure change consequently. It is a static process and can be solved directly by steady CFD numerical simulation with several iterative steps. For the background response, the coupling effects are mainly induced by the effect of the spatial correlation of fluctuating wind, that is to say, we have to find these critical distributions of fluctuating wind pressure which can make structure produce maximum or minimum steady response. It is a quasi-static process in which the dynamic amplificatory effect can be ignored and only some modes of steady deformation are considered. For the resonant responses, dynamic coupling between the higher frequency parts of fluctuating wind and structure is mainly considered, it means that the resonant response of structure is mainly induced by those small-scale eddies. Due to the effect of those small-scale eddies is a random process, the suitable method for solving the resonant responses is nonlinear random vibration analysis methods in time domain. It is worth to explain that the calculation of each component will based on the result of the calculation on the former component.

To sum up, the wind-structure interaction can be divided into three parts (Fig.3): static interaction, steady interaction and transient interaction. Mean response belongs to the static interaction, background response belongs to the steady interaction, and resonant response belongs to transient interaction. The static interaction and the steady interaction should be studied specially by means of CFD numerical simulation. The transient interaction should be studied by means of nonlinear random simulation in time domain.

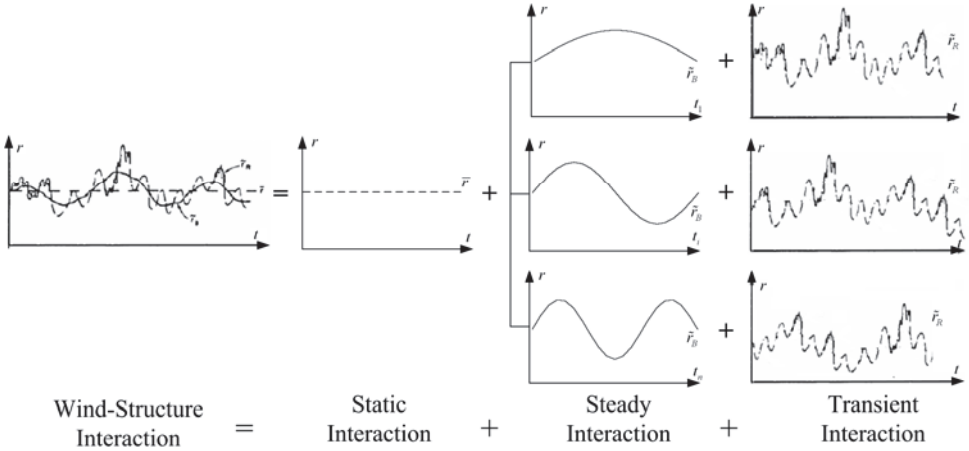

Fig. 3 the sketch of wind-structure interaction

3 GENNERAL FORMULATIONS

3.1 *Static Interaction*

Static interaction is expressed as follow:

$$K_{s0} \cdot \overline{x}_0 = \overline{p} \tag{1}$$

Where $\overline{x}_0$ is the mean response; K_{s0} and $\overline{p}$ are the stiffness and mean wind pressure corresponding to the mean deformation respectively; $\overline{p}$ can be calculated by means of CFD simulation.

3.2 *Steady Interaction*

Steady interaction is expressed as follow:

$$K_{s1} \cdot x_1(t) = p(t) \tag{2}$$

Where $p(t)$ is the fluctuating wind pressure, which can be calculated by CFD simulation.

According to the Proper Orthogonal Decomposition (POD) technique, $p(t)$ can be decomposed as follow:

$$p(x,y,z,t) \approx \sum_{i=1}^{n} \hat{p}_i(x,y,z,t) = \sum_{i=1}^{n} a_i(t)\,\mathrm{G}_i \tag{3}$$

where G_i is the *i*th eigenmode of the wind pressure field, $a_k(t)$ is the corresponding principal coordinate, $\hat{p}_i(t)$ is the wind pressure time history corresponding to the *i*th eigenmode, represents the dominant wind pressure distribution on structural surface.

Substitute Eq.(3) into Eq.(2), Eq.(2)can be rewritten as:

$$K_{s1} \cdot x_1(t) = \sum_{i=1}^{n} \hat{p}_i(t) \tag{4}$$

Assuming the steady deformation is the summation of the effects of each eigenmode

$$K_{s1} \cdot x_{1i}(t) = \hat{p}_i(t), \quad x_1(t) = \sum_{i=1}^{n} x_{1i}(t) \tag{5}$$

where $x_{1i}(t)$ is defined as the time-history of the quasi-static response induced by the *i*th eigenmode. Then the variance of background response σ_1 can be expressed as

$$\sigma_1 = \sqrt{\sum_{i=1}^{n} {\sigma_{1i}}^2} \tag{6}$$

where σ_{1i} is the variance of steady deformation $x_{1i}(t)$ induced by the *i*th eigenmode. So the following formula can be used to estimate the contribution of each eigenmode to the whole steady deformation.

$$\gamma_{1i} = \frac{{\sigma_{1i}}^2}{{\sigma_1}^2} \tag{7}$$

According to the POD technique, Eq. (4) can be expressed as:

$$K_{s1} \cdot x_{1i}(t) = a_i(t)\,\mathrm{G}_i \tag{8}$$

From Eq. (8), it is educed that the vibration mode of $x_{1i}(t)$ is determined by the stiffness K_{s1} and the *i*th eigenmode G_i, and the vibration amplitude of $x_{1i}(t)$ is determined by the principal coordinate $a_i(t)$. So the maximal steady deformation $x_{1i}(t_j)$ of $x_{1i}(t)$ can be determined by finding the moment t_j, which is corresponding to the peak value of $a_i(t)$.

3.3 *Transient Interaction*

Transient interaction is expressed as follow:

$$M_s\ddot{x}_{2i}(t)+C_s\dot{x}_{2i}(t)+K_s x_{2i}(t)=\tilde{p}\left(t,x_{2i}(t),\dot{x}_{2i}(t),\ddot{x}_{2i}(t)\right) \tag{9}$$

$$\tilde{p}\left(t,x_{2i}(t),\dot{x}_{2i}(t),\ddot{x}_{2i}(t)\right)=\tilde{\tilde{p}}(t)+f\left(x_{2i}(t),\dot{x}_{2i}(t),\ddot{x}_{2i}(t)\right) \tag{10}$$

Where $x_{2i}(t)$ is transient deformation relative to the peak steady deformation of the *i*th eigenmode; $\tilde{p}(\cdot)$ represents the high frequency part in fluctuating wind including the motion-induced aerodynamic force; $\tilde{p}(\cdot)$ can be decomposed into $\tilde{\tilde{p}}(t)$ which does not consider the structure vibration and $f(\cdot)$ which is induced by structure vibration. $\tilde{\tilde{p}}(t)$ is gained from the high frequency parts of results of CFD simulation, which based on the form corresponding to each peak steady response; $f(\cdot)$ is added aerodynamic term which can be transformed into added mass M_a and aerodynamic damp C_a by means of simplified aeroelastic model theory[9]. So Eq.(8)can be rewritten as:

$$(M_s+M_a)\ddot{x}_{2i}(t)+(C_s+C_a)\dot{x}_{2i}(t)+K_s x_{2i}(t)=\tilde{\tilde{p}}(t) \tag{11}$$

It is especially emphasized that transient interaction is based on the possible peak steady deformation of the *i*th eigenmode $\left\{\overline{x}+x_{1i}(t_j)\right\}$, i.e. different $\left\{\overline{x}+x_{1i}(t_j)\right\}$ correspond to different transient interaction response.

3.4 *Peak Response*

The peak response of structure is solved by means of superposition theory after getting $\overline{x}$, $x_{1i}(t)$ and $x_{2i}(t)$:

$$x_{\max}=\overline{x}+\sum_{i=1}^{n}\sigma_{1i}^2+\max\left(\sigma_{2i}^2\right) \tag{12}$$

Based on the theory mentioned above, the flowchart of the combined numerical approach is shown as figure 4.

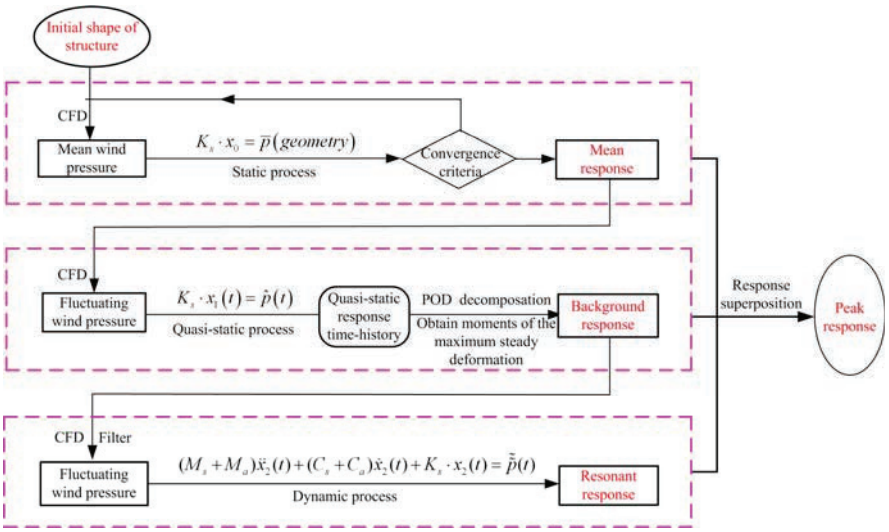

Fig. 4 Flowchart of the combined numerical approach

4 NUMERICAL EXAMPLE

4.1 *Coupling Effects of One-Way type roofs*

The roof span is 40m and 10m high, the computational domain is shown in figure 5. The inflow velocity profile is defined by $V(y) = 30(y/10)^{0.16}$ m/s， leading to a velocity value of 30m/s at roof level. Thus, the Reynolds number becomes $\mathrm{Re} = 2.07 \times 10^7$. The fixed wall is assumed as no-slip flow boundary, local one-way condition is adopted on the boundary of the outlet, and the gradient of flow speed of the outlet is zero; non-dimensional time step $\Delta t = 0.005$. Here we assume the roof is a cable structure, the mass per length g is 5kg/m, the prestressing tension force T is 20kN. According to the results of computation, the first and second frequency of structure is 0.82Hz and 2.34Hz, respectively.

Figure 6 shows the streamline drawing of flow around the fixed roof, it means that the coupling effect does not been considered. Figure 7 shows the streamline drawing of flow around the elastic roof with the consideration of coupling effect. It can be seen that, because the shape of the elastic roof changes with wind action, which directly change the boundary of the fluid field, so the characteristics of flow around a elastic roof is much different from those of rigid roof. For the elastic roof, the separation point of airflow appears at the back of the front of the roof, and the effects of vortex dropping weaken significantly. The whole average wing pressure on the elastic roof is close to that of rigid roof, but the pulse wind pressure decrease significantly, which illustrates that when vortex downstream along the roof, coupling effect induced energy dissipation lead to minor pulse pressure.

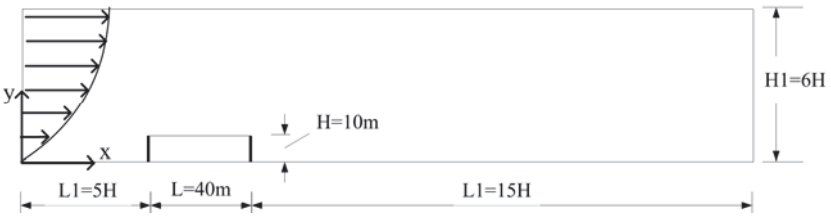

Fig. 5 Computational domain for flow around a one-way type roof

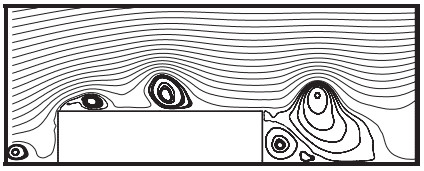
It worth to be explained that the above result was gotten from the method in ref. [6], here we call it as direct numerical method, which can be seen as a accurate method. It can be seen that by the direct numerical method, we can get the entire information of the coupling process. But from the viewpoint of engineering, we usually only concern about those statistic information, such as the mean and peak value, it means that we spend a large amount of time to get those useless information. Next, the combined procedure proposed in this paper will be adopted to calculate that statistic information. The result is shown in figure 8. It can be seen that the result of combined approach seems very close to that of direct numerical method, but quite different to the result of random vibration analysis. It shows that by using the combined approach we can also get fairly accurate result, and the time consuming by this method is quite small compare to the direct numerical method.



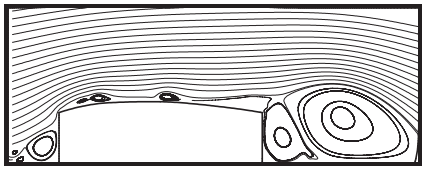


Fig. 6 Streamline around the fixed roof

Fig. 7 Streamline around the elastic roof

We also calculate the one-way type roof with 1/10L sag (as shown in fig. 9) and with 1/10L rise (as shown in fig. 10). It can be seen that for these two different shape roofs, the combined procedure can get very close results to that of accurate method. For the arch-shaped roof, the effect of fluid-structure interaction seams very small, it can be explained that the roof shape plays an important role to the coupling effect. The coupling effect will change the structural shape from bluff body to streamlined body, if the structural shape close to streamline body, then the coupling effect will be small.

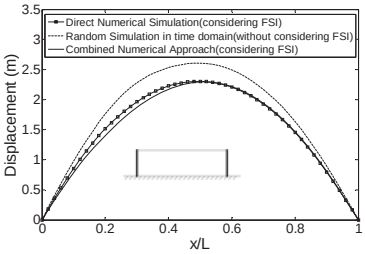

Fig. 8 Maximum response of flat roof

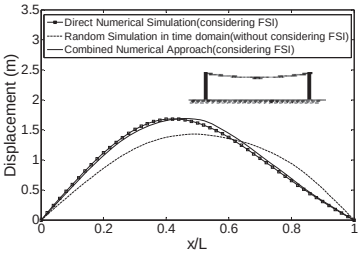

Fig. 9 Maximum response of suspension roof

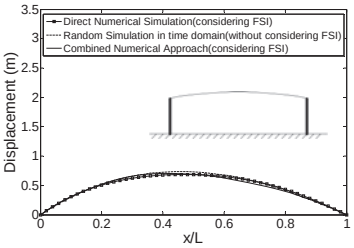

Fig. 10 Maximum response of arch roof

4.2 *Coupling Effects of Shaddle-Shape Membrane Structures*

The roof span L is 28m, the ratio of sag to span (*f*/L) is 1/16, the mass per area is 1.25kg/m^2, the tension force is 2.5kN/m. The first and second frequency of structure is 2.26Hz and 3.03Hz, respectively. The calculate model is shown in figure 10. The other calculate parameters are same as the two-way type roof.

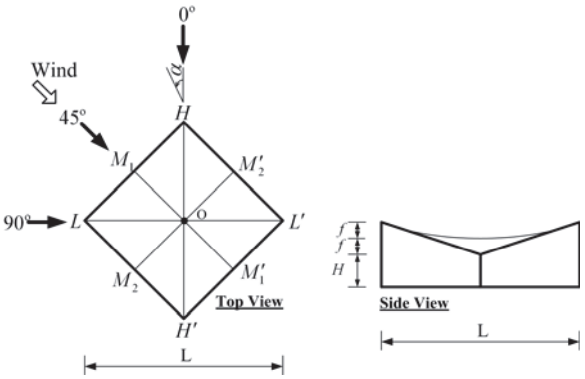

Fig. 10 The calculate model

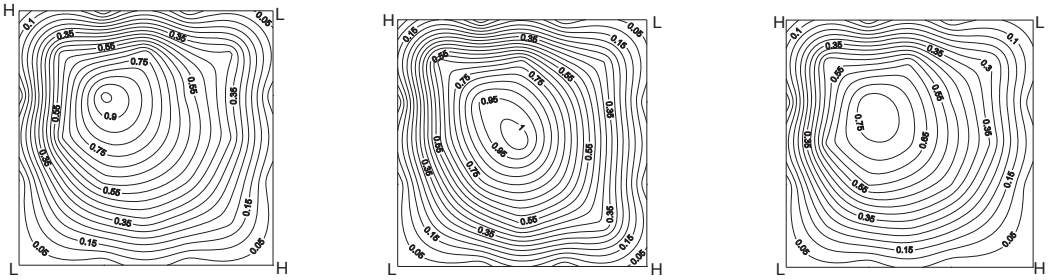
Figure 11 shows the maximum displacement of membrane structure calculated by these three methods. It can be seen that the coupling effect of 3-D structures seems more complicate than 2-D structures, but if we compare the maximum displacement point between the results of these three methods, it is also show that the result from combined procedure seems fairly close to the direct numerical method, but larger than the result of random vibration analysis.



a) Combined Approach b) Direct Numerical Method c) Random vibration analysis

Fig. 11 Maximum displacement on roof by different methods

5 CONCLUSION

In this paper, a combined numerical approach for solving the fluid-structure interaction for tension structures was proposed. With the comparison to the direct numerical method and random vibration method, it can be seen that the combined approach seems more accurate than the random vibration method and more efficient than the direct numerical method.

According to the calculate result of two-way type, it can be conclude that the coupling effect trend to change the structural shape from bluff body to streamlined body, so if the structural shape close to streamline body, then the coupling effect will be small.

ABSTRACT: It has long been studied about the flow around bluff bodies, but the effect of aspect ratio on the sharp-edged bodies in a thick turbulent boundary layer is still argued. The study is aiming to understand the surface pressure distribution around the bodies such as the suction pressure in the leading edge on the top surface when the aspect ratio of bodies is changed. Therefore, the authors firstly carried out the wind tunnel measurement around a series of rectangular bodies ($40^d \times 80^w \times 80^h$, $80^d \times 80^w \times 80^h$, $160^d \times 80^w \times 80^h$, $80^d \times 40^w \times 80^h$ and $80^d \times 160^w \times 80^h$ in mm) placed in a deep turbulent boundary layer. With modern numerical calculations, the RANS based on the k-ε model and the DES turbulence model were used, and the numerical results were compared with wind-tunnel experiments. The results show that the transverse width has a substantial effect on the surface pressure around the bodies, while the longitudinal length has a little influence on the surface pressure.

1 INTRODUCTION

The flow characteristics on a bluff body immersed in a turbulent flow has long been of fundamental interest in the study of fluid dynamics. Such investigations are critical in the design and development of practical objects such as windmills, buildings and bridges, etc. Above all, the study of flow characteristics around a bluff body is generally considered to be important in academic circles as well as in the engineering applications and now there are still lots of topics left to be studied.

Regarding to the flow around buildings or all kinds, there have been numerous empirical data and comparisons between wind-tunnel and full-scale (field) data. One of the well-cited papers in this area is the wind-tunnel experiments of Castro & Robins (1977)[1] (hereafter denoted by CR), which measured the flow around the surface-mounted cubes. In addition, Tieleman & Atkins (1996)[2] reported that the variation of the base/side surface pressure of surface-mounted rectangular prisms was determined by the interaction of the incident turbulence with the separated shear layers. More recently, Cigada et al. (2006)[3] investigated the fluid-dynamic forces acting on a rectangular cylinder for unbounded flow conditions. Especially, they focused on the effects of a fixed wall placed at various distances from a rectangular cylinder and observed that the force component acting on the cylinder depends on the periodical motion and provides the dynamic characterization of the loading and of the wake shedding. In addition, the aspect ratio of the body governs effects of the wall condition on the force coefficients and the Strouhal number. Then, Larose & Auteuil (2008)[4] made a wind tunnel measurement on rectangular prisms with aspect ratio of 2, 3 and 4 at high Reynolds number.

With regard to the CFD techniques, there have been a substantial change in the numerical modeling as well as the hardware development and it still develops rapidly. There have been a lot of attempt for simulating the precise flow around a various bodies by solving the governing Navier–Stokes equations. Especially, in the early stage, there were a lot of turbulence models to solve the complicate turbulent flow around a body and some of them were compared each other for the systematic efficiency of the models (i.e. Murakami (1993)[5]; Zhang et al. (1996)[6]; Meroney et al. (1999)[7]). What they found is that the accuracy of the numerical calculation was highly dependent of the choice of the turbulence model. However, most previous studies have been focused on the typical Reynolds-Averaged Navier–Stokes (RANS) method, especially the standard k- ε model (see e.g. Iaccarino et al. (2003)[8]; Li and Stathopoulos (1997)[9]; Tominaga and Stathopoulos (2009)[10]) was one of kinds. However, it was reported that the RANS simulation was unsuccessful as usual. In contrast to RANS method, rather the large-eddy simulation(LES) resolved large-scale unsteady motions and it showed a good agreement with wind tunnel experiments (i.e. Krajnovic´ and Davidson (1999)[11], (2001)[12]; Shah and Ferziger (1997)[13]), whereas the LES simulation was a bit costly and spent much more time and had a high request for the CPU time. Therefore, in a very recent time, there has been a trend to use an eclectic approach to balance the computational costs and the precision of calculation, namely Detached Eddy Simulation (DES) method. Due to the limited number of papers, Jochen & Dominic (2008) [14] was one of them describing the usefulness and high potential of the LES/RANS turbulence models for using a practical application.

The immediate emphasis in this paper is on the flow characteristics around the rectangular bodies with various aspect ratio. The aspect ratio is responsible for the type of generated wake and, ultimately, for the structural loading and pressure and especially structure excitation. For example, the drag coefficient of an elongated rectangular-section body in a flow is a function of the width of the body. (see Fig.1) As shown in the figure, the drag is a function mainly of the elongation d/w of the body. Therefore, the paper consists of a carefully designed set of experiments and numerical simulation on a simulated turbulent boundary layer flow, which is tailored in the atmospheric environment condition, over a surface-mounted various rectangular obstacles. In the numerical calculation, the standard k-ε and the DES model were used and finally compared with the experimental data (i.e., the wind tunnel and the field study).

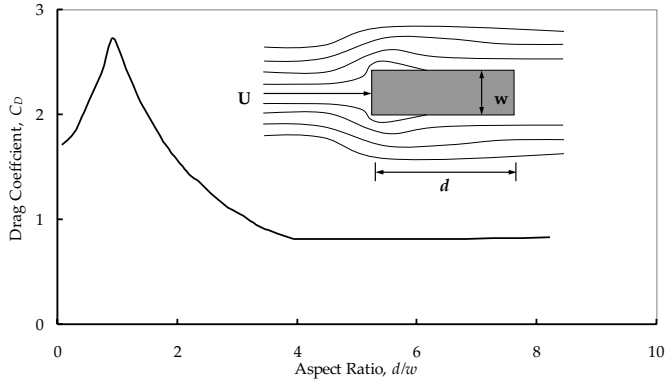

Figure 1. Drag coefficient versus aspect ratio of rectangular body. (Simiu and Scanlan, 1996[15]).

The following section §2 outlines the experimental techniques, §3 describes the computational techniques, §4 summarizes the surface pressure characteristics, as well as some findings and discussions about the major results around the models under a simulated turbulent boundary layer , finally §5 gives the major conclusions.

2 EXPERIMENTAL TECHNIQUES

2.1 *Atmospheric boundary layer wind tunnel*

Figure 2 illustrates the set-up, showing the model location in the wind tunnel. Experiments were conducted in the middle closed-circuit subsonic wind tunnel, whose working section dimension is $0.6m^{wide}\times0.72m^{high}\times6m^{long}$ having a maximum wind speed of about 40m/s at the Pohang University of Science and Technology in South Korea. It is suitable for generating an artificial boundary layer and is also equipped with modern hot-wire anemometry (IFA100) and a PIV system for optical measurements of the airflow. The rectangular models used in the study are made of plexiglass, and they consist of 3 bodies - a cube ($80^{d}\times80^{w}\times80^{h}$ in mm for 1×1) for comparing the existing results in a reference, two rectangular bodies ($40^{d}\times80^{w}\times80^{h}$ for 2×1s and $160^{d}\times80^{w}\times80^{h}$ for 1×2), and especially the flow around rectangular bodies could make two more aspect-ratios rotating it 90^{o} (e.g., $80^{d}\times40^{w}\times80^{h}$ for 1×2s and $80^{d}\times160^{w}\times80^{h}$ for 2×1).

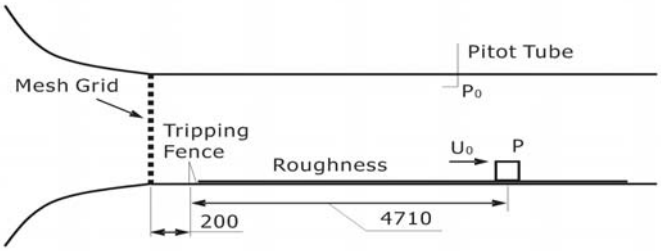

Figure 2. The 0.6m×0.72m×6m wind tunnel test section and model set up.

2.2 *Simulated atmospheric boundary layer*

Thick boundary layers were generated using a technique often employed by wind-engineering practitioners, first devised by Cook (1978)[16]. Toothed barriers spanning the floor of the working section near its entry, followed by a square section, bi-planar mesh across the entire working section and an appropriate rough surface thereafter can together be designed to yield mean-velocity profiles which are closely logarithmic over a significant portion of the working-section height, with turbulence stresses and spectra similar to those found in atmospheric neutrally stable boundary layers. Since it was intended to make comparisons with the existing data such as wind tunnel and field data(e.g. a 6m height cube in Silsoe, UK[17]) - less than one-tenth of the height of the logarithmic region - maximizing the depth of this region was deemed the most important. It is crucial to design the barrier wall and mixing grid geometries in tandem with the intended roughness, since any mismatch will yield unacceptably long fetches before reasonably well-developed flows are attained. In the present case, commercially available artificial plastic artificial grass was used to provide the surface roughness. This gave a roughness length, z_0, of 0.17mm, where z_0 is defined in the usual way via the mean velocity log law expressed as:

$$\frac{U}{u_*}=\frac{1}{\kappa}\ln\frac{(z-d)}{z_0} \tag{1}$$

where u* = the friction velocity; d = 'zero plane displacement'.

Obtaining the three unknowns (u*, d and z_0) from the mean velocity profile alone is, as is well-known, a very ill-conditioned process. In the present study, u* was deduced from an extrapolation of the measured turbulence shear stress to the surface (see Lim et al., 2007[18]), with d and z_0 then following from a best fit of the mean velocity data to eq.(1). In the tunnel, the barrier wall had a height of 50mm, with triangular cut-outs at the top, of pitch 50mm and depth 50mm, and the mixing grid consisted of a biplanar grid of 10mm bars at a pitch of 50mm.

3 COMPUTATIONAL THCHNIQUES

3.1 *Numerical methods*

The schematic diagram of the numerical tunnel with a wall-mounted cube is shown in Fig.3. For an appropriate calculation, the proper domain size is a prerequisite in the beginning state so that the cube (e.g., see $80^d \times 80^w \times 80^h$) has the computational domain size of 14h×4h×7h in Cartesian coordinate system, where h is the cube's height. The origin of the domain is located at the wind-side foot of the cube bottom. The computational grid was made by a preprocess software ICEM CFD, and the boundary conditions are shown in the Fig.3. Then the software FLUENT calculates the governing equation depending on the boundary conditions. Even though the geometry of the flow configuration is rather simple, the flow characteristics are essentially unpredictable, which has multiple separations and large and small-scale vortex regions.

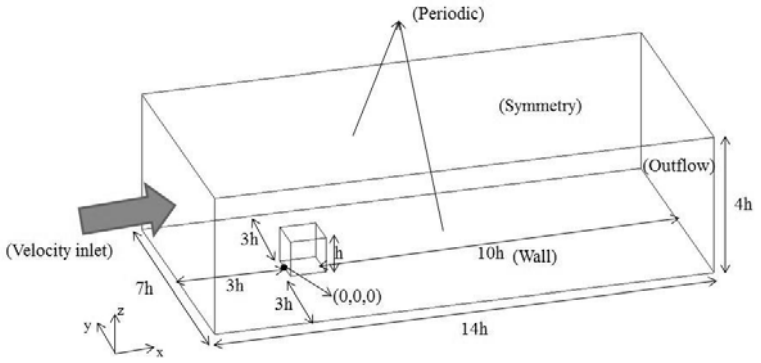

Figure 3. The computational domain and boundary conditions.

In terms of the mesh size to resolve the small-scale turbulent flow, 178×73×115 nodes were used, while the first grid spacing near the wall was 0.025h to ensure the y^+ was acceptable. For example, the inlet surface grid mesh is just like Fig.4, it required such a fine mesh resolution near the (model) wall. When the aspect ratio of the models varies, the computational domain and the number of grid should be reconstructed as listed in Table 1.

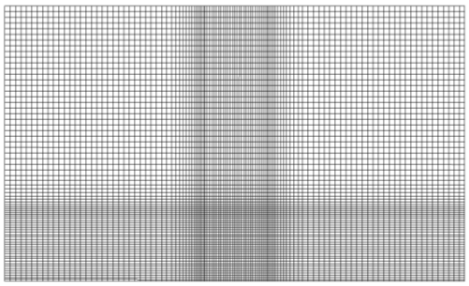

Figure 4. Frontal view of grid mesh in the inlet condition.

Table 1. Calculation domain and grid nodes of all cases

Case	Domain	Grid nodes	Abbrev
1	14h×4h×7h	178×73×115	1×1
2	14h×4h×8h	178×73×145	2×1
3	15h×4h×7h	208×73×115	1×2
4	13.5h×4h×7h	163×73×115	2×1s
5	14h×4h×6.5h	178×73×100	1×2s

3.2 *Turbulence models*

The present numerical simulation has been carried out according to the experiment study. The Reynolds number based on h (model height) and U_h (mean inlet velocity at h) was 4.6×10^4. The inlet mean-velocity profiles were compiled by UDFs, which are shown in Fig.5 (a) compared with the experiment profiles. As shown in the vertical wind profiles, it can be seen that a fully developed shear flow was made in the wind tunnel as well as numerical tunnel, which were specifically designed to be similar to the (rural) atmospheric boundary layer. Two approaching methods (i.e., Reynolds-averaging (RANS model) and filtering methods (LES model)) were employed to render the Navier-Stokes equations tractable so that the small-scale turbulent fluctuations do not have to be directly simulated. Firstly, what we consider in this study is the standard k-ε model. Here, the self-developed code of the turbulence kinetic energy (k) and its dissipation rate (ε) was used to obtain the turbulence intensity, which should be consistent with the experiment, see Fig.5 (b). As the LES simulation takes usually a high computational cost, herein, we select the DES model which is often referred to as the hybrid LES/RANS models. In this case, the DES model is based on the one-equation Spalart-Allmaras model and the transient calculations were carried out with the time step 0.0001s.

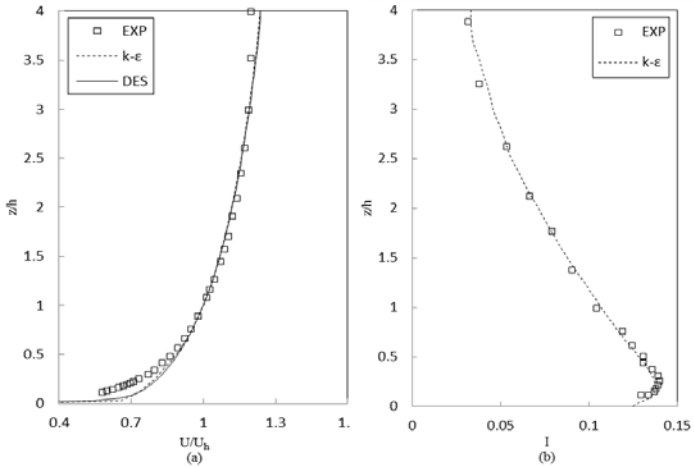

Figure 5. Mean velocity (a) and turbulent intensity (b) profiles.

4 RESULTS AND DISSCUSSION

4.1 *Surface pressure distribution - a cubical model (1×1)*

Firstly, the surface pressure distributions along the centerline around the 1×1 model are shown in Fig.6. The variation of the mean static pressure coefficient C_p ($=(p-p_r)/(0.5\rho U_h^2)$, where p_r is the mean static pressure in the upstream flow) is compared between numerical and experimental results. In addition, the figure also includes the existing results - wind tunnel(WT) and full field scale(FS) measurement, which is as a function of the measurement location *x/h*; *x*=0 corresponds to the foot at the front face of the model body - actually depending on the wind direction (e.g., see the solid line on the right figure). Note that the rest of the subsequent figures are arranged in a similar manner to this figure. It is no doubt that the profiles in the figure has an expected shape, in that the largest negative pressures occur just beyond separation at the leading edge and are followed by a substantial pressure recovery on the top surface, as shown frequently by previous studies. Note that the experiment data agree well with the earlier field data of LCH's (Lim, Castro & Hoxey, 2007[19]) but are significantly different from the wind-tunnel data of CR (Castro &

Robins, 1977). The latter are similar to those of Murakami & Mochida (1988) [20] and, in agreement with CR's discussion, are undoubtedly a result of very much higher upstream turbulence levels, leading to much earlier attachment and pressure recovery on the top surface. In addition, the k-ε model data are nearly similar except the region on the just right corner of the position x/h=1 which has a negative peak. This seems to be caused by the turbulence model itself so that in this regard, the DES model seems to have better performance than the k-ε model when simulating the flow around a sharp-edged bluff body.

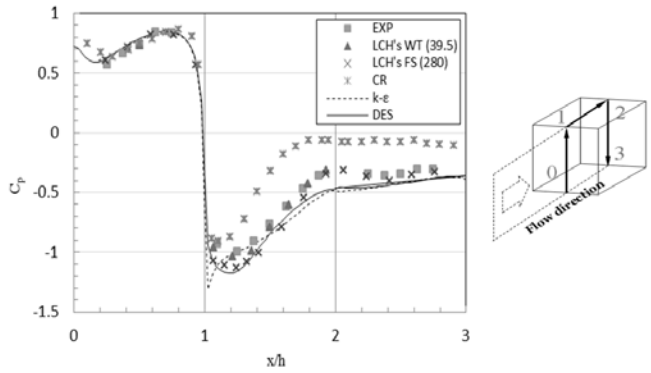

Figure 6. Mean surface static pressure coefficient along the central section with wind normal to face.

Figure 7 shows the mean surface pressure along the mid-height of the cube. As shown in the figure, the experiment data agree well with the field measurement data except the CR's result which has been explained before. The k-ε model data are similar to the experiment data, but still has a significant difference on the just right corner of the position x/h=1, whereas the DES model data seem to improve the accuracy of the prediction in this region - a negative peak. However, the numerical data show relatively low value compared to the other experiment data. Perhaps, this can be explained that the upstream turbulence level in the approaching flow is not high enough so that the attachment and pressure recovering seem to be delayed.

Even though the current experiment and numerical data in this section are showing the simple comparison with the existing results, the immediate implication is that the comparison with the existing results confirms the high accuracy and reliability of the current study, and the identical condition with the field measurement yields the significant reduction of the measurement and calculation errors. Therefore, the current section could be a precursor of the rest of the pressure profiles and the next section will discusses the pressure profiles around the rectangular obstacles with the same boundary layers.

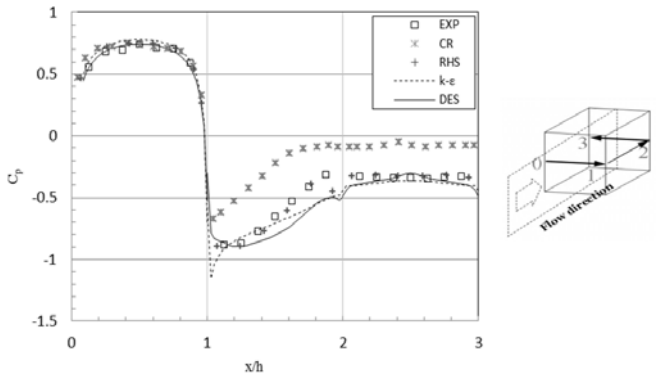

Figure 7. Mean surface static pressure coefficient at the mid-height of the cube.

4.2 *Surface pressure distribution - models with aspect ratio*

Mean surface static pressure profiles along the centerline of the models with the three different aspect ratios are plotted in Fig.8. The figure shows how the surface pressure on the top as well as on the front and rear face changes with changing of the width of the body. Note that several subsequent figures are arranged in a similar manner to Figure 8, i.e. the experiment pressure profiles are shown on the upper-left and the CFD (k- ε model) pressure profiles are shown on the upper-right. In addition, models to compare each other are shown underneath, to easily visualize the measurement locations around the body. The immediate implication of the data in Fig.8 is that the width variation while maintaining the depth makes the surface pressure on the top surface more negative, whereas the front and rear face are almost consistent for the width variation. In addition, as it can be seen, the solid arrow shows the direction of the pressure drop as the width changes.

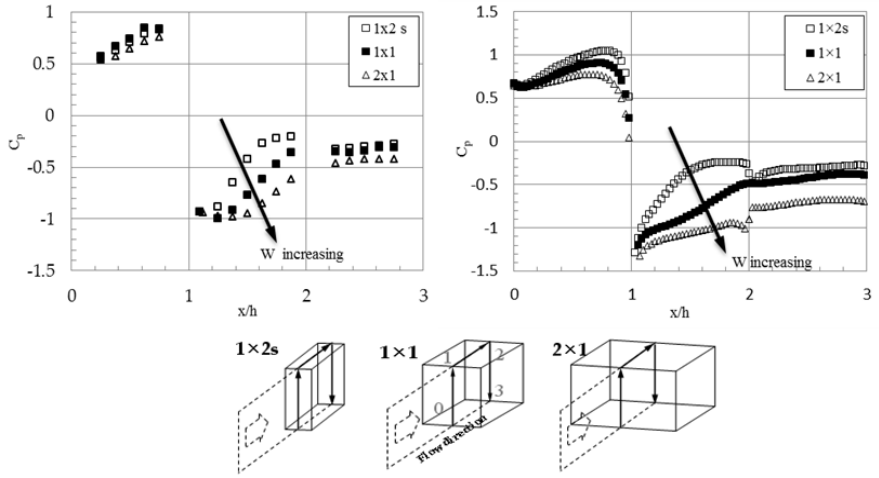

Figure 8. Mean surface static pressure coefficient along the centerline with changing transverse width.

In Figure 9, the mean surface static pressure along the side face at the mid-height of the three different boxes with changing transverse width is presented. The abscissa in the figure is normalized with the body height. As consistent with the previous figure, the pressure drop with increasing width was noticeable to the negative direction. These results demonstrate that with an increase in the horizontal width, i.e. as increasing the aspect ratio, there is a concurrent suction pressure drop on the side face.

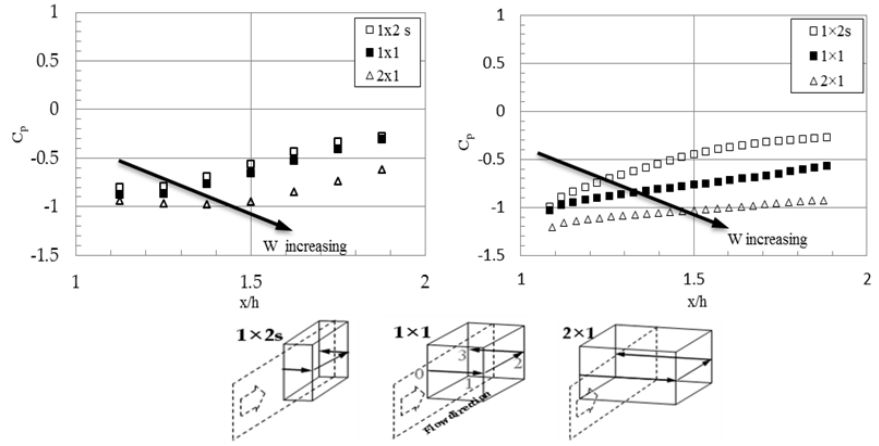

Figure 9. Mean surface static pressure coefficient at the mid height with changing transverse width.

Figures 10 and 11 show the mean surface static pressure profiles along the centerline and the mid-height of the models with changing longitudinal length(i.e. the depth). The different size of the depth maintaining the front face area makes different length of the side face - the ratio of 1:2:4, respectively. The flows around wall-mounted sharp-edged models usually have separation and often attachment around the body so that the pressure profiles in the figure have the similar shape, as shown in the above results. The pressure profiles seem to have a similar trend and it is noted that the overall distribution of the surface pressure makes good agreement and the longitudinal length of the body only affects the recovery region on the top surface, and there appears a little discrepancy in the side face.

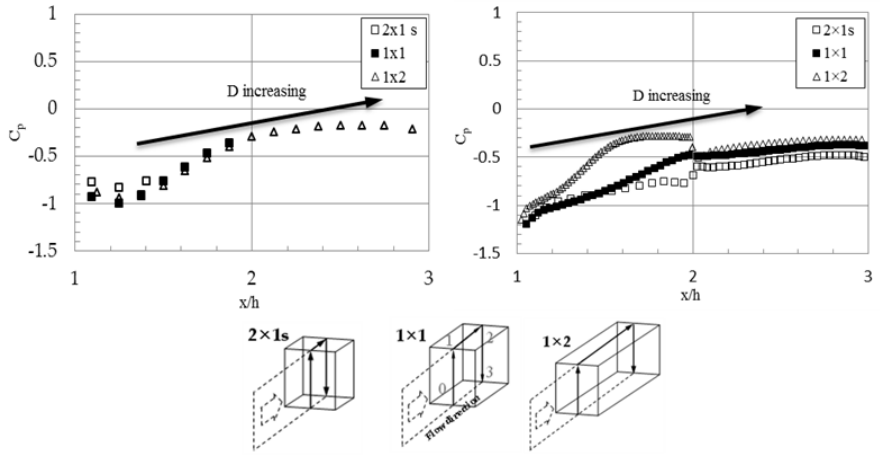

Figure 10. Mean surface static pressure coefficient along the centerline with changing longitudinal length.

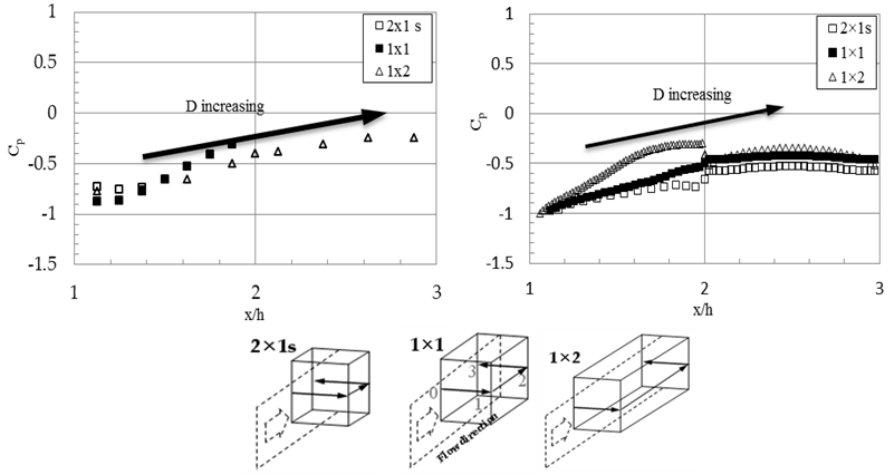

Figure 11. Mean surface static pressure coefficient at the mid height with changing longitudinal length.

Figure 12 presents the variation of the mean static pressure C_p appropriately normalized as making a proper scaling. Note that the above two pictures are the experiment data and the following two pictures are the CFD (k- ε model) data. It is also noted that the abscissa in the previous section was presented as a non-dimensional axis normalised by a body height h, whereas the current axes are normalized along the the axial centerline of the models by the characteristic length - the width(W, width effect) and the depth(D, the depth effect), respectively. In the figure, they are generally in good agreement. Therefore, it can be described that even

though the length and width of the rectangular body are changed, the characteristics of the static surface pressure profiles along at least the centerline itself remains unchanged, if any, it ought to be a litter scatter.

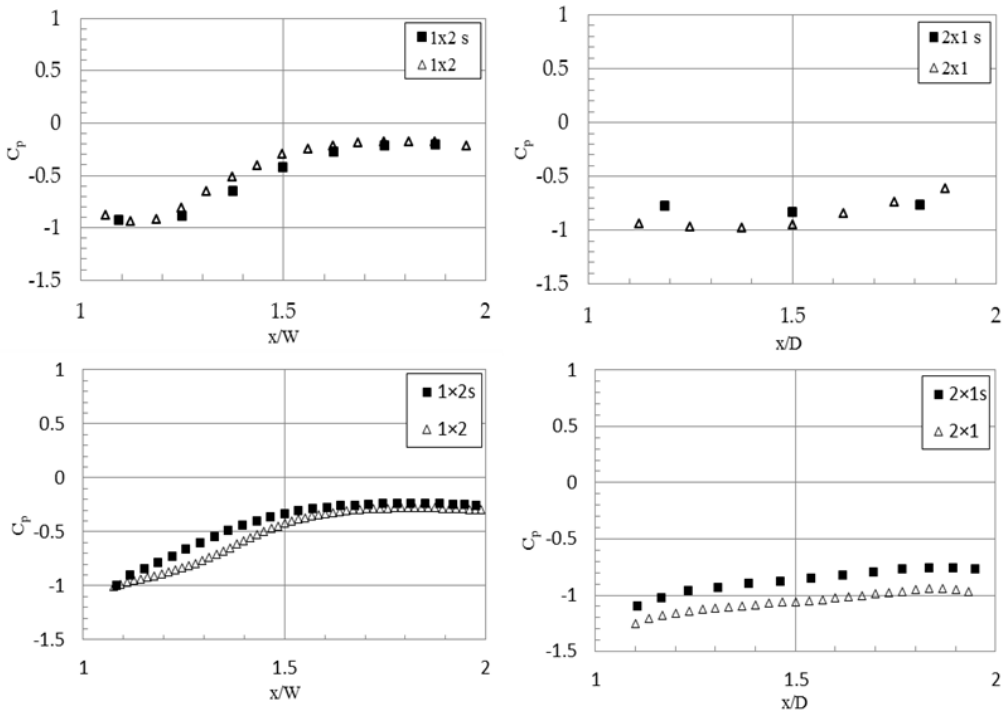

Figure 12. Mean surface static pressure coefficient along the centreline on the various boxes with the normalization of width (W) and the depth (D), respectively.

5 CONCLUDING REMARKS

Although more comparisons are needed to end up with the conclusions, the study has contributed in making the following conclusions:

(1) As a usual, the CFD results agree well with the experiment results, as well as the earlier field results, but there still appears a litter discrepancy, which should be discussed in detail in the next study.

(2) In this comparison, the DES model seems to be better than k-ε model when simulating the wind flow around a variety of bluff body.

(3) When the aspect ratio of a rectangular body changes, the transverse width has a substantial effect on the surface pressure around the bodies, while the longitudinal length shows a little influence on the surface pressure.

Flow conditions for aerolastic stability of modular slender structures

Elena Dragomirescu[a], Yarzar Tun [a]

[a]*University of Ottawa, 161 Louis Pasteur, Ottawa, Canada*

ABSTRACT: While the wind flow around conventional shapes was well studied, and its aerodynamic mechanisms were well established, for structures as buildings and bridges with geometric shapes of particular modulations, a distinctive investigation is required. In terms of wind flow-structure interaction and the aerodynamic stability, among all the studied structural shapes, one has distinguished as exceptionally stable for high wind speeds. The structure itself is a post-modernist sculpture entitled "Endless Column", created by C. Brancusi in 1916. The sculpture, which fells under the UNESCO patronage, was the object of several wind tunnel studies, which acknowledged the stability of the Column and the lack of galloping vibrations. However, considering the limitations of the experimental facilities, a clear explanation for these phenomena was difficult to provide. The current research completes the experimental series performed on the Column, through analytical means of CFD (Computational Fluid Dynamics), and provides a better understanding of the flow-structure interaction for this particular modular shape. For wind velocity of 5.45 m/s and, angles of attack of 0° and 10° were found to have certain influence on the formation of three-dimensional vortices on the rear side of the Column; the most stable case with a regular flow pattern behind the Column was identified for 45° angle of attack, where a vertical motion along each module was detected.

KEYWORDS: Endless Column, Wind-structure interaction, Flow pattern, CFD simulation.

1 INTRODUCTION

Constructed in 1916 as a commemorative monument for the victims fallen in the First World War, The Endless Column is situated in the central part of Romania, in the city of Tg. Jiu. Its creator, the famous post-modernist sculpture C. Brancusi has envisioned a slender shape for his masterpiece, composed by a repetition of 15 pyramidal modules of dimensions 45 x 90 x 45 cm, plus two halves-modules at the extremities. The cast iron modules have inside a rectangular steel shaft, which spans the entire height of the column of 30 m (Fig. 1 a). For a structure of such dimensions, taller than most of the surrounding buildings and slenderer than a chimney, the stability to wind would be a main concern; however, the Column has intrigued the aerodynamicists of our times through its stability. Some researchers considered the interaction between wind flow and the Column's modular shape as an explanation for this stability, and they characterized the Column as "aerolastic indifferent" (Safta et al, 2003, Sofronie et al, 2001, Gabbai et al, 2007). In 2000 when the Column was dismantled for rehabilitation, Column's structural characteristics, such as natural periods, distributed mass and damping were determined through in-situ measurements (Lungu et al, 2001), and consequently wind tunnel experiments were performed, for a fixed scaled segment of 4 modules of the Column, under laminar flow conditions (Solari et al, 2002). In 2005 a complete series of wind tunnel experiments were carried out for a scaled segment of 6 modules and for a complete three-dimensional Column model (Fig. 1 b), which preserved the geometric and dynamic properties from its original prototype through aerodynamic scaling (Yamada et al, 2005, Dragomirescu et al, 2009). Tests on a conventional square shape column were also performed for comparison. Both wind tunnel experiments have shown that the Endless Column model is very stable for high wind speeds, where the square model will encounter already galloping vibrations. However, for the lower wind speeds, the resonant phenomenon of lock-in was encountered with similar magnitudes of vibrations for both models, the square and the Endless Column.

Figure 1: Endless Column, Tg. Jiu, Romania (a) Site location (Dragomirescu et al, 2009), (b) Wind Tunnel Experiment (Yamada et al, 2005)

Several countermeasures in the form of dimples, helical spires, etc., exist already for overcoming the resonant lock-in phenomenon for slender structures; for galloping wind induced vibrations however, more complicated measures or control devices, such as dampers, must be considered. Unexpectedly, the "aerolastic indifference" of the Endless Column, manifested through stability for high wind speeds, might be considered as a geometric countermeasure against galloping. Nevertheless, none of the performed wind tunnel experiments have included a three-dimensional visualization of the wind flow around the Endless Column, and a clear explanation of the flow-structure interaction could not be expressed, hence the usage of its modular shape as a countermeasure for galloping could not be attested. Therefore, the current research employs an extensive 3D Computational Fluid Dynamics (CFD) simulation for elucidating the flow formation at different levels of the Endless Column and the induced aerodynamic forces.

2 SIMULATION ALGORITHM

The flow around The Endless Column was simulated in a rectangular domain; the dimensions of the Column were considered as per the aerolastic model described in Yamada et al, 2005 and Dragomirescu et al, 2009, namely 1,467 cm height, 4.5 cm module's big base and 2.25 cm module's small base which corresponds to a scale of 1:20 from the prototype. The grid system had the major axis of 5H, the minor axis and the thickness were 1.33 H, where H = 1.4675 m, is the height of the Column, as schematically represented in Figure 2 a. The Cartesian referential system x, y and z axes were chosen for along stream-wise direction, transverse to the stream-wise direction and the column-span direction respectively. A total number of 1.5 million tetrahedral cells and 250,000 nodes were employed. The non-slip boundary condition was specified on the surfaces of the Column, and the in-flow boundary condition was set to ux = 5.45 m/s uy = uz = 0.

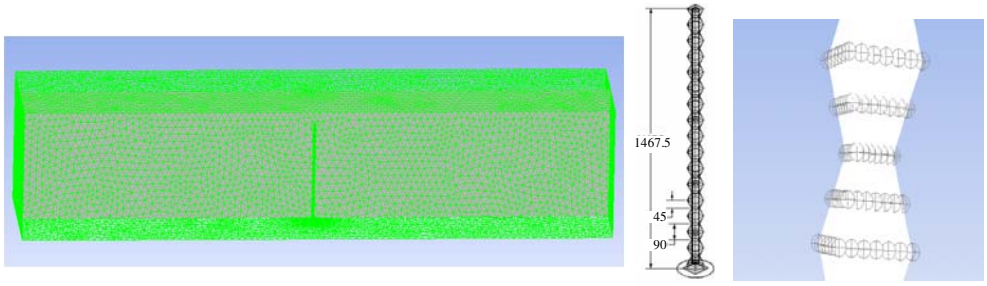

Figure 2: CFD Simulation details (a) Mesh Characteristics, dimensions in mm, (b) Monitored points

Pressure was monitored along an entire pyramidal module by sampling data from 5 rings (Fig. 2 b). This arrangement will help identify the influence of the geometric shape upon the wind induced pressure and the disturbance of the wind flow created by one module. The previous experimental investigations (Yamada et al, 2005) have shown a better response of the column for 45° and a slight vibration for 0° and 10°, starting at a wind speed of 5.45 m/s. Hence, three wind directions were investigated herewith, for angle of attack of $\alpha = 0°$, 10° and 45°.

The large eddy simulation (LES) with the Smagorinsky subgrid-scale model was employed for the CFD simulation. The three dimensional incompressible Navier-Stokes equation and the equation of continuity in non-dimensional form are:

$$\frac{\partial \mathrm{u_i}}{\partial t} + \mathrm{u_j}\frac{\partial \mathrm{u_i}}{\partial t} = -\frac{\partial P}{\partial \mathrm{x_i}} + 2\frac{\partial}{\partial x_\mathrm{i}}\left(\frac{1}{\mathrm{Re}} + v_{sgs}\right)D_{ij} \tag{1}$$

$$\frac{\partial \mathrm{u_i}}{\partial \mathrm{x_i}} = 0 \tag{2}$$

where u_i is the velocity component of grid-scale, and P is the sum of the grid-scale pressure and the residual stress. $D_{i,j}$ in Eq. (1) is the strain-rate tensor on the grid-scale velocity components:

$$D_{ij} = \frac{1}{2}\left(\frac{\partial \mathrm{u_i}}{\partial \mathrm{x_j}} + \frac{\partial \mathrm{u_j}}{\partial \mathrm{x_i}}\right) \tag{3}$$

The subgrid-scale eddy-viscosity, v_{sgs}, in Eq. (1) is expressed as:

$$v_{sgs} = \left(C_s\Delta\right)^2\sqrt{2D_{ij}D_{ij}} \tag{4}$$

where Δ is the filter width and was given as the cubic-root of grid volume and the C_s, Smagorinsky constant, was set to 0.1 in this study. The invicid flux vector was determined by a standard upwind, flux-difference splitting through the low-diffusion Roe approach. For estimation of the secondary diffusion terms and velocity derivatives, the least square cell based spatial discretization was used and Third-Order MUSCL equation was considered for the flow density-based solver. The time step was chosen as t = 0.003 s; pressures along the entire surface of the model was integrated, and lift and drag aerodynamic forces were determined. More convenient, drag and lift coefficients C_D, C_L, were extracted from the definition formulas below (Simiu and Scanlan, 1996):

$$\mathrm{F_D} = \frac{1}{2}\rho \mathrm{U^2 B C_D} \quad \text{and} \quad \mathrm{F_L} = \frac{1}{2}\rho \mathrm{U^2 B C_L} \tag{5}$$

Where F_D, F_L are the drag and lift aerodynamic forces, ρ is density of air, U is wind speed upstream from the model deck and B is the nominal diameter of the Column's model.

3 TWO-DIMENSIONAL FLOW-STRUCTURE INTERACTION

In order to determine the effect of the pyramidal module upon the aerodynamic stability of the Column, localized velocity field distribution were recorded at different heights along the module for 0°, 10° and 45° (Figs. 4 a to f).

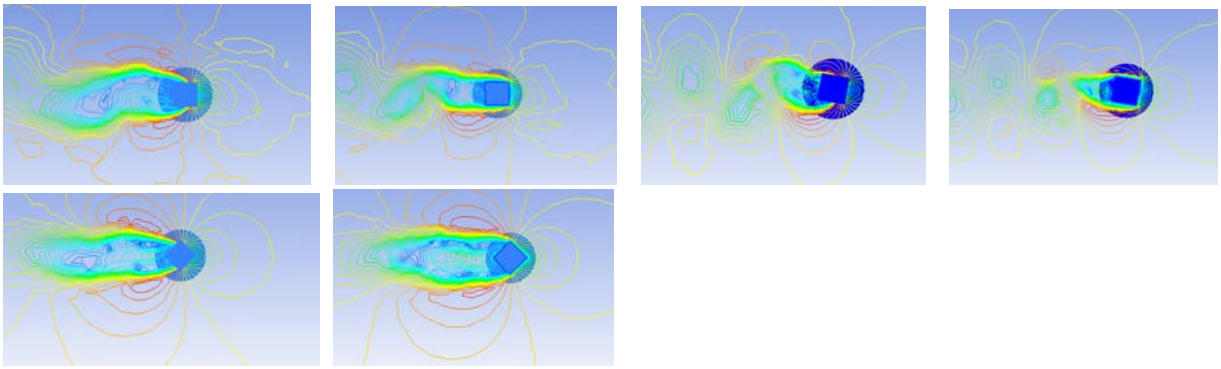

Figure 3. Two-dimensional instantaneous velocity isolines for (a) Small base, $\alpha = 0°$, (b) Large base, $\alpha = 0°$, (c) Small base, $\alpha = 10°$, (d) Large base, $\alpha = 10°$, (e) Small base, $\alpha = 45°$ and (f) Large base, $\alpha = 45°$.

For 0°, around the small base of the module (Fig.3 a), alternation of shear layers is noticed from both edges of the Column which, however, will not interfere with each other downstream the flow. For the large base of the same module (Fig.3 b), the streamlines of the velocity field have a similar evolution; however downstream the Column these shear layers tend to connect generating turbulent flows. Shedding of several vortices downstream the Column was noticed for 10°, generated by the shear layers which detach from the edges of the Column, around both small and large base of the module (Figs. 3 c and d) while for 45° a slight turbulence can be noticed within the shear layers which envelop one major vortex, which varies in intensity and shape with the position along the Column, e.g. smaller vortex behind the small base of the module (Fig. 3 e) and bigger vortex formation behind the larger base of the module (Fig. 3 f).

Pressure monitored around the module at the small and large base location showed that after a dominant positive pressure at the incoming flow, the Column was dominated by suction especially on its rear side. For $\alpha = 0°$, pressure varied between 19 Pa, on the front side of the column, where the incoming flow directly hits the structure, and a suction of up to - 17 Pa downstream the Column was noticed, for the crest of the module where surface exposed to wind is higher (Fig. 4 a). On the small base of the module, an earlier flow detachment is noticed. Also behind the Column after the shear layers detach from the edges, a constant region of negative pressure is noticed, indicating that no vortex formation appeared in the vicinity of the Column surface. For 10° angle of attack, after the sudden drop in pressure from 10 Pa to -20 Pa, indicating the shear layer detachment from both edges of the Column, a variation in the suction monitored on the rear side was noticed, of the as it can be seen in Figure 4 b; this might be due to the alternate vortex formations, which might be a possible cause of unbalanced lift force and appearance of incipient vibrations described during the experiments (Dragomirescu et al, 2009). The maximum induce pressure, was in the same range of 19 Pa, however the suction created on the rear side of the Column and through the vortex formation, was - 27 Pa, much lower than for 0° and 45°. A gradual transition from the strong pressure induced by the incoming flow, towards the negative pressure registered on the rear of the Column could be noticed for 45°, caused by the triangular exposed shape (Fig. 4 d). A constant suction on the rear side of the Column indicated that no vortex or turbulent flow formations will reattach to the module in this area. No significant difference was noticed between the flow acting on the small base and on the large base of the module.

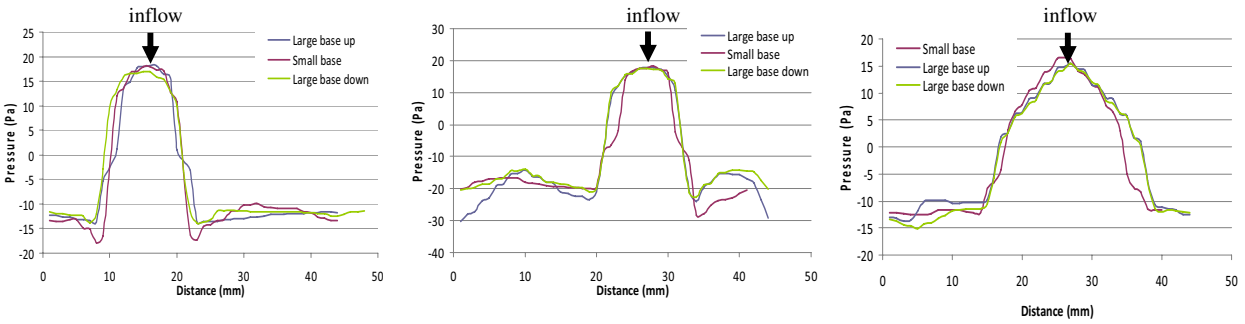

Figure 4. Average pressure on the surface of the Column, for different heights along the module for (a) $\alpha = 0°$, (b) $\alpha = 10°$, and (c) $\alpha = 45°$.

The coefficients C_D and C_L, represented by hollow triangles in Figures 5 a and b, were found to be in good agreement with the experiments performed by Solari et al, 2000, represented by hollow dots, and with those performed by Dragomirescu et al, 2009, represented by full dots in the same figure. The highest lift force is registered for 10°, as also indicated by the previous experiments, while the drag force would be dominant for 45°; when the wind speed is perpendicular to the front face of the Column, ($\alpha = 0°$) both aerodynamic forces were within moderate limits. In spite of the averaged values of the aerodynamic forces, the experiments (Yamada et al, 2005, Dragomirescu et al, 2009) have shown that if the Column is allowed to vibrate in smooth flow, the highest across-wind vibrations for 5.45 m/s are registered for $\alpha = 10°$ followed by $\alpha = 45°$. It should be mentioned that the same experiments have revealed that a square column tested under the same conditions would have four times higher vibration amplitude.

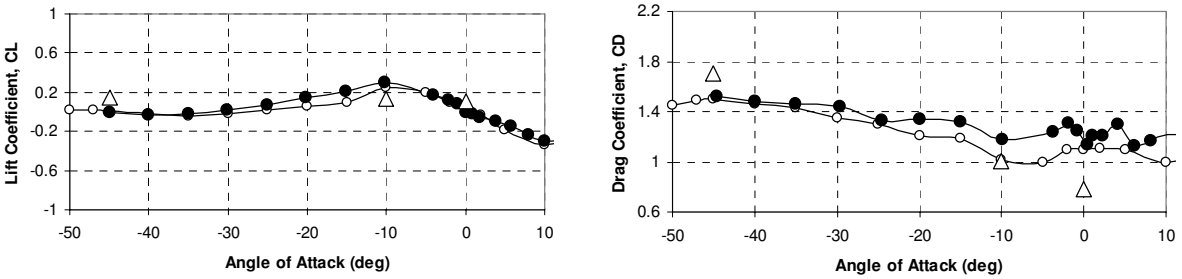

Figure 5. Variation of aerodynamic coefficients with the angle of attack: (a) Lift Coefficient, C_L, (b) Drag Coefficient, C_D

4 THREE-DIMENSIONAL FLOW-STRUCTURE INTERACTION

The particular shape of the Endless Column was considered to provide certain stability against galloping vibrations at high wind speeds and this was certified by several wind tunnel tests (Solari et al, 2000, Yamada et al, 2005). Most of the aerodynamic theories consider the cross section as a reference nominal area; however a two-dimensional cross section in this case would be reduced to a basic square shape, for which aerodynamic characteristics are much below the structural capacities of the Endless Column. Hence a three-dimensional interpretation of the wind flow structure interaction is required for better understanding the aerodynamic stability of this particular structure.

The flow visualization was conducted by sampling instantaneous velocity streamlines, simulation very similar to smoke visualisation practiced in the experiments. The velocity stream-

lines indicated a vertical motion along the Column, initiated by the free-end effect, in spite of the horizontal direction of the incoming wind flow, and sometimes rotational flow formations appeared between the modules behind the Column. At $\alpha = 0°$, when the entire front side of the modules is facing the incoming wind flow of initial velocity 5.45 m/s, the impact with the Column will determine a change in direction of the velocity streamlines, otherwise horizontal, and will produce vertical downwards flow movements, periodically re-attaching to the Column in the module's crest region (Fig. 6 a). For the case of 10°, the modules will accelerate slightly the lateral streamlines of velocity up to 6.0 m/s. Also, due to the trough between the modules and the inclination of the wind direction, the wind velocity was redirected downwards along the Column, which changed their linear pattern into a more irregular one (Fig. 6 b). When the corner of the Column is directly exposed to the wind ($\alpha = 45°$), acting as a wind breaker (Fig. 6 c), the regular velocity streamlines were partially maintained even after encountering the structure, a slight disturbance being observed only downstream the Column, at a distance of 0.2 m.

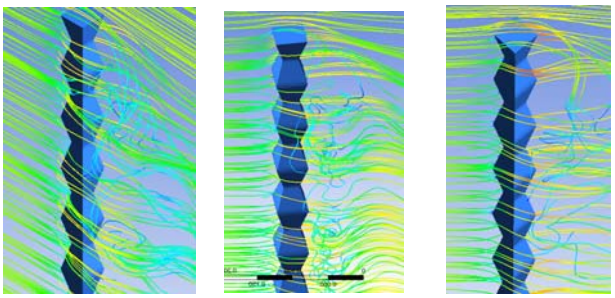

Figure 6. Three-dimensional flow pattern streamlines for (a) $\alpha = 0°$, (b) $\alpha = 10°$ and (c) $\alpha = 45°$,

Whenever the vectors of the velocity curl are extracted, indicating the rotation axis and the sense given by the right-hand rule for each rotational formation appearing around the structure, was noticed that, for all the investigated cases, $\alpha = 0°$, 10° and 45°, often on the edges of the Column, where wind detaches after the impact, the vectors will have opposite senses, hence cancelling out the motion along each of the modules, as represented in Figures 7 a to c. The rotational activity on the vertical direction is not entirely absent, but appears on the rear side of the Column, having very small intensity, of 1.36 s^{-1} and which is more concentrated in the troughs for the case of 0°. For 10°, the velocity curl reaches higher values of 1.04 x 10^3 s^{-1}, and is unevenly distributed along the rear side of the Column and along the edges; dominant direction of the flow will remain the along-wind direction. For 45°, lower intensity of the rotational activity was recorded, and opposite vectors appear clearly on the right side and left side along the edges, where detachment is encountered and more organized patterns and dominant along-wind flow vectors were noticed surrounding the Column.

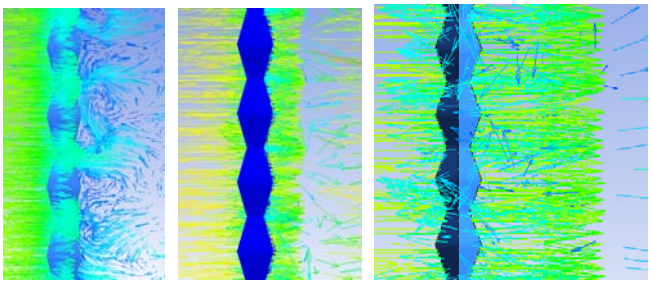

Figure 7: Velocity curl vectors for 5.45 m/s for the Endless Column at (a) $\alpha = 0°$, (b) $\alpha = 10°$ and (c) $\alpha = 45°$,

In Figures 8 three-dimensional flow formation around the entire Column are depicted. For $\alpha = 0°$, well defined three-dimensional turbulent formations are shed from both edges of the structure, and form a series of vertical flow patterns, which travel until 0.4 m downstream the Column. The measurements showed suction on the edges of the Column, of about -20 Pa, in the trough region, while on the crest of the modules, positive pressure of up to 19 Pa is recorded. The three-dimensional turbulent formation is also present downstream the Column at $\alpha = 45°$ (Fig. 8 c) however it seems to be only one single vertical vortex behind the Column instead of several shed vortices as for 10°, and the distance spanned by it is much lower, of 0.52 m. the most critical case of $\alpha = 10°$ showed a complex flow formation behind the Column, with several vertical vortices which travel in their consistent shape on higher distances of up to 0.8 m downstream the Column (Fig. 8 b). The color code indicates suctions of up to -40 Pa were achieved at the detachment surfaces.

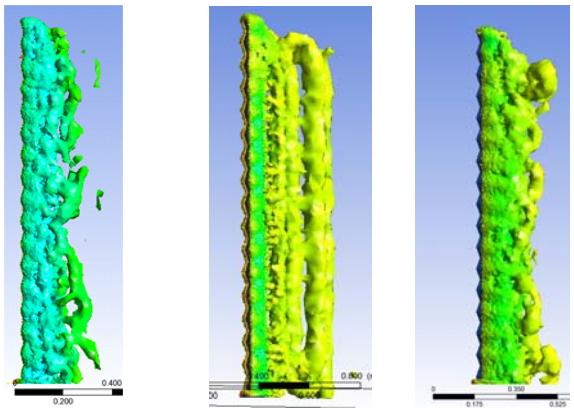

Figure 8: Three-dimensional flow formation around the Endless Column for (a) $\alpha = 0°$, (b) $\alpha = 10°$ and (c) $\alpha = 45°$.

A section through the three-dimensional flow formations revealed the vertical pressure distribution for angles of attack 0°, 10° and 45° (Figs. 9). Clear shedding of turbulent flow can be noticed initiated from the large base of each module towards downstream and local pressures of -10 Pa to -20 Pa alternate for the regions between two consecutive crests for 0° (Fig. 9 a). Several rows of vortices were confirmed along the height of the Column, of different intensities and induced pressures.

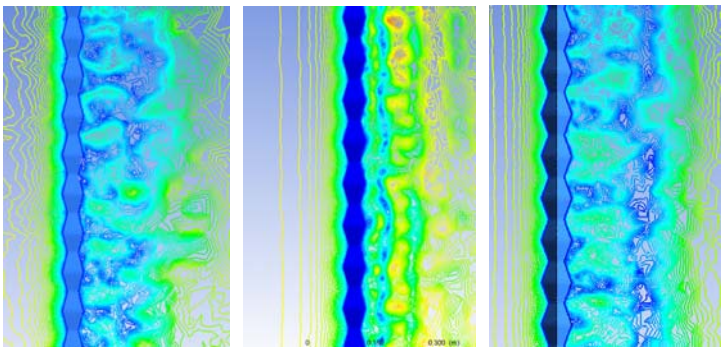

Figure 9: Pressure distribution around the Endless Column for (a) $\alpha = 0°$, (b) $\alpha = 10°$ and (c) $\alpha = 45°$.

The pressure measured on the exterior three-dimensional vortices shed downstream the Column was of 27 Pa; the interior of the vortices however, will exhibit a strong suction of -25 Pa, in the immediate vicinity of the Column and -12 Pa, when departed from it, for the α =10° (Fig. 9 b). The vertical pressure distribution for 45° clearly showed the main vertical vortex formed on the rear side of the Column had a local pressure of -10 Pa and only localized spots of -20 Pa, which dissolved quickly in the flow (Fig. 9. c).

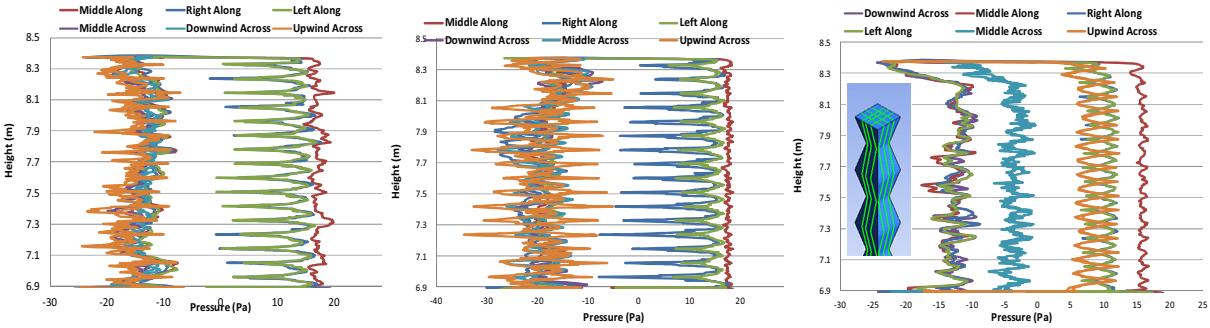

Figure 10. Instantaneous pressure on the height of the Endless Column, for (a) α = 0°, (b) α = 10°, and (c) α = 45°.

Figures 10 a, b and c show the pressure distribution at the surface of the Column for the incoming wind direction considered as the middle position and at 0.1 m left and right from the middle position. Also on the across-wind direction the middle line was monitored and the two lines at 0.1 m towards the incoming flow (upstream) and towards the downstream of the Column, as it can be seen in the detail of Figure 10 c.

For the α = 0°, mainly suction (-15 Pa to -20 Pa) was registered on the middle line in the across-wind direction indicating the shear layer detachments showed also in Figures 3 a and b, while the middle line in the along-wind direction, as expected high pressure of almost 20 Pa was registered on one side and suctions of -10 Pa were registered on the other side of the structure. Little fluctuation was noticed for both middle lines. For the other two lines in the along-wind direction (left and right) however, high fluctuations were noticed at the incoming flow along the modules, reaching 19 Pa at the large bases and almost 0 Pa at the small base of the modules, while limited fluctuation is shown on the rear side of the Column the right along- and left along-wind lines. For the across-wind direction, the upwind line showed the highest pressure fluctuations of -10 Pa to -20 Pa, which indicates that turbulent flow around the Column is already formed before the shear layers detach from it. The pressure on the downwind across-wind line had similar values and variations as for the middle across-wind line.

Consistent positive pressures of around 19 Pa were registered for the incoming wind surface of the Column on the middle line for α = 10°, as it can be seen in Figure 10 b, while the left and right lines for the same along-wind direction had similar pressure patterns as for the α = 0°. On the across-wind direction the upwind line had extreme variations along the modules spanning from -10 Pa to -30 Pa which is consistent with the pressure distribution and the vertical vortices formations reported in Figures 8 b and 9 b. The downwind line will also register fluctuations along the module's height however the pressures are not very high, being in the region immediate after detachment.

The case of α = 45°, was the most stable in terms of pressure distribution on the across- and along-wind directions as follows (Fig. 10 c): the middle line for the along-wind direction registered smaller pressures of around 16 Pa due to the minimum nominal area exposed to wind and had a very limited fluctuation along the modules. The across-wind middle line registered the smaller suction of -5 Pa which confirms the absence of any turbulent or vortex formation down-

stream, in the immediate vicinity of the Column. The left and right lines on the along-wind direction will have similar patterns as for the 0° and 10°, however the values of the recorded pressure are much lower of around 5 Pa to 10 Pa on the incoming wind face and -10 Pa to -15 Pa for the rear side of the Column. The main difference for the $\alpha = 45°$ is that the upwind across-wind line will yield only positive pressures which indicates a flow attached to the outside edges of the Column, which does not appear in any of the above figures. The downwind across line will register only negative pressures as for the other two cases of 0° and 10°.

5 CONCLUSIONS

The three-dimensional flow visualization was conducted through CFD simulations for the Endless Column, in order to clarify the effect of the modular shape upon the stability to galloping vibrations and to determine the detailed flow-structure interaction. The dimensions of the model, the wind speed and angle of attack were chosen so that it followed the wind tunnel experiments reported by Dragomirescu et al, 2009.

The effect of the geometric shape of one pyramidal module was investigated and was determined that the crest regions of the module would have less influence upon the aerodynamic activity, while the crest regions would establish a continuous accumulation of suction on the rear side of the Column, which indicates the existence of a vortex formation. The velocity streamlines, pressure contours and vertical flow formations re-attested the fact that the Column facing the wind at an attack angle of 10° would be the most inconvenient arrangement; these wind directions would produce an earlier detachment of the incoming wind flow, after the impact with the structure, and would determine the creation of several three-dimensional vertical vortices of high suction behind the Column, in its immediate vicinity and up to 0.8 m downstream. The negative pressure will determine an unbalanced lift force which might explain the incipient vibrations reported by the wind tunnel experiments (Yamada et al, 2005, Dragomirescu et al, 2009).

The angle of attack of 45°, when the corners of the aligned pyramidal modules are facing the incoming flow acting as a wind breaker, would ensure a smoother flow detachment, hence the vertical vortices behind the Column will register a weaker suction on the rear side which would confer a higher aerodynamic stability for the entire Column. Also was noticed that the vertical fluid motion was cancelled for trough regions along the modules, indicated by the opposite sense of the curl vectors. However, for completely understanding the lack of galloping for the “Endless Column” and the effect of its particular shape composed of a repetition of pyramidal modules, numerical CFD simulations should be conducted for a broader range of wind speeds, of up to 15 m/s, where the experiments were stopped due to limitations of the instrumentation.

Study on turbulence effects on flow patterns around rectangular cylinders

Panpipat Sangchuwong [a], Hitoshi Yamada [b], Hiroshi Katsuchi [c]

[a,b,c]*Dept. of Civil Engineering, Yokohama National University, 79-5 Tokiwadai, Hodogaya-ku, Yokohama, Kanagawa, JAPAN*

ABSTRACT: Wind tunnel experiments were performed to study the flow pattern around bluff bodies. Flows around square and rectangular cylinders with various slenderness ratios were studied. Flows with turbulence intensity ranging between 5.66% to 11.43% were generated by installing a grid in the wind tunnel. The study concentrated on the effect of turbulence properties on the flow structures around bluff bodies.

KEYWORDS: small-scale turbulence, turbulence partial simulation, reduced turbulence intensity, bluff-body, rectangular cylinder, wind tunnel.

1 INTRODUCTION

Flow patterns around bluff bodies have long been interesting topics among researchers but the relationships between flow patterns and flow parameters such as turbulence intensity are still vague.

Nakamura and Ohya [1] showed that flow structures strongly depend on small-scale turbulence in the incoming flow. It increases negative base pressures of a long rectangular cylinder (a rectangular cylinder which has slenderness ratio more than 0.6). Nakamura and Ozono [2] stated in their research that if the turbulence scale has more magnitude than twice the frontal dimension (or depth of a cylinder; D), the effect of the turbulence scale will approach to that of smooth flow. Then, large turbulence scale will have no significant effect on the mean pressures on the side surfaces.

However, Cherry et al.[3] and Kiya and Sasaki [4] argued that explaining by using only the magnitude of mean pressures is inadequate to describe the behavior of complicated natural flow fields. Haan et al. [5] defined that turbulence intensity or turbulence scale alone cannot fully explain changes of aerodynamic behavior of bridge decks.

Irwin et al. [6] stated that because past studies discovered that small-scale turbulence affects flow pattern and aerodynamic parameters, then it is reasonable to match the power spectrum of turbulence only at high frequencies which is the range that small-scale turbulence dominates the flow. This approach is called “turbulence partial simulation”.

Matching between the power spectrum of a wind tunnel model and that of the prototype (full-scale) can be formulated as shown in Equation 1.

$$\left(f\frac{S_u}{U^2}\right)_m = \left(f\frac{S_u}{U^2}\right)_p \tag{1}$$

where f = frequency; S_u = power spectrum of the longitudinal component of turbulence; and U = mean wind speed.

Irwin et al. also recommended that turbulence partial simulation would be more reasonable to compare wind-induced vibration of bridge decks between wind-tunnel test and full scale observation.

Katsuchi and Yamada [7] initiated to use new parameter "reduced turbulence intensity" combining turbulence intensity and turbulence scale together. Formulation of reduced turbulence intensity begins with assuming the Karman type PSD in Equation 2.

$$f\frac{S_u}{\sigma_u^2}=\frac{4\left(fL_u^x/U\right)}{\left(1+70.8\left(fL_u^x/U\right)^2\right)^{5/6}} \tag{2}$$

where σ_u = fluctuating part of wind speed; L_u^x = length scale of turbulence (or turbulence scale).

Equation 2 can be transformed to Equation 3 by determining the simulation of a high frequency part of the power spectrum.

$$f\frac{S_u}{\sigma_u^2}=\left(\frac{fL_u^x}{U}\right)^{-2/3} \tag{3}$$

Multiplying (U^2/U^2) in the left hand side of Equation 3 leads to

$$f\frac{S_u}{U^2}=I_u^2\left(\frac{fL_u^x}{U}\right)^{-2/3} \tag{4}$$

where I_u = turbulence intensity = σ_u/U

The dimension of *f/U* is inverse dimension of length, then *f/U* can be transformed to *1/D* (where *D* = representative length). Equation 4 can be rewritten in the term of *1/D*.

$$f\frac{S_u}{U^2}=\left(\frac{I_u}{\left(L_u^x/D\right)^{1/3}}\right)^2 \tag{5}$$

After that, substituting Equation 5 into Equation 1 leads to Equation 6.

$$\left(\frac{I_u}{\left(L_u^x/D\right)^{1/3}}\right)_m=\left(\frac{I_u}{\left(L_u^x/D\right)^{1/3}}\right)_p \tag{6}$$

Katsuchi and Yamada named the new parameter obtained from Equation 6 as "reduced turbulence intensity" which is equal to turbulence intensity divided by cubic root of the ratio between turbulence scale and the representative length (L_u/D, this parameter will be called length scale ratio hereafter).

$$I_r=\frac{I_u}{\left(L_u^x/D\right)^{1/3}} \tag{7}$$

It can be seen from Equation 6 that reduced turbulence intensity of the prototype is equal to that of the wind-tunnel model. Moreover, this parameter also represents the effect of small scale turbulence as explained above. Then, it is expected that using reduced turbulence intensity as a new representative will be more reasonable and give us better understanding than using only turbulence intensity or length scale ratio alone.

The aim of this study is to understand more clearly the effects of the turbulence parameters of flow fields on the flow structures around bluff bodies by focusing on the reduced turbulence intensity.

2 EXPERIMENTAL SETUP

Experiments were carried out in a closed-circuit wind tunnel located at Yokohama National University. Its working section is 1.3 m. (width) x1.8 m. (height). Three square cylinders with breadth (B) and depth (D) of 100 mm. were used in this experiment. Each cylinder had four pressure probes installed in each side, giving a total of 16 pressure probes per section in a cylinder. In order to study the effect of slenderness ratio (B/D), we adjoined 2 or 3 square cylinders to be a rectangular cylinder with a slenderness ratio of 2.0 or 3.0 respectively. The cylinder was mounted between two acrylic end plates in the center of the working section. It could also be rotated in order to study the effect of angle of attack.

Representative wind speeds in this experiment were 6 m/s and 9 m/s, giving the corresponding Reynolds number of 40,000 and 60,000 respectively.

Turbulent flow fields were generated by using a wooden grid with bar size of 60 mm. and bar spacing of 240 mm. The grid was installed at 3 different locations upstream of the cylinder. Turbulent flow properties such as turbulence intensity and turbulence scale were measured by using a hot-wire anemometer. There were four types of flow fields studied in this experiment. They were smooth flow and turbulent flow with turbulence intensity of 5.66%, 7.40%, and 11.43%.

Pressure data measured from the pressure probes were sent to an A/D converter to transform from analog signal to digital signal. After that the data were sent to a personal computer for recording.

Turbulence scales were calculated by using the peak frequency method which was suggested by Fichtl and McVehil [8]. The frequency that the power spectrum reaches to the maximum value will be brought to calculate the turbulence scale as shown in Equation 8.

$$L_u^x = \frac{1}{2\pi}\left(\frac{U}{f_{peak}}\right) \tag{8}$$

Reliability of the turbulence scale obtained from this method has been proved by comparing an experimental power spectrum with that obtained by substituting the turbulence scale into Equation 1. An example of the comparing results can be seen in Figure 1.

It can be seen from Figure 1 that calculated power spectrum matches the experimental power spectrum very well. Thus, the turbulence scales calculated from the peak frequency method are reasonable.

Turbulence parameters in this study such as turbulence intensity, turbulence scale and reduced turbulence intensity are shown in Table 1. Figure 2 shows the power spectrums of all cases corresponding to the data in Table 1.

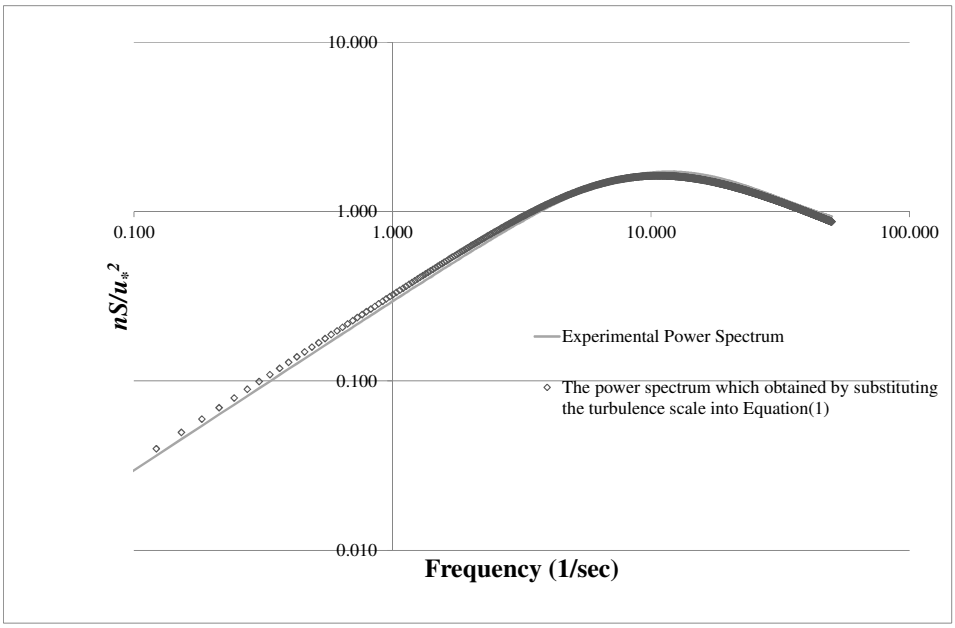

Figure 1. An example of the comparing results of power spectrum.

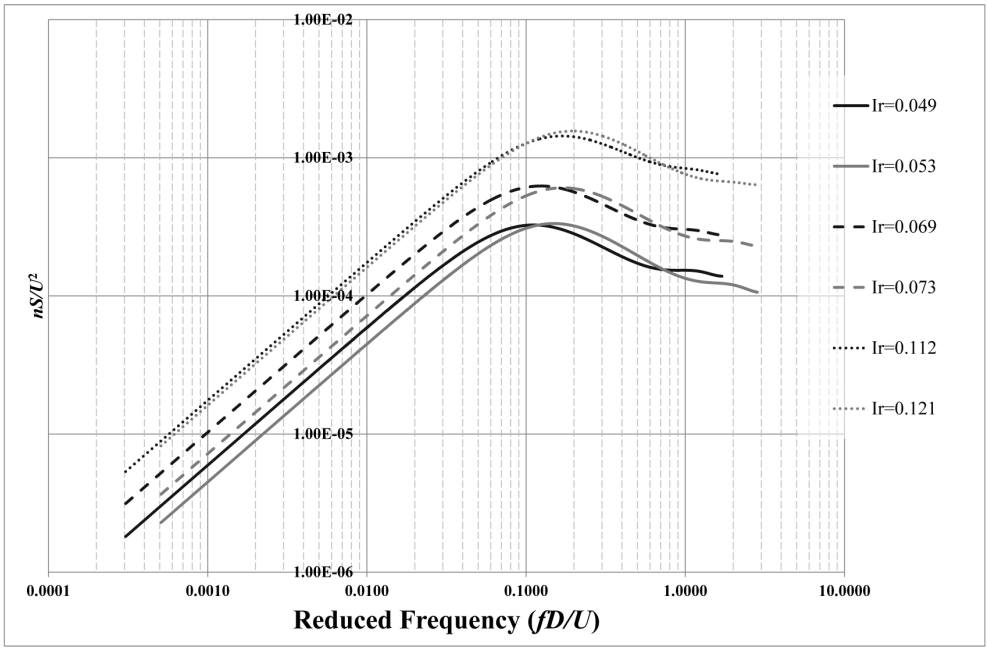

Figure 2. Power spectrums obtained from the experiment.

Table 1. Turbulence parameters.

Wind speed :U (m/s)	Reynold No.	I_u	L_u (cm)	L_u/d	$I_r = I_u/(L_u/d)^{1/3}$
6.0	40,000	0.0537	0.11	1.06	0.0526
		0.0715	0.09	0.93	0.0732
		0.1125	0.08	0.81	0.1206
9.0	60,000	0.0552	0.14	1.38	0.0496
		0.0728	0.12	1.17	0.0692
		0.1102	0.09	0.92	0.1134

3 EXPERIMENTAL RESULTS

Some results obtained from the experiment can be seen in Figure 3 which illustrates mean surface pressure coefficients (C_p) for every cases of reduced turbulence intensity around a square cylinder and a rectangular cylinder with a slenderness ratio of 2.0 and 3.0. The figure shows that increasing reduced turbulence intensity clearly makes the side surface pressures on the after-body decrease especially in a long rectangular cylinder. The peaks of the mean pressures can be also seen more obviously and shift closer to the leading edge. This means that re-attachment of the flow around bluff bodies is induced by increasing reduced turbulence intensity. Negative pressures on leeward surface were also reduced due to growth of turbulence level.

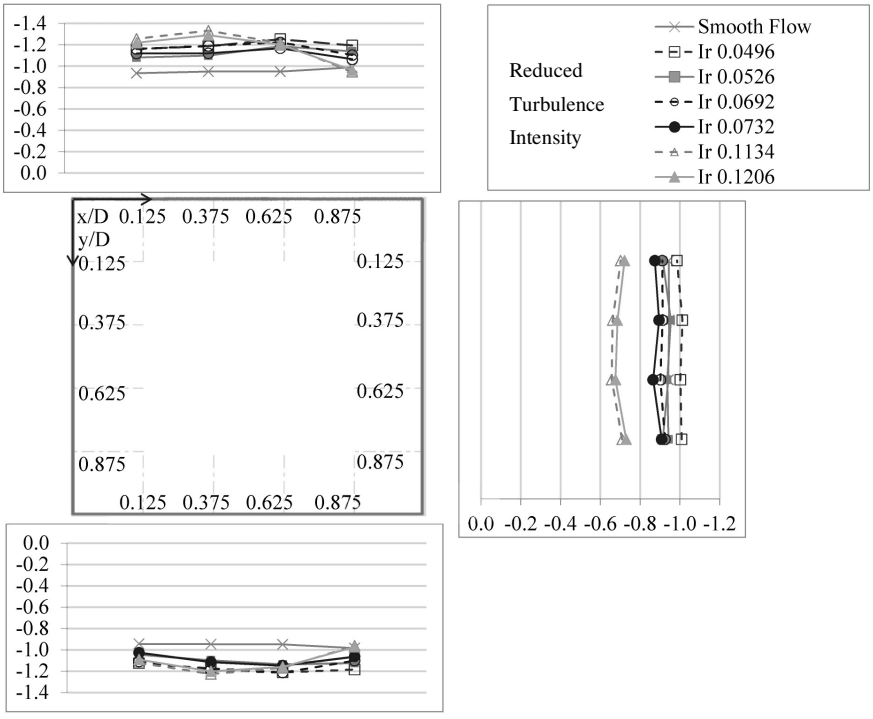

Figure 3a. Mean surface pressure coefficients (C_p) around a square cylinder

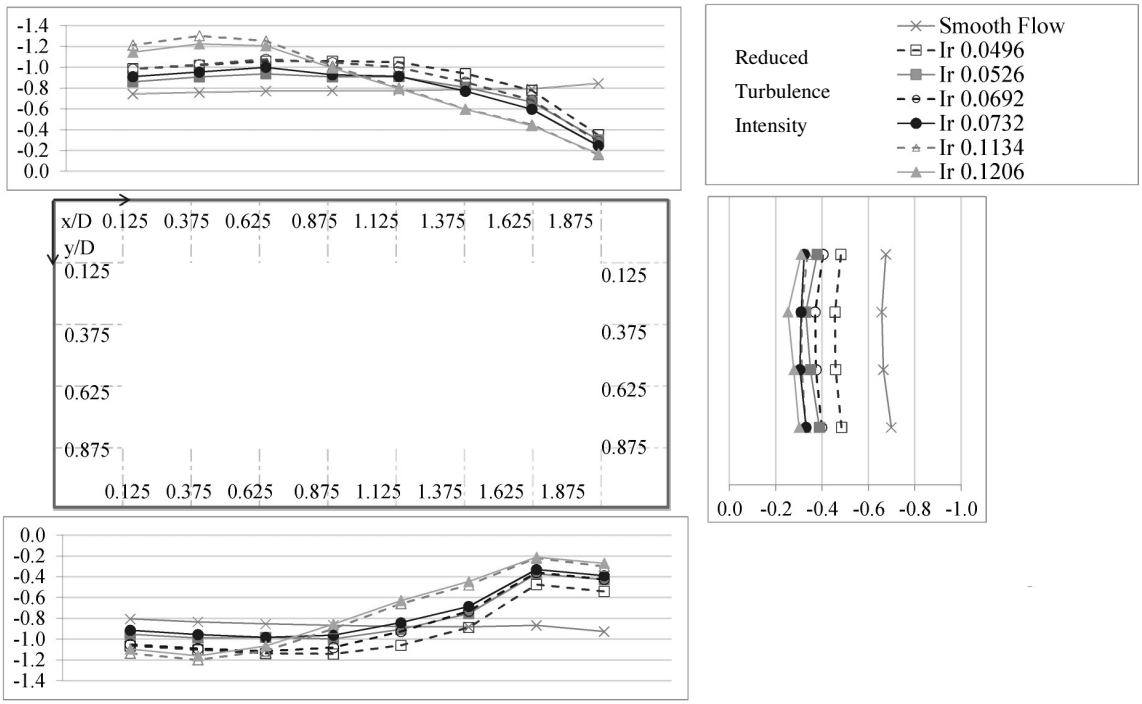

Figure 3b. Mean surface pressure coefficients (C_p) around a rectangular cylinder with a slenderness ratio (B/D) of 2.0

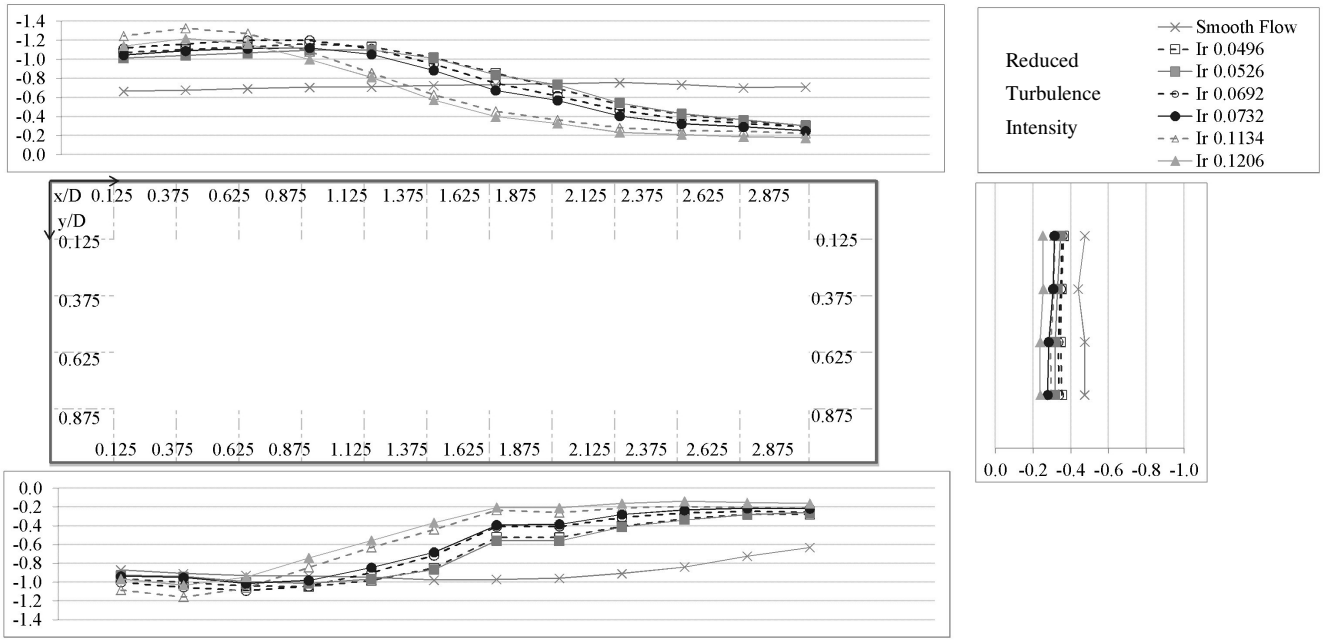

Figure 3c. Mean surface pressure coefficients (C_p) around a rectangular cylinder with a slenderness ratio (B/D) of 3.0

The capability to be a representative for turbulence level of reduced turbulence intensity will be pointed out in this section. In the case of 0.0496 and 0.0526 reduced turbulence intensity, the surface pressures of the rectangular cylinder with a slenderness ratio of 2.0 decrease obviously against increasing reduced turbulence intensity. On the contrary, the surface pressures decrease with reduction of turbulence intensity from 0.0552 (corresponding to 0.0496 of I_r) to 0.0537 (corresponding to 0.0526 of I_r). It might be because turbulence intensity in this case almost does not change (from 0.0552 to 0.0537) but turbulence scale ratio decreases from 1.38 to 1.06 , then corresponding reduced turbulence intensity calculated from the first two parameters also decreases. This means that reduced turbulence intensity might be the better representative than turbulence intensity because it can capture change of the flow while turbulence intensity cannot in this case.

Locations of the peak of mean surface pressures were identified by fitting mean surface pressure curves with sixth order parabola equations. The locations of the peak pressures of the rectangular cylinder with a slenderness ratio of 2.0 and 3.0 are shown in Table 2. It can be seen that the locations of the peak pressures on both top and bottom surface shift to the leading edge when reduced turbulence intensity increases. The locations of the peak pressures on the top surface are not identical to that of the bottom surface. It can be noticed from the locations of the peak pressures or from the pressure graphs in Figure 3 that the flows are not symmetric as they should be. The reason of this behavior is still obscure but it might be because two-dimensional flow behaviors were not fully developed due to the grid or other reasons.

Table 2. Locations of the peaks of mean surface pressures.

Locations of the peak of mean surface pressures (x/D)				
I_r	Cylinder with a slenderness ratio of 2.0		Cylinder with a slenderness ratio of 3.0	
	Top	Bottom	Top	Bottom
0.0496	0.87	0.63	0.85	0.75
0.0526	0.75	0.55	0.92	0.80
0.0692	0.71	0.58	0.72	0.66
0.0732	0.60	0.58	0.73	0.69
0.1134	0.42	0.42	0.38	0.33
0.1206	0.47	0.40	0.40	0.34

Therefore, this phenomenon leads a net mean lift force not to be zero. Table 3 summarizes the net mean lift coefficients (C_L). It can be noticed that in the case of the rectangular cylinder with a slenderness ratio of 2.0, the net mean lift coefficient decreases to be negative value (or downward direction) against increasing reduced turbulence intensity. On the other hands, the net mean lift coefficient of the rectangular cylinder with a slenderness ratio of 3.0 does not change significantly and the magnitude of the coefficient is negative in every cases. The cause of this inconsistency is still unclear but it might be because of some effects of complicated three-dimensional flow fields as stated before.

Table 3. Net mean lift coefficient (C_L).

I_r	Net mean lift coefficient (C_L)	
	Cylinder with B/D of 2.0	Cylinder with B/D of 3.0
0.0496	0.019	-0.134
0.0526	0.008	-0.121
0.0692	-0.026	-0.158
0.0732	-0.035	-0.144
0.1134	-0.101	-0.146
0.1206	-0.107	-0.153

4 CONCLUSION

The results from this experiment emphasized that increasing turbulence level will enhance the re-attachment of the flow on sharp-edged bluff bodies. Therefore, there will be pressure recovery occurring on the after-body. The size of recirculation bubbles become smaller and shift closer to the leading edge due to the effect of turbulence. Reduced turbulence intensity can be efficiently used as a representative for turbulence level of the flow. The results also showed that the flow was not symmetric as it should be. Therefore, a net lift force was not zero due to asymmetric flow. The reason of asymmetric flow is still unclear but it was predicted that might be because three-dimensional flow effects.

Flow visualization around bluff bodies will be studied in the future for observation of the mechanisms of the flow fields around these bodies. The authors believe that studying flow visualization could make effects and mechanisms of turbulence on flow structures more understandable.

Numerical simulation and visualization of flow around rectangular bluff bodies

Xuyong Ying[a], Fuyou Xu[b], Zhe Zhang[c]

Faculty of Infrastructure Engineering, Dalian University of Technology, China
[a]yingxuyong@hotmail.com, [b]fuyouxu@hotmail.com, [c]zhangzhe@dlut.edu.cn

ABSTRACT: A comprehensive study of unsteady flow around rectangular cylinders at Reynolds number of 21400 is presented in this paper. The influence of different simulation parameters, such as grid quality, turbulence model etc., are investigated in detail. Unsteady computations are performed using 2D Reynolds averaged Navier-Stokes (RANS) models and 3D large eddy simulation (LES). Time-averaged global quantities such as the mean drag coefficient, the *rms* value of lift coefficient, the Strouhal number, the recirculation length, and the surface pressure coefficient are calculated and compared with the available wind tunnel test results proposed in the literature. A series of instantaneous and time- and spanwise-average velocity, streamlines and vorticity magnitude iso-surface are also presented.

KEYWORDS: Unsteady flow; Square cylinder; Rectangular cylinder; Computational Fluid Dynamics (CFD); Large eddy simulation; Reynolds averaged Navier-Stokes;

1. INTRODUCTION

As modern long-span bridges and buildings become more flexible, the dynamic response under unsteady wind load has a greater impact on the design of these structures. Accurate prediction of wind effects on these structures is becoming increasing significant. In this respect, aerodynamic characteristics of rectangular cylinders, because of their common use in bridge and building industry, have received particular interest from both practical and academic standpoints. Bodies with a rectangular cross-section are termed as bluff bodies, in which the shear layer separated from windward corner, reattachment characteristics of the flow and vortices shedding into the wake are dependent on the cylinder's aspect ratio (width to height, *B/D*). Thus, it is important to study their aerodynamic characteristics and flow structures in details.

Okajima [1] and Tamura et al. [2] conducted detailed experimental studies to understand the aerodynamic characteristics of square cylinder and rectangular cylinders with different aspect ratios. As a consequence of the rapid growth of computation power and improvement of Computational Fluid Dynamics (CFD) technology, the numerical approach based on CFD provides a new approach for investigating aerodynamic characteristics of structures. The main purpose of the current study is to investigate to which extent a numerical simulation based on CFD can be employed to reasonably predict aerodynamic characteristics and flow structures of such a bluff body. Since the numerical approach is relatively affordable and easy to use, it is especially interesting for industrial and civil applications. Iaccarino et al. [3] examined the accuracy of RANS turbulence model in predicting complex flow with separation. The unsteady flow around square cylinder and over a wall-mounted cube were simulated and compared with experimental data. Their study demonstrated that the unsteady RANS does indeed predict periodic shedding, and leading to good concurrence with available experimental data. Shimada

and Ishihara [4] numerically predicted flow features around rectangular cylinders with various aspect ratio ranging from B/D=0.6 to 8.0 by a two-layer modified $k-\varepsilon$ model. Recently, Sohankar [5] successfully reproduced the turbulent statistics of flow around rectangular cylinders with B/D=0.4~4.0 as well as the aerodynamic forces by employing unsteady and 3D large eddy simulation (LES).

In present paper, we identify a reliable CFD approach for evaluation of bluff-body flows through the simulation of flow around a square cylinder. The influence of different simulation parameters, such as grid quality, turbulence model etc., is analyzed. The numerical results are compared with the available wind tunnel test results proposed in the literature. In all the computations presented in this paper the body geometry is kept fixed and the Mach number is very low, so that compressibility effects are negligible. Furthermore, unsteady flows with zero incidence attack angle over rectangular cylinders with B/D=2.0~10.0 are numerically simulated. Also, the flow field around rectangular cylinders are analyzed in 2D and 3D space.

2. NUMERICAL METHODS

A commercial computational fluid dynamics (CFD) code, ANSYS FLUENT, was used to perform present numerical simulations. The turbulent models used in this study are the standard $k-\varepsilon$ model, RNG $k-\varepsilon$ model, realizable $k-\varepsilon$ model, standard $k-w$ model, SST $k-w$ model, RSM model, and LES model. The more detailed descriptions for all turbulent models may be found in ANSYS FLUENT Theory's Guide [6].

The ANSYS FLUENT uses the finite-volume method (FVM) to solve the governing equations for a fluid. The second order implicit scheme is used for time discretization and the second order upwind scheme is used for spatial discretization. SIMPLE (semi-implicit pressure linked equations) algorithm is employed for solving the discretized equations.

In order to obtain reliable and accurate results, it is important to choose carefully the length and width of the computational domain and boundary conditions. The computational domain and boundary conditions used in the present study are given in Figure 1. The dimensions of x_1, x_2, x_3, y_1, and y_2 adopted in the present work are summarized in Table 1. As can be seen in Table 1, for rectangular cylinders, the computational domain covers $50D$~$105D$ in streamwise direction and $30D$ in normal direction, which is larger than that adopted by Sohankar [5] or Sun et al. [7]. The reason for such a choice is to estimate the flow obstacle effect on the inflow and outflow boundary condition, as discussed by Murakami [8].

Considering the mesh number must be as low as possible as we could accept for efficient computation, the hybrid grids are used in the whole computational domain. The traditional finite difference method uses a structured grid, which requires a body-fitted grid transformation from physical domain to computational domain. The mesh near and aligned with the wall surfaces must be refined and stretched with the viscous boundary layer grid. The finite volume method is adopted in the present study, which makes the mesh generation flexible since it has the capacity of deal with both structured grid and unstructured grid. Figure 2 shows the grid arrangement for the rectangular cylinders. The primary characteristic of this mesh style is that the section model is nested in a rectangular area about three times larger than itself. For zone in the nesting rectangular area, the structured quadrangular grid is generated while for zones outside the nesting rectangular area, the unstructured triangular grid is applied. The height of the first layer Δy near the surface of rectangular cylinders is chosen to be $0.005D$. This treatment makes it easier to generate a mesh fine enough in the vicinity of the cylinder surface while keeping the mesh in zones far away from the cylinder surface unchanged or in a proper coarser state. Details of

various mesh system can be seen in Table 1. As LES simulation requires three-dimensional domain, we select the spanwise dimension to be 4D which is a typical spanwise length widely chosen in the other 3D simulations. The 3D grid is obtained by the structured projection of the 2D hybrid grid along the spanwise direction z. As the mean flow is two-dimensional, the spanwise grid spacing, normally taken to be uniform, is usually larger than the grid spacing in the other directions [9]. For LES simulation, we select the number of grid points N_z from 5 to 40 for discretising the spanwise length, as can be seen in Table 2.

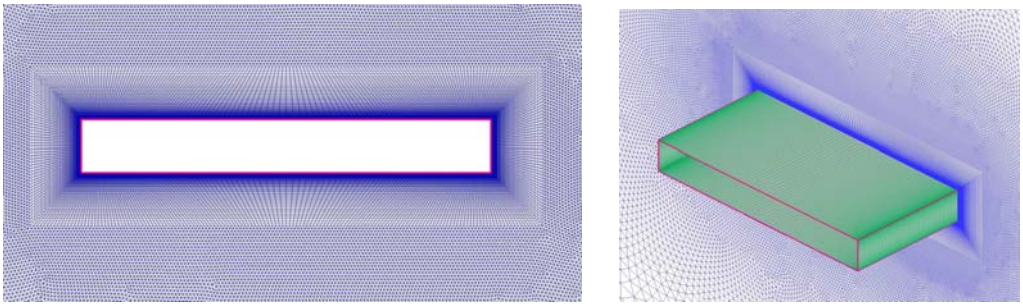

Figure 2. Grid near the surface of B/D=8 rectangular cylinder (Case 4).

The flow calculations are advanced by using a short time step (dt) to get the time dependent flow characteristics. In the present study, the time step is taken to be 0.001s. The use of smaller values of time-step did not produce any significant change in the root mean square (*rms*) and average value of the drag and lift coefficients. The time-averaged quantities for all cases have been obtained by integrating the instantaneous field over a long period of not less than 40 shedding cycles, but without including the initial transients. It is found that this period is sufficient to get a converged time-averaged flow field.

3. INFLUENCE OF MODELING PARAMETERS

3.1 *Spatial discretization*

A spanwise grid-refinement study is performed for the unsteady flow around 3D square cylinder at Reynolds number of 21400 in this section. The LES with standard Smagorinsky sub-grid model is employed. Table 3 and Figure 3 summarize typical flow parameters from the present simulation include the mean drag coefficient (C_d), the rms value of lift coefficient (*rms* C_l), the Strouhal number ($S_t=fD/U$) of the vortex shedding, and the recirculation length (l_R/D). All flow parameters are referred to the body width D. Spectral analysis was performed on the lift coefficient time history, to obtain the Strouhal number (S_t). The recirculation length (l_R/D) is the distance over which the time-averaged streamwise velocity on the rear side of the cylinder is negative. Comparisons are made with the experimental data and other numerical results in the literatures.

Table 3. Result Comparison of flow past square cylinder

Authors	Method	C_d	*rms* C_l	S_t	l_R/D

As can be seen in Table 3 and Figure 3, C_d is overestimated, while *rms* C_l, S_t and l_R/D are underestimated with the coarse grid. Passing to the fine grid, the accuracy of the calculated results is enhanced and a non-negligible jump is observed in C_d, *rms* C_l, S_t and l_R/D. In contrast, the results change very little passing from the fine to the finest grid. It seems possible to affirm that a reasonable convergence is reached with the fine grid, which is adopted hereafter for all the computations.

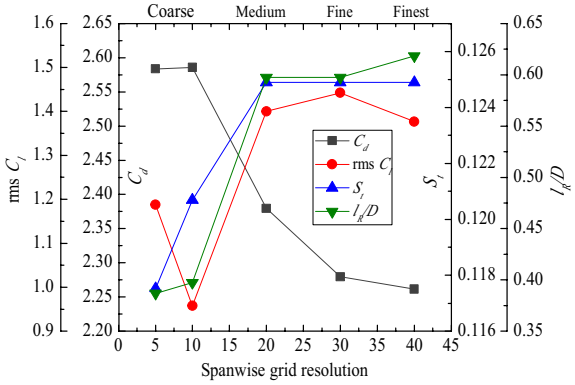

Figure 3. Grid-convergence study results

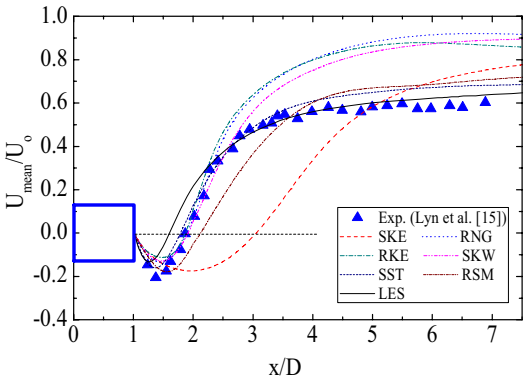

Figure 4. Averaged streamwise velocity along the centerline

3.2 *Turbulence modelling*

The influence of the turbulence model on the results is investigated in this section, and the simulated flow parameters by various turbulence models are also summarized in Table 3. From Table 3, we find that C_d and *rms* C_l predicted by all 2D RANS and 3D LES turbulence models agree well with the experiments and also with the other numerical results. Comparatively speaking, the standard $k-\varepsilon$ model underestimate C_d and *rms* C_l considerably. Most RANS calculations and LES with fine grid yield the correct value of S_t=0.125-0.140, and it appears that St is not very sensitive to the choices of turbulence model. The recirculation length varies most widely with different choices of turbulence model. The experiment and most numerical simulations yield the value of l_R/D≈0.56-0.96. The RSM model overestimates the value of l_R/D slightly while the standard $k-\varepsilon$ model gives the incorrect quantity of l_R/D. These similar results was also found in the calculations of Rodi [10] and Lee [11] in simulating the flow around the square cylinder. It indicates that the standard $k-\varepsilon$ model is not capable of simulating complex unsteady turbulent flow around a bluff body.

The distributions of the time-averaged streamwise velocity U_{mean} along the centerline are displayed in Figure 4. There the results reflect the recirculation length l_R/D behavior discussed already. The standard $k-\varepsilon$ model overpredicts the length of the recirculation zone considerably; introducing the RNG and Realizable modifications improves the calculations. The approach to the free-stream velocity is however faster than the measurement by Lyn et al. [15]. Turning to the $k-\omega$ calculations, it can be seen from Figure 4 that the standard $k-\omega$ model show an unrealistically distributions of U_{mean} along the centerline while the SST model show better behavior. In the near-wake region, the SST calculations show very good agreement with experiments. The SST results are even superior to those obtained by much more complex RSM model which overestimates slightly the recirculation region. Although the LES model underestimates the recirculation region, it approach the exact free-stream velocity compared with Lyn's measurement.

The distribution of the *rms* value of velocity along the centerline, shown in Figure 5, is determined to be too low if the standard $k-\varepsilon$ model is used. This is due to the overproduction of turbulent kinetic energy in front of the cylinder, resulting in a too strong damping of the periodic shedding motion in the wake of cylinder. It should mentioned that there are considerable differences to the calculations of Rodi [10], who with the same model, obtain a much higher lever of fluctuations. This indicates that the results are sensitive to the details of the simulation parameters. The peak values of fluctuations due to the revised $k-\varepsilon$ models, RNG and Realizable, show slight closing to the experiments. The standard $k-\omega$ model underpredicts the

rms streamwise velocity, while the SST and RSM models overpredicts this quantity. The LES computation gives approximately the correct level and distribution of *rms* streamwise velocity. Turning to the *rms* lateral velocity, the standard $k-\omega$ and RSM models also give an unrealistic level and distribution of this quantity, while the SST and LES models improve the calculations. Due to the underestimation of recirculation region, the LES model yields the pick value of *rms* lateral velocity a little to the left.

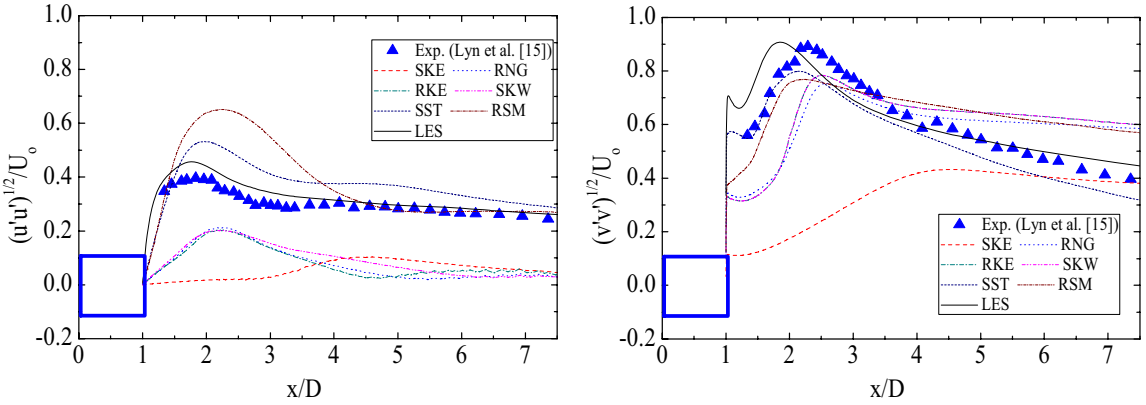

Figure 5. *rms* streamwise velocity and *rms* lateral velocity along the centerline

4. EFFECT OF ASPECT RATIO

The turbulent flow around rectangular cylinders with different aspect ratios ranging from *B/D*=2.0 to *B/D*=10.0 are simulated using SST $k-w$ and LES model in this section. A Reynolds number of 21400 is again performed. Mean drag coefficients, Strouhal number, and *rms* value of lift coefficients of present work are compared in Figure 7 with the wind tunnel experimental results and results of other 3D LES simulations.

In general, the present SST and LES results are almost consistent with both the experimental results and other numerical analysis. The mean drag coefficients and the fluctuating lift coefficients decrease monotonically with increasing aspect ratio. According to the experiments conducted by Okajima (1983), the Strouhal number has a minimum value around *B/D*=2.0, and a maximum around *B/D*=3.0. This fact is well reproduced in the present simulation. Figure 8 shows the streamlines of sections with typical aspect ratios of 2.0, 3.0, 5.0 and 8.0 predicted by SST model. As can be seen in Figure 8, the recirculation vortices are generated near the upper and lower face of the *B/D*=2.0 rectangular cylinder, and the flow separated at the leading edge is not reattached to the wall. In addition, the location of the generated of the vortex behind the cross-section is far away from the surface, and result in the relatively small of Strouhal number. For *B/D*=3.0 and *B/D*=5.0 rectangular cylinder, the flow separation at the leading edge is developed and the separated flow cannot detach themselves fully from the surface but reattach above or below the section during a period of vortex shedding. Also, as can be observed in Figure 8(b) and Figure 8(c), the intermittently reattachment, which results in a narrowing of the wake, accompanied by the discontinuity in Strouhal number between *B/D*=2.0 and *B/D*=3.0. Another discontinuity in Strouhal number can be recognized between *B/D*=6.0 and *B/D*=8.0. From the streamlines plot in Figure 8(d), there is a steady reattachment just behind the leading edge of *B/D*=8.0 rectangular cylinder, and flow finally separates at the trailing edge. The transition of the separated flow from a periodical reattachment type to a steady reattachment type, which leads to a increase in Strouhal number, is predicted well in present calculations. As the aerodynamic behavior of rectangular cylinders with different aspect ratios is characterized by

the absence or presence of reattachment of the shear layer, the rectangular cylinders considered in present simulation is divided into three categories: separated type (B/D=1.0 and B/D=2.0), intermittently reattached type (3.0≤B/D≤6.0), and fully reattached type (7.0≤B/D≤10.0).

(a) B/D=2.0 (b) B/D=3.0

(c) B/D=5.0 (d) B/D=8.0

Figure 8. Instantaneous velocity contours with streamlines

In Figure 9(a), 10(a) and 11(a), the mean pressure distribution on the side of rectangular cylinders with different aspect ratios is presented. The x-axis in the figure is normalized with the cylinder width. For separated-type rectangular cylinders, the mean pressure remains almost constant along the cylinder surface. The pressure on the side face of B/D=2.0 rectangular cylinder are higher (less negative) than those of a square cylinder, due to the influence of the afterbody on the separated flow. With an increase in the streamwise body width, i.e., aspect ratio, there is a concomitant pressure recovery on the side face due to the reattachment of the flow. Furthermore, the present LES and SST simulations are in good agreement with the experimental data and other LES results.

In Figure 8(b), 10(b) and 11(b), the *rms* pressure fluctuations on the side of rectangular cylinders with different aspect ratios are compared, revealing that for square cylinder and B/D=2.0 rectangular cylinder, a local minimum on the side surface does not exist, but for 3.0≤B/D≤10.0 rectangular cylinders minima are observed. This is also due to the reattachment of the flow. In general, the present simulated *rms* pressure fluctuations are in good agreement with the experimental data and other LES results. However, the present SST simulations slightly underestimate the *rms* pressure fluctuations compared to LES data and experimental results. It should be noted that the total pressure fluctuation includes periodic fluctuation component and stochastic fluctuation component of the pressure, and the stochastic fluctuation component is not

modelled explicitly in any current RANS models. Thus, its value is always underestimated compared to the exact value of its fluctuation.

The 3D flow field around various rectangular cylinders are obtained by LES simulations and the instantaneous vorticity magnitude iso-surface of square cylinder and *B/D*=8.0 rectangular

cylinder are shown in Figure 12. From a qualitative point of view, 3D flow structures clearly appear even though the flow field 2D main features. Generally speaking, the further the location from the separation point at the leading edge, the more significant the 3D features of the flow structures. The wake structure of square cylinder and *B/D*=8.0 rectangular cylinder is irregular and 3D, as clearly seen in Figure 12.

4. CONCLUSIONS

Numerical simulation results of unsteady flows with zero incidence attack angle over rectangular cylinders at Reynolds number of 21400 has been presented in this paper. Despite the simple geometry of the obstacle, the flow develop in its vicinity is very complex with multiple, unsteady flow, various kinds of vortices and strong curvature. The effectiveness of the turbulence models and numerical treatment for simulating the bluff-body flows are investigated in detail. Some partial conclusions can be made:

(1) The spanwise grid dependent results give an idea of the degree of grid refinement necessary to correctly simulate the 3D flows around bluff bodies.

(2) Seven turbulence models have been tested: the 3D LES model can provide satisfactory prediction for the unsteady flow field features of a square cylinder. 2D RANS approach is able to predict the main features of this complex flow reasonably well, while at the same time not being very CPU demanding. The SST $k-\omega$ model is found to be the best choice among RANS models and has accuracy enough to be suitable for practical problems.

(3) Based on the simulated results of the flow around rectangular cylinders with aspect ratio ranging from *B/D*=2.0 to 10.0, it is found that the mean drag coefficients and the fluctuating lift coefficients decrease with increasing aspect ratio. Between *B/D*=2.0 and 3.0, a discontinuity in Strouhal number occurs duo to intermittently reattachment of separated flow. When the aspect ratio *B/D* reaches to about 7.0, a steady reattachment behind the leading edge occurs, which leads to a increase in Strouhal number. The pressure coefficients distribution of rectangular cylinders, simulated by present 2D SST model and 3D LES model, are found to be almost consistent with both the experimental results.

ABSTRACT: The paper deals with the results obtained in measurements of vertically placed rectangular cylinders in the wind tunnel. The distributions of mean wind pressure coefficients C_p on the cylinders surfaces were analyzed. The influence of the following aspects was taken into account: 1. wind structure (described by the mean wind speed profile, the turbulence intensity profile, the power spectral density functions), 2. the angle of wind attack, 3. aspect ratio of models, 4. side ratio of the cross-sections of models. The results presented during the 13th ICWE, 2011 are developed here in this paper.

KEYWORDS: rectangular cylinder, wind tunnel, pressure coefficient, surface distribution, aspect ratio, side ratio, wind structure, angle of wind attack.

1 INTRODUCTION

Wind load acting on tall buildings of square or rectangular cross-sections was reported by many researchers who carried out model or full-scale studies as well as numerical simulations. In general investigations performed in wind tunnels considered 2D or 3D models more often of square than of rectangular cross-sections.

Wind action on 3D models were investigated by: Kareem and Cermak (1984) (square, the influence of turbulence), Kareem (1990) (rectangle with side ratio of 1:1.5, the influence of turbulence), Surry and Djakovich (1995) (square and the modified cross-section – diamond or with cut edges, the influence of boundary layer), Sitheeq et al. (1997) (square, the influence of boundary layers), Huang and Chen (2007) (square, different heights), Kim and Kanda (2010) (square and modified cross-sections – with a step changing and tapered), Butler et al. (2010) (square with different aspect ratio, the case of gust front profile which occurs before the storms), Wacker (1994) (rectangles with side ratios of 3:1, 2:1, 1.5:1, 1:1, 1:1.5, 1:2, 1:3, and different heights), Liang et al. (2002) and Liang et al. (2004) (rectangles with side ratios of 1, 2, 3, 4 and different heights), Lin et al (2005) (square and rectangles with side ratios of 0.34, 0.5, 0.63, 1.0, 1.59, 2.0, 2.98, the influence of elevation, aspect ratio and side ratio), Butler and Kareem (2007) (rectangles with side ratios of 1:1.5 (0.67) and 1.5:1 (1.5) different boundary layer), Tamura et al. (2008) (square and rectangles with side ratios of 0.34, 0.4, 0.5, 1 and different heights, the angle of wind attack), Zasso et al. (2008) (rectangle with side ratio of 1:2.56, the influence of turbulence and the angle of wind attack (±90°), Cheng and Tsai (2009) (square and rectangles with side ratios of 1:5, 1:4, 1:3, 1:2, 1:1, 2:1, 3:1, 4:1, 5:1 and aspect ratios of 3, 4, 5, 6 and 7, different boundary layers), Zhang and Gu (2009) (rectangles with side ratios of 1:1, 1:1.5, 1:2, 1:3, 1.5:1, 2:1, and 3:1, two cases of boundary layer), Bartoli and Riciardelli (2010) (rectangle with side ratio of 1:1.5, two different heights, two cases of boundary layer).

Wind load changes associated with the angle of wind attack, with the side ratio of the cross-section and with aspect ratio of the model as well as with the influence of approaching flow characteristics are examined here in this paper.

2 RESEARCH DESCRIPTION

2.1 *Models*

The experiments were carried out in the boundary layer wind tunnel of the Wind Engineering Laboratory in Cracow, Poland. The rectangular cylinders were placed vertically on the rotational table in the working section of the wind tunnel (Fig. 1c). Pressures in points located on surfaces of five models of dimensions collected in Table 1 were measured.

The influence of the slenderness ratio (aspect ratio) of the model (H/B, H = height of the model, B = longer side of cross-section) as well as the slenderness ratio (side ratio) of the cross-section (B/D, D = shorter side of the cross-section) on pressure patterns was investigated. So, three models with side ratio of 2:1 (1:2) and two models with side ratio of 1:4 (4:1) and different aspect ratios were considered.

All measurements were performed for the angle of wind attack, which was changing from 0˚ (the flow is parallel to longer side of the cross-section) to 90° with the step of 15°.

Table 1. Models used in wind tunnel tests.

Model	*H*	*B*	*D*	*H*/*B*	*B*/*D*
	[cm]	[cm]	[cm]	[-]	[-]
R1	100	40	20	2.5	2
R2	100	40	10	2.5	4
R3	100	20	10	5	2
R4	100	20	5	5	4
R5	100	10	5	10	2

2.2 *Wind conditions*

The influence of wind characteristics – wind mean speed profiles, turbulence intensity profiles and PSD functions – on the mean pressure coefficient distributions were examined. Over 40 cases of flows were analysed in details, and for further measurements six of them were selected. Information about wind field can be found in by: Bęc et al. (2011), Lipecki et al. (2011, 2012).

2.3 *Experiment set-up*

Pressure taps were installed on the circumference of each cylinder at 16 level distributed along the height as it is presented in Figure 1a, b. The top covers of models were also equipped with pressure taps in order to discover the influence of 3-D flow.

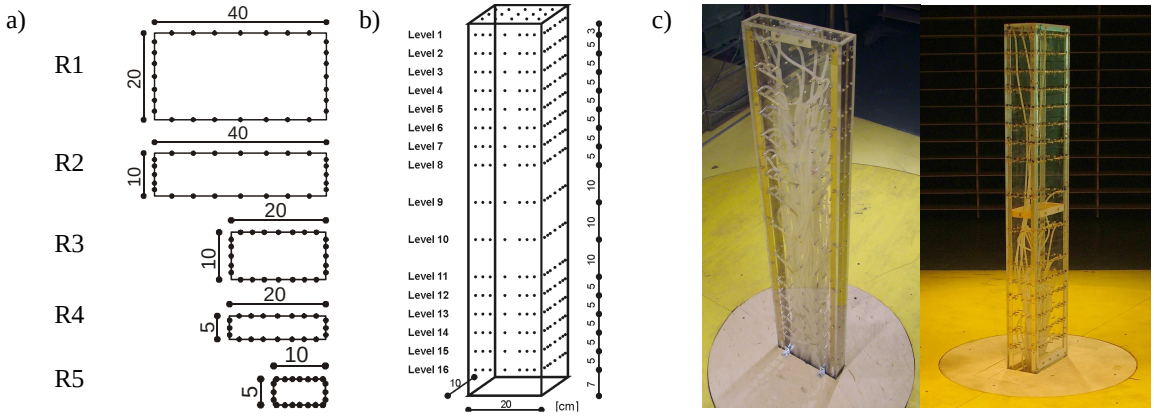

Figure 1. Models: a) pressure taps around circumference, c) pressure taps along height, c) views in the wind tunnel.

Mean pressure coefficients were calculated according to the rule:

$$C_p = p / p_0 \quad (1)$$

where: p = mean dynamic pressure measured at the given location on the cylinder surface, p_0 = reference mean dynamic pressure calculated from: $p_0 = 0.5\rho v_0^2$, where: ρ = 1.25 kg/m^3 = air density, v_o = wind velocity measured in the right front of the model in undisturbed flow at the height of h = 70 cm. Values of mean pressure coefficients were calculated from 6000 steps, with sample frequency 500 Hz which gave time of averaging t equal to 30 sec.

3 RESULTS

3.1 *Surface pressure distribution*

Chosen results concerning: spatial distributions of C_p on windward, leeward and side walls; circumferential distributions at different horizontal levels; vertical distributions of C_p in different vertical cross-sections are presented below with respect to different cases of the approaching flow and changes in the angle of wind attack.

Surface distributions of C_p for the model R2 are presented in Figures 2-6. Results concern changes of C_p in dependence on the angle of wind attack in case of profile 1 (Fig. 2) and in dependence on wind structure for angles 0° and 90° (Figs 3 and 4). The angle of wind attack equal to 0° was established at the position in which the longer side is perpendicular to the mean wind direction. In such position A is a windward wall, B and D – side walls, C – leeward wall. Figures 5-6 are focused on differences in C_p values between models in two cases of wind attack angles – 0° and 90° and for profile 1. For symmetric orientations (0° and 90°) the distributions on walls B and D (angle 0°) and on A and C (angle 90°) are similar, so, only one wall is presented. Limits of C_p values are the same in each figure according to the legend (C_{pmax} = 1.6, C_{pmin} = -1.8).

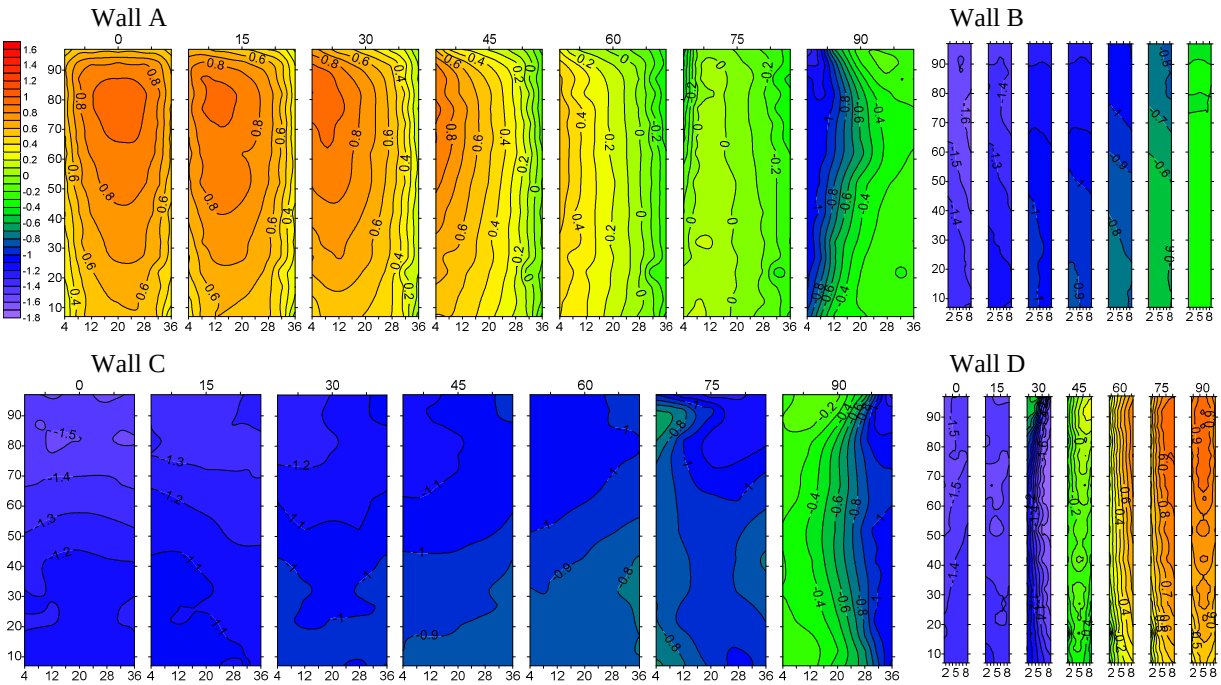

Figure 2. Pressure coefficient C_p, model R2, profile 1, the dependence on the angle of wind attack.

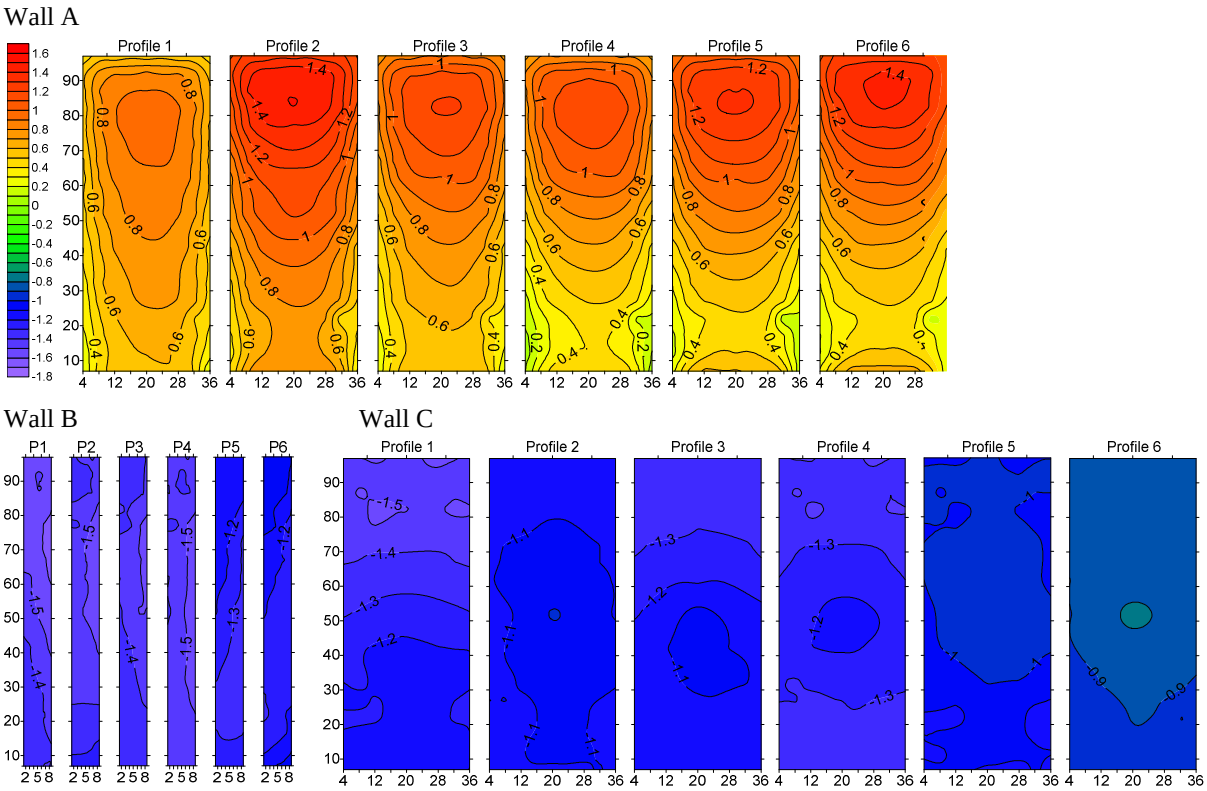

Figure 3. Pressure coefficient C_p, model R2, the angle of wind attack 0°, the dependence on wind structure.

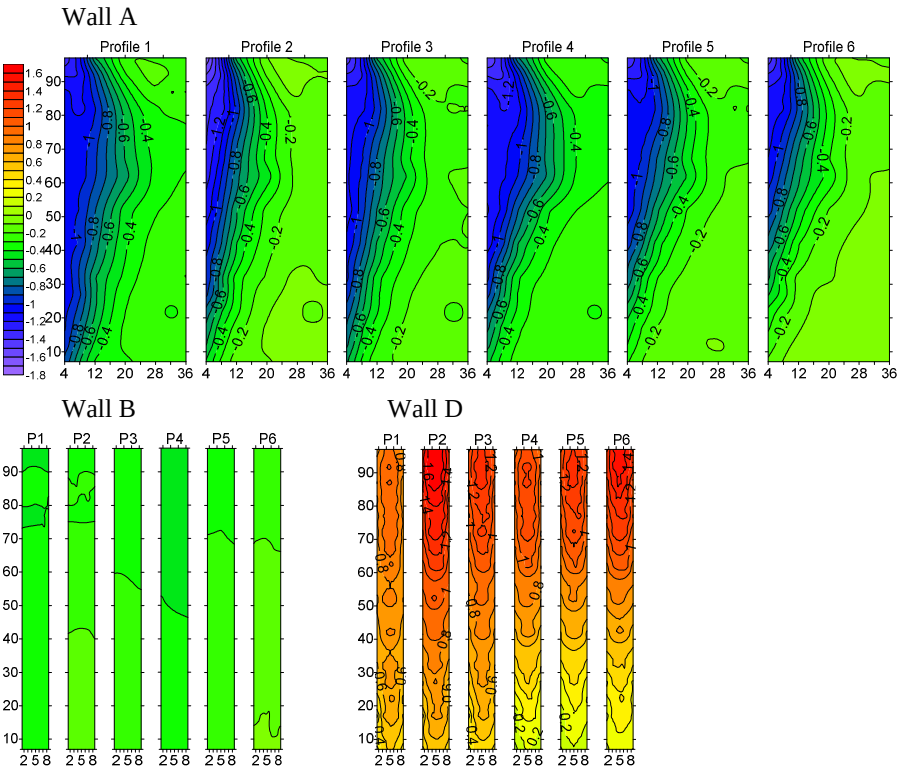

Figure 4. Pressure coefficient C_p, model R2, the angle of wind attack 90°, the dependence on wind structure.

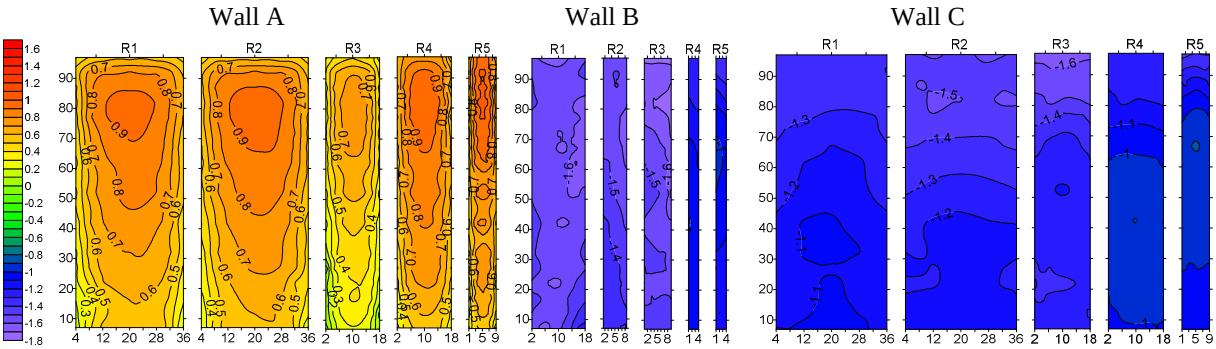

Figure 5. Pressure coefficient C_p, all models, the angle of wind attack 0°, profile 1.

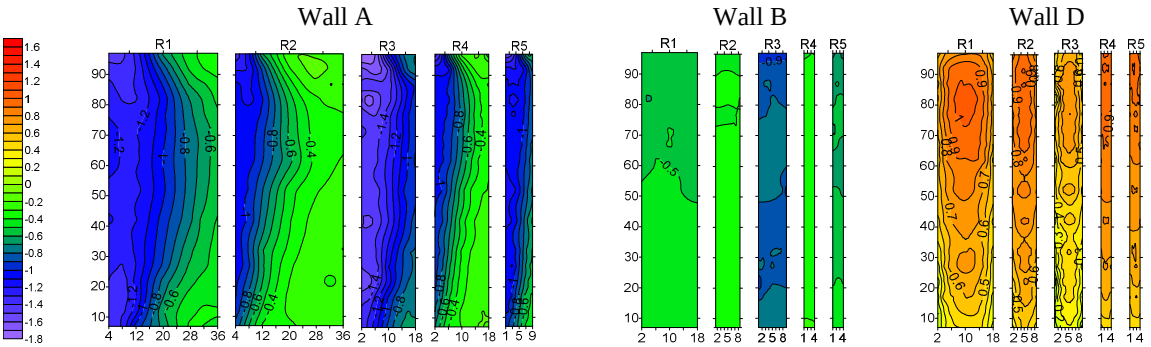

Figure 6. Pressure coefficient C_p, all models, the angle of wind attack 90°, profile 1.

3.2 *Circumferential distributions*

Difference in the value of C_p with respect to the case of the boundary layer can be better noticed at circumferential distribution plots. Three levels (2 – 12 cm, 3D effect associated with the free-end is almost reduced; 9 – 52 cm, the centre of the model; 15 – 12 cm, near the base where the influence of terrain roughness is visible) for two models R1 and R2 are presented in Figures 7-8.

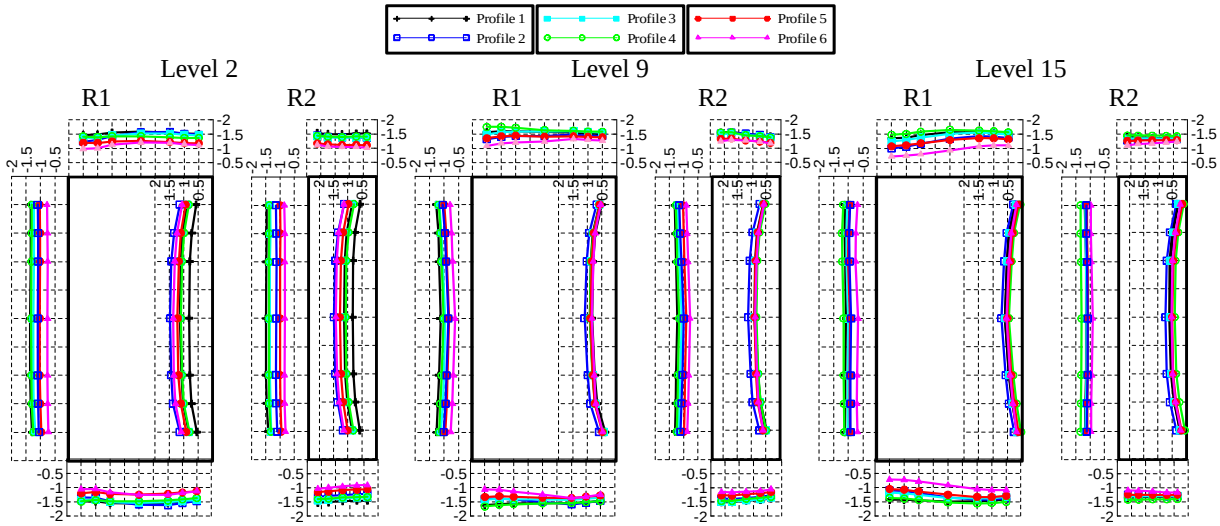

Figure 7. Circumferential distributions of C_p, models R1 and R2, the angle of wind attack 0°, levels 2, 9, 15, the dependence on wind structure.

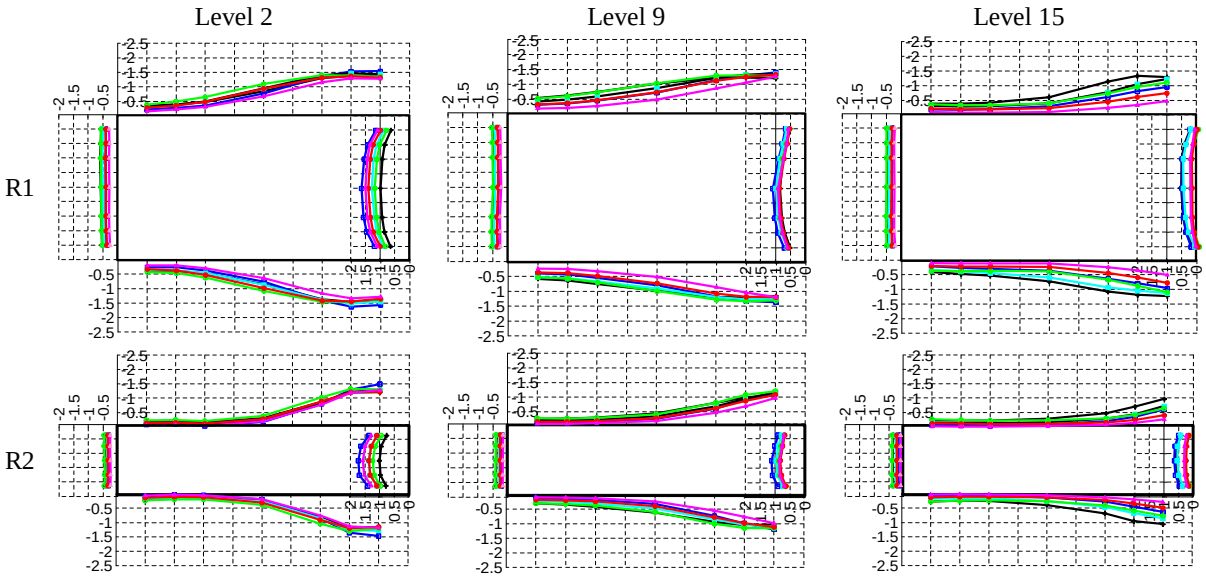

Figure 8. Circumferential distributions of C_p, models R1 and R2, the angle of wind attack 90°, levels 2, 9, 15, the dependence on wind structure.

3.3 *Vertical distributions*

Fluctuation of C_p in different cases of boundary layers along the height of the model for the angle of wind attack 0° together with an explanation of points numbers are presented in Figure 9.

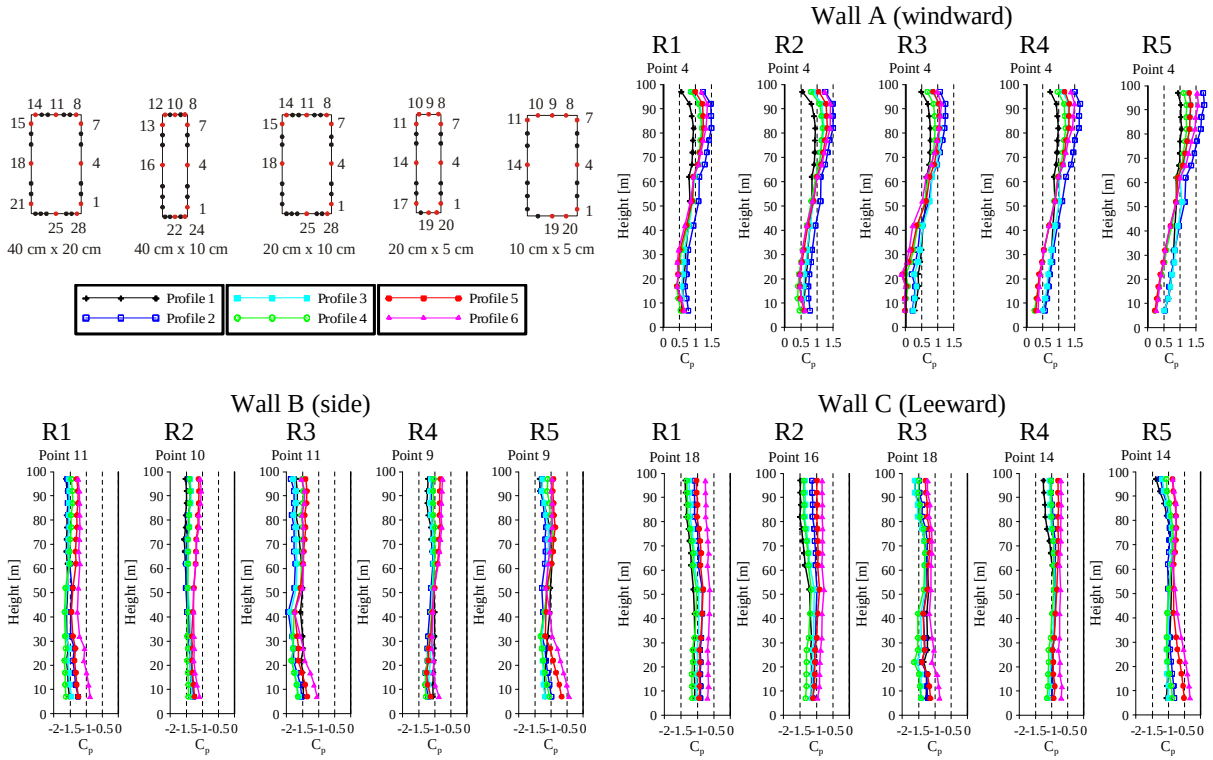

Figure 9. Vertical distributions of C_p, the angle of wind attack 0°, central points of walls, the dependence on wind structure.

4 ANALYSIS OF RESULTS

All three sets of plots illustrate changes of pressure coefficient distribution C_p along the height and around circumference of the model. For angles of wind attack equal to 0° and 90° (Figs 3-4) pressure distributions are symmetrical, pressure occurs on the windward wall, and suction occurs on the side and the leeward walls. The highest values of pressure occur in the middle of windward wall at the height of about 80 - 90% of the model independently from the wind structure. The decrease of pressure appears above this level due to the 3D character of flow around the free-end of the model. On levels lying closer to the base roughness of the terrain increases, and thus the flow turbulence and friction in the boundary layer also increase causing a decrease in wind velocity and then surface pressures. Suction may occur on the windward wall near the edges at the lowest levels. Values of C_p on the windward wall also change along the circumference and reduce close to the edges of the wall. Vortex detachment appears at the edges as a result of friction in the boundary layer and so pressure changes to suction on the side and the leeward walls. The highest values of suction on the side walls are close to the edges with the windward wall.

Analysing changes in the angle of wind attack (Fig. 2) it can be noticed that the lines connecting points of equal values of C_p for angles 15°-75° are arranged in parallel to the vertical edges of the model, with a distinct drop near the top due to 3D flow around the free-end.

Taking into account the surface changes of C_p with respect to models (Figs 5-6) it can be observed that for all cases of flow pressure distributions for all angles are similar, however, there are significant differences in the values. The exemplary percentage differences of C_p values in the case of the model R1 is collected in Table 2 (maximum pressure and suction for all rotations), Tables 3 and 4 (maximum pressure and suction, for angles of wind attack 0° and 90° on particular walls). Comparing C_p distributions by models it appears that higher values of pressure on the windward wall are for smaller models R5 and R4. Almost uniform suction occurs on the side walls and its value is lower for smaller models R5 and R4 for the angle of wind attack 0°. On the other hand, for the angle of 90°, there is the significant decrease in suction on the side walls in direction from the edge with the windward to the leeward wall, and is greater for models R1 and R2, so models with walls of the length of 40 cm. Suction is relatively uniform at particular levels on the leeward wall and increases with the height of the model.

Considering the circumferential distributions of C_p (Figs 7-8) it can be noticed that the order of C_p plots at a given level is similar for different models. The order changes with levels altitude and along side walls for longer walls. For higher cross-sections (level 1), and the angle 0° the lowest pressure is for the profile 1, then 4, 3, 5, 6 and 2. The differences are more apparent in the middle of the cross-section and are better marked for models with aspect ratio of 1:4. On the side walls significantly lower suction is for profiles 5 and 6, higher and similar is for 4, 3, 2, 1. On the leeward wall the lowest suction is for profile 6 then 5 4 3 2 and the highest for 1. Differences on the windward and the leeward walls between profiles are decreasing when the level is getting lower (level 9). At the lowest levels (level 15), these differences increase slightly again and change the sequence of graphs. On the windward wall lower pressure occurs for cases: 6, 5, 4, and higher for 3, 2, 1. At side walls the lowest suction is for 6, the other cases are similar and slightly larger. The difference between the value of C_p close to the windward edge (higher suction) and the leeward edge (lower suction) is larger. On the leeward wall the smallest suction is for profile 6, whereas the highest for 4. In case of the angle equal to 90° observations are generally similar but differences between plots are smaller than for the angle 0°, though they are still significant on the windward wall. The decrease in the suction from the windward to the leeward edge on the side walls is better marked. These differences are lower at levels close to the base. In addition, the sequence of graphs along the wall is changing. For example, the highest suction on the side wall is for the case 2 close to the windward edge, decreases along the wall and becomes one of the smallest at the leeward edge. Values of C_p are nearly constant along the wall and differ slightly between profiles on the leeward wall. The exemplary comparison of percentage changes of C_p around circumference is presented in Tables 5-6 for the model R1, at level 4.

Considering vertical distributions (Fig. 9) it can be seen that for the windward wall, for higher levels the order of C_p plots is as follows: the highest values are for case 2, then 6, 5, 3, 4, 1. The coefficient obtained for the profile 2 at the bottom levels is almost equal to coefficients for cases 3 and 1, which give the highest values. The lowest values at the bottom are for profiles 6, 5, 4. The vertical distributions clearly show the dependence of the mean wind pressure coefficient on the mean wind speed profile. Above 70 cm (reference point) the sequences of C_p plots and profiles is the same. At bottom levels, this relationship is not unique due to the strong influence of turbulence. Changes of C_p along the height of the model are insignificant in the case of profile 1, while for the other profiles, these fluctuations are relatively high. The lowest suction on the side walls occurs for cases 6 and 5 almost along the whole height. The profile 1 produces the highest values of C_p at the top and one of the lowest at the base whereas highest suction at base is for profiles 3 and 4. Quite similar sequence of plots appears at the leeward wall and differences between profiles along the height seem to be smaller. An example of percentage changes of C_p value along the height is presented in Tables 7-8 in case of the model R1, for central points of walls (Fig .9)

Connection between C_p and PSD functions of the flow is not unique. It can be found that for profile 2 the highest values of the coefficient were obtained at a height above 70 cm in each case of the model. The maximum of PSD function reaches one of the greatest values at levels above 70 cm for that profile. Similar remarks can be formulated for profile 6, for which the maximum of PSD function is even higher, but the pressure coefficient values are slightly lower. Comparison of spectra for profiles 2 and 6 shows that for low frequencies the higher values of the spectrum were obtained for profile 2, which probably results in higher values of pressure although wind speed is greater for profile 6.

5 CONCLUSIONS

Distribution of pressure coefficient is strongly affected by the wind structure characteristics. The influence of the mean wind speed profile is clear whereas the effect of PSD function and turbulence is not unique and needs to be investigated in details. It can be expected that further

considerations focused on estimation of local and global drag and lift forces will clarify that dependence.

Patterns of C_p for various angles of wind attack are similar for all cases of flows and between models.

Differences in values of C_p appear between various cases of the approaching flow as well as along the height of the model and around the circumference of the cross-section within single profile. Such differences as shown in Tables 2-8 can be significant. Moreover, the change of the sequence of C_p plots for particular flows is possible along the height and the circumference.

The aspect ratio of the models has the influence on values of C_p but the sequences of plots remains the same.

The free-end effect is distinctly marked in each case of the flow and models.

ABSTRACT: Vortex induced vibration (VIV) is caused by regular alternatively shedding vortices from structure surface; the critical wind velocity where vibration onset can be approximately calculated by Strouhal relation. While, according to quasi-steady galloping theory, the galloping occurrence is originated from aerodynamic instability of specific structure cross sections. The negative slope of lift force coefficient of cross sections is an essential condition to predict the onset velocity of galloping. For those structures, where critical wind velocity by VIV and galloping are very close, the actual structural vibration type is unknown. With the aim of knowing more about the mechanism of this new type vibration, several comparable experiments of rectangular cylinders were conducted; the main results are reported in the present paper. The different experimental cylinders varied in aspect ratios and Scruton numbers. When the predicted critical wind velocity of VIV and galloping were very close to each other, the test results indicated that the cylinders tended to undergo a very different vibration type. There was neither VIV lock-in phenomenon nor galloping divergent type vibration, but consistently increasing vibration amplitude with increased wind velocity. While, for the cases of predicted VIV and galloping critical velocities were deviated largely, the VIV lock-in and divergent type galloping were observed separately. And it is seems that the interaction of VIV and galloping brought relatively large VIV amplitude during lock-in range.

KEYWORDS: Interaction; VIV; Galloping; Amplitude; Rectangular cylinders; Onset velocity

1 INTRODUCTION

Slender structures such as the hangers of large span arch bridges, lateral beams of electricity transmission towers .etc, are inclining to wind induced vibrations. In particular, for the rectangular cross section hangers, the VIV and galloping are the two most frequently occurred vibrations. (Chapin and Bearman, 2005a; Ge, 2008).

To predict the critical wind velocity at which VIV onset in engineering practices, Strouhal relation was used as the most efficient method. The Strouhal number was determined by the structural cross section, Reynolds number, surface roughness, turbulence intensity .etc. Over the past decades' research concerning VIV, mathematical models were developed to describe the vortex excited force and predict the VIV lock-in range; well known reviews about these topics were given by Bearman (1984), Sarpkaya (2004) and Williamson and Govardhan (2004). These models can be basically classified into single Degree of Freedom (SDOF) and two DOF two types in total. Moreover, the SDOF model subdivided into force coefficient based model and negative aerodynamic damping based model. With the beforehand identified aerodynamic parameters, the prevailing Van der Pol-type nonlinear model was verified to reflect the VIV lock-in very well.

Similarly, in order to determine the galloping instability critical point, a relation derived from quasi-steady galloping theory is also available. It takes the consistently changed static force which was caused by relative motions between structure and flow as the original force for galloping instability. The negative slope of lift force coefficient of cross section is an essential requirement for the galloping occurrence, and the onset velocity is positively proportional to the Scruton number and natural frequency. The vibration is considered to divergent after the critical wind velocity threshold which calculated from quasi-steady galloping theory. Nevertheless, Ziller and Ruscheweyh (1997) suggested a new approach to determine the onset velocity of galloping instability, taking into account the nonlinearity of the aerodynamic damping characteristic. Hortmanns and Ruscheweyh (1997) even developed a method to calculate galloping amplitudes considering nonlinear aerodynamic coefficients measured with the forced oscillation method.

To the authors' knowledge, the mechanisms of VIV and galloping are very different, so that the critical wind velocities of these two kinds of vibration can be obtained separately. Therefore, for certain structures, if the critical wind velocity of VIV and galloping are very close, the vibration mechanism is hard to be predicted. More importantly, the better understanding of the mechanism is pretty helpful for the following design of vibration suppressions measures, like the design of tuned mass damper.

2 THEORETICAL ANALYSES

2.1 VIV

The nonlinear vortex induced excitation force model suggested by Scanlan and Ehsan (1990), which was characterized by Van der Pol-type oscillator, the vortex induced excitation force was expressed as follow:

$$P(t)=\frac{1}{2}\cdot\rho\cdot U^2\cdot D\cdot[Y_1(K)\cdot(1-\varepsilon\cdot\frac{v(x,t)^2}{D^2})\frac{\dot{v}(x,t)}{U} + Y_2(K)\cdot\frac{v(x,t)}{D}+\frac{1}{2}\cdot\tilde{C}_L(K)\cdot\sin(\omega\cdot t+\phi)] \tag{1}$$

Where, $v(x,t)$ = the structural displacement response; $Y_1(K)$, $Y_2(K)$, ε, $\tilde{C}_L(K)$, ϕ =the aerodynamic coefficients; ρ = the air density; U =mean wind velocity; D =cross flow dimension; ω = vortex shedding frequency.

For structures undergoing VIV by wind action, the vibration frequency was almost identical to the natural frequency, hence, the aerodynamic stiffness term was negligible (Zhu, 2005); then Eq.(1) became:

$$P(t)=\frac{1}{2}\cdot\rho\cdot U^2\cdot D\cdot[Y_1(K)\cdot(1-\varepsilon\cdot\frac{v(x,t)^2}{D^2})\frac{\dot{v}(x,t)}{U}+\frac{1}{2}\cdot\tilde{C}_L(K)\cdot\sin(\omega\cdot t+\phi)] \tag{2}$$

Moreover, during the large amplitude vibration period of lock-in range, the vortex shedding force can also be neglected compared to the motion induced one, then the final vortex induced excitation force formula was simplified as:

$$P(t)=\frac{1}{2}\cdot\rho\cdot U^2\cdot D\cdot[Y_1(K)\cdot(1-\varepsilon\cdot\frac{v(x,t)^2}{D^2})\frac{\dot{v}(x,t)}{U}] \tag{3}$$

Marra et al. (2011) had proved its accuracy to describe the VIV by the beforehand identified aerodynamic coefficients $Y_1(K)$, ε.

The critical wind velocity at which vibration starts off is set by Strouhal relation, defined as following:

$$St = \frac{f \cdot D}{U} \tag{4}$$

Where, f = natural frequency; St = Strouhal number which is associated with cross section, Reynolds number, surface roughness, turbulence intensity .etc; D = cross flow dimension; U = mean wind velocity.

2.2 Galloping

The aerodynamic force of galloping was originated from continuously changed static force, which was caused by continuously changed relative wind attack angle between structure and approaching flow. (Chen, 2005; Borri et al, 2002).Ignoring the unsteady flow around the structure, the quasi-steady galloping theory was employed. Uniform flow passed through the bluff body, the 2D flow condition was shown in Fig.1.

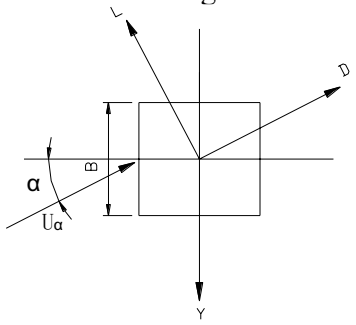

Fig.1. Plane of 2D flow condition

Under the coordinate system of wind direction, the static drag force and lift force assume following form:

$$D(\alpha) = \frac{1}{2}\rho U_\alpha^2 B C_D(\alpha) \tag{5}$$

$$L(\alpha) = \frac{1}{2}\rho U_\alpha^2 B C_L(\alpha) \tag{6}$$

Where, $C_D(\alpha)$ = drag force coefficient; $C_L(\alpha)$ = lift force coefficient; α = relative wind attack angle; B = cross flow dimension; U_α = mean wind velocity.

The combined vertical force F_y obtained:

$$
\begin{aligned}
F_y &= \frac{1}{2}\rho U_\alpha^2 B\left(-C_D(\alpha)\cdot\sin\alpha - C_L\cdot\cos\alpha\right) \\
&= \frac{1}{2}\rho U^2 B\left(-C_D(\alpha)\cdot\sin\alpha - C_L\cos\alpha\right)\cdot\frac{1}{\cos^2\alpha} \\
&= \frac{1}{2}\rho U^2 B\left(-C_D\cdot\tan\alpha - C_L\right)\cdot\sec\alpha
\end{aligned}
\tag{7}
$$

Where:

$$
\begin{aligned}
U_\alpha &= \sqrt{U^2+\dot{y}^2} \\
\alpha &= \arctan\frac{\dot{y}}{U}
\end{aligned}
\tag{8}
$$

While, $\dot{y}=\frac{dy}{dt}$ = structural vibration velocity. Spreading the Eq. (7) as Taylor's series at $\alpha=0$, then Eq. (7) became:

$$
F_y = -\frac{1}{2}\rho U^2 B\cdot[(\frac{dC_L}{d\alpha}+C_D)\cdot\alpha+\frac{1}{2}\cdot(C_L+\frac{d^2C_L}{d\alpha^2}+2\cdot\frac{dC_D}{d\alpha})\cdot\alpha^2+\triangle(\alpha^n)] \tag{9}
$$

Before the large amplitude galloping occurs, the tiny vibration velocity $\dot{y}$ is negligible compared to the approaching wind velocity U, and one can assume that:

$$
\alpha = \arctan\frac{\dot{y}}{U} \doteq \frac{\dot{y}}{U} \tag{10}
$$

The relations between $\alpha=\arctan\frac{\dot{y}}{U}$ and $\alpha=\frac{\dot{y}}{U}$ was plotted in Fig.2, from which can be clearly observed that $\alpha=\arctan\frac{\dot{y}}{U}\doteq\frac{\dot{y}}{U}$ when $\frac{\dot{y}}{U}<0.2$. Actually, at the very tiny vibration period, the high order terms of formula (9) are negligible with respect to the fundamental ones, hence, the formula can be simplified as following:

$$
\begin{aligned}
F_y &= -\frac{1}{2}\rho U^2 B\cdot(\frac{dC_L}{d\alpha}+C_D)\cdot\alpha \\
&= -\frac{1}{2}\rho U^2 B\cdot(\frac{dC_L}{d\alpha}+C_D)\cdot\frac{\dot{y}}{U}
\end{aligned}
\tag{11}
$$

The galloping instability onset velocity U_{cri} obtained by the simplified aerodynamic force of formula (11):

$$
U_{cri} = \frac{-4m\xi\omega}{\rho B\left(\frac{dC_L}{d\alpha}+C_D\right)} \tag{12}
$$

Where, m = equivalent mass; ξ = damping ratio; ω = circular natural frequency; the meaning of other symbols just as mention above.

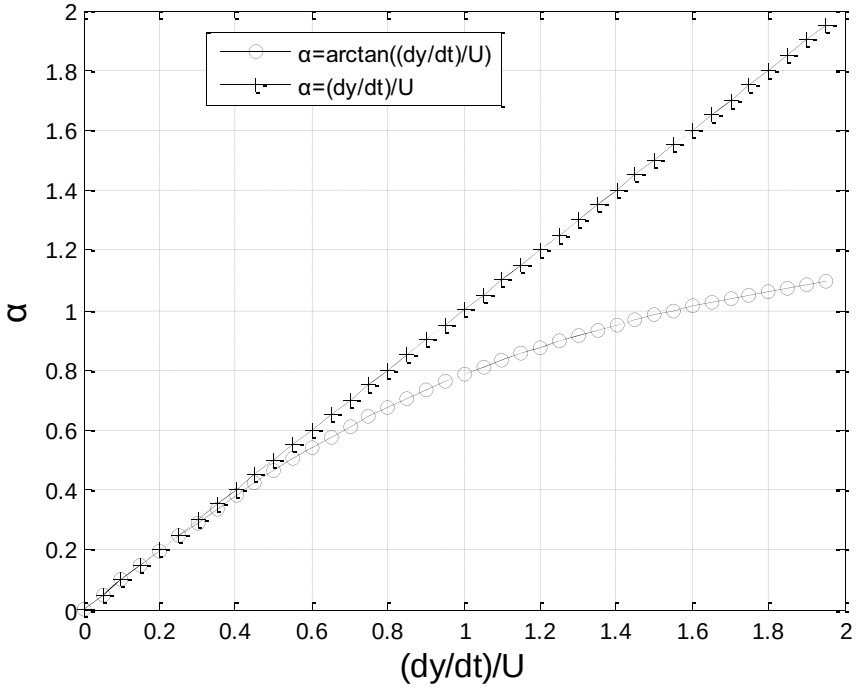

Fig.2. Comparison of $\alpha = \arctan\frac{\dot{y}}{U}$ and $\alpha = \frac{\dot{y}}{U}$

The quasi-steady galloping theory can interpret the galloping onset threshold very clear, and it can be considered that a divergent type vibration after the critical point will appear which is due to the negative damping. However, for the vibration regime after the starting point, the theory cannot help in predicting it. Because, the high order terms of formula (9) cannot be ignored anymore, on the contrary, they played a very important role to the aerodynamic force.

3 EXPERIMENTAL DETAILS

Taking into account the practical engineering background of arch bridge hangers, four groups of rectangular cylinders were selected as section model wind tunnel tests objects. The four groups of cylinders had different cross section aspect ratios, Scruton number and natural frequencies. Static forces tests and flexibly mounted section model tests were performed for each group separately. The section model wind tunnel tests installation set up are shown in Fig.3. Regarding the flexibly mounted section model tests, as shown in the second column of Fig.3, were the flexibly mounted rigid section models. Eight springs supported the model as stiffness system; the physical mass of section model, participating mass of springs and the supporting system mass formed the total mass system. Four force transducers were equipped at the bottom of the model system, connecting the lower four springs with fixed boundary. Vibration signals of heaving, pitching, rolling mode can be easily extracted from the recorded data of the four force transducers.

With respect to the static force tests, just as shown in the third column of Fig.3, rigid section models with end plates were vertically installed in the wind tunnel, the static force measurement scale equipped at the bottom of model.

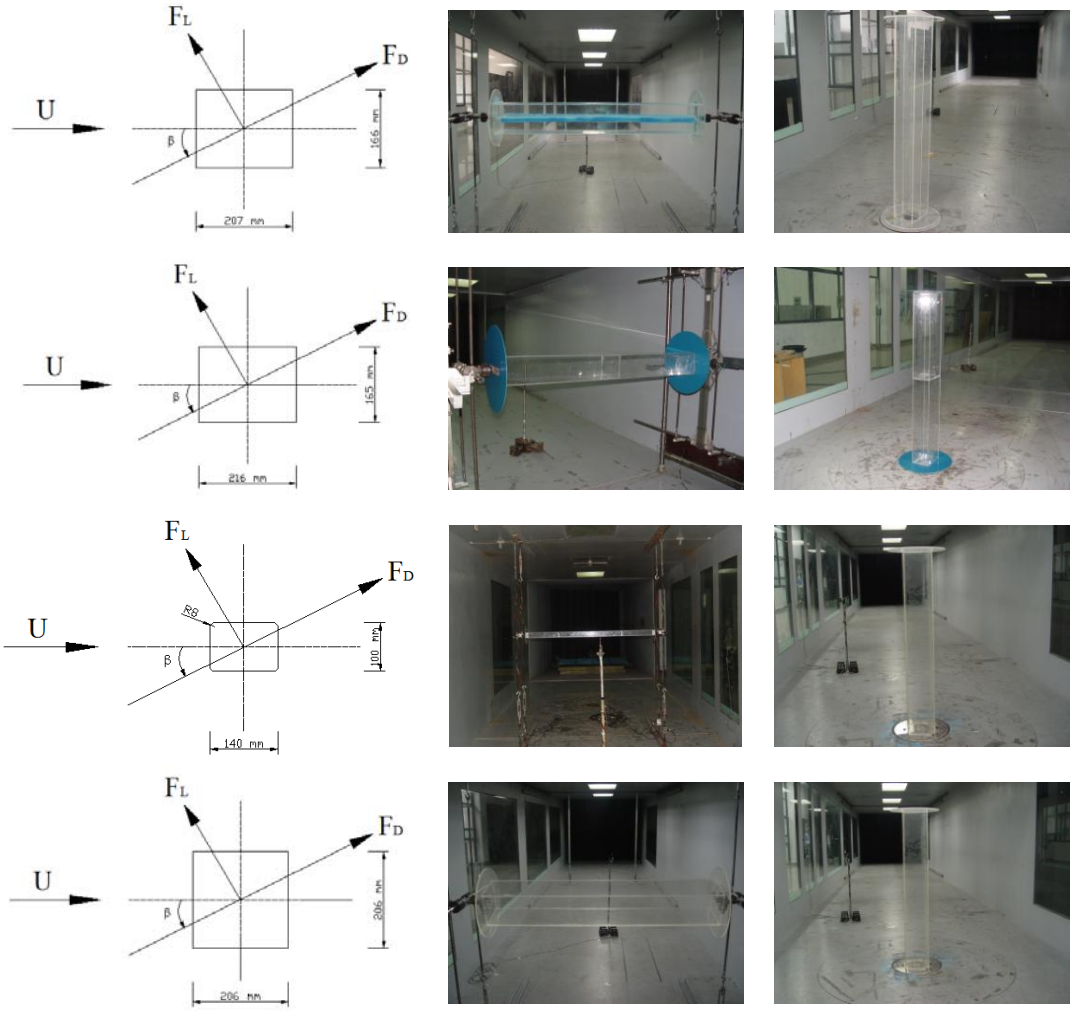

Fig.3 Overview of the four test groups. The consecutively first row to the fourth row indicates the details of Group 1to Group 4, separately. And the first column is the 2D cross section dimensions of each group; flexibly mounted section model rests setup photos are shown in the second column; while the last column is the static force tests photos.

Table.1~Table.4 shows the details of each group Damping ratio identification tests using the best decay estimation method, data analysis was conducted by the recorded decaying signals after the imposed initial displacement. The natural frequencies could also be obtained by FFT of the recorded decaying time series. Strouhal number identification tests were conducted with the same section model; the final values were determined by the Strouhal relation. The galloping instability coefficient was calculated from the static force coefficient curves according to the quasi-steady theory. It was definitely noted that the identical model is characterized by different galloping instability coefficients ($C_L'+C_D$) and Strouhal numbers (St) when the width and height of the cross section weren't identical. Finally, with the previously obtained Strouhal number and the natural frequencies of section model, the critical wind velocity of VIV can be predicted by Strouhal relation. Meanwhile, the galloping instability onset velocity can also be calculated based on quasi-steady galloping theory.

The static force coefficient and galloping instability result curves are shown in Fig.4. The wind attack angles were defined as 0° when the section model anti-wind with their short edges, therefore, the wind attack angles must be 90° when the model anti-wind with their long edges. The static force coefficient results were shown in the first column of Fig.4. And the galloping

instability coefficients were calculated exclusively through the static force coefficient curves according to the quasi-steady galloping theory.

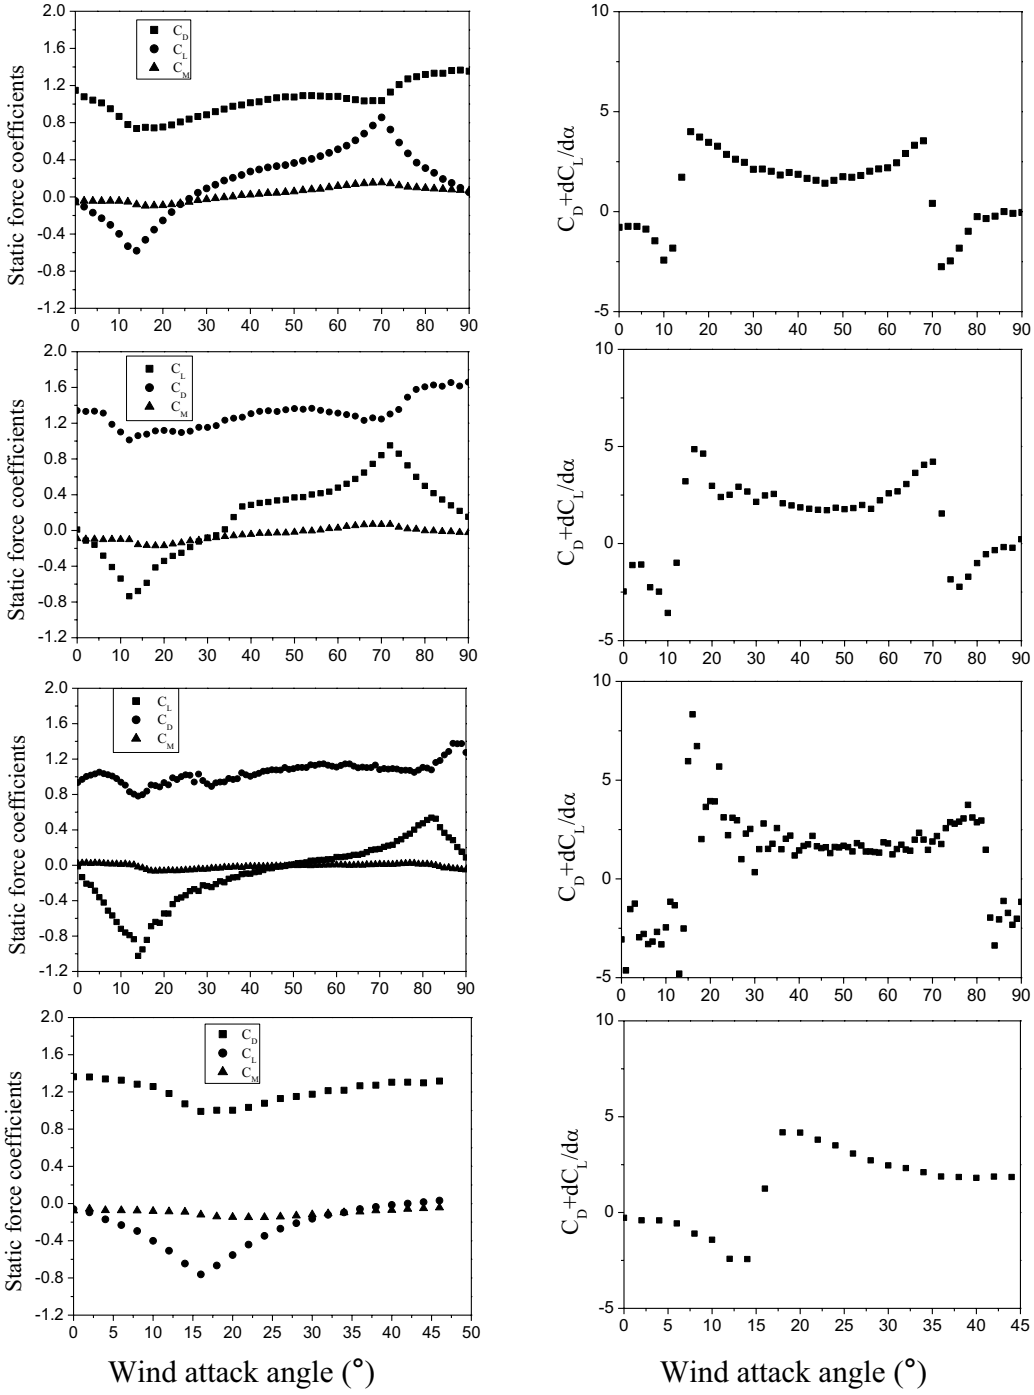

Fig.4. Static force coefficients and galloping instability coefficients curves vs. wind attack angles for the four experimental groups. The 1st to the 4th rows are representing the results of the Group 1to Group 4, separately. While, the first column are the static force coefficient curves and the second column are the galloping instability coefficient curves.

4 RESULTS AND DISCUSSIONS

In this section, the aerodynamic responses were reported by comparing the time series and vibration frequencies of heaving, pitching and rolling modes. The final response curves of each group were also shown together with the corresponding estimated critical normalized wind velocity of VIV and galloping. In particular, for each run of every case, enough time was allowed for the vibration to stabilize before collecting the test data.

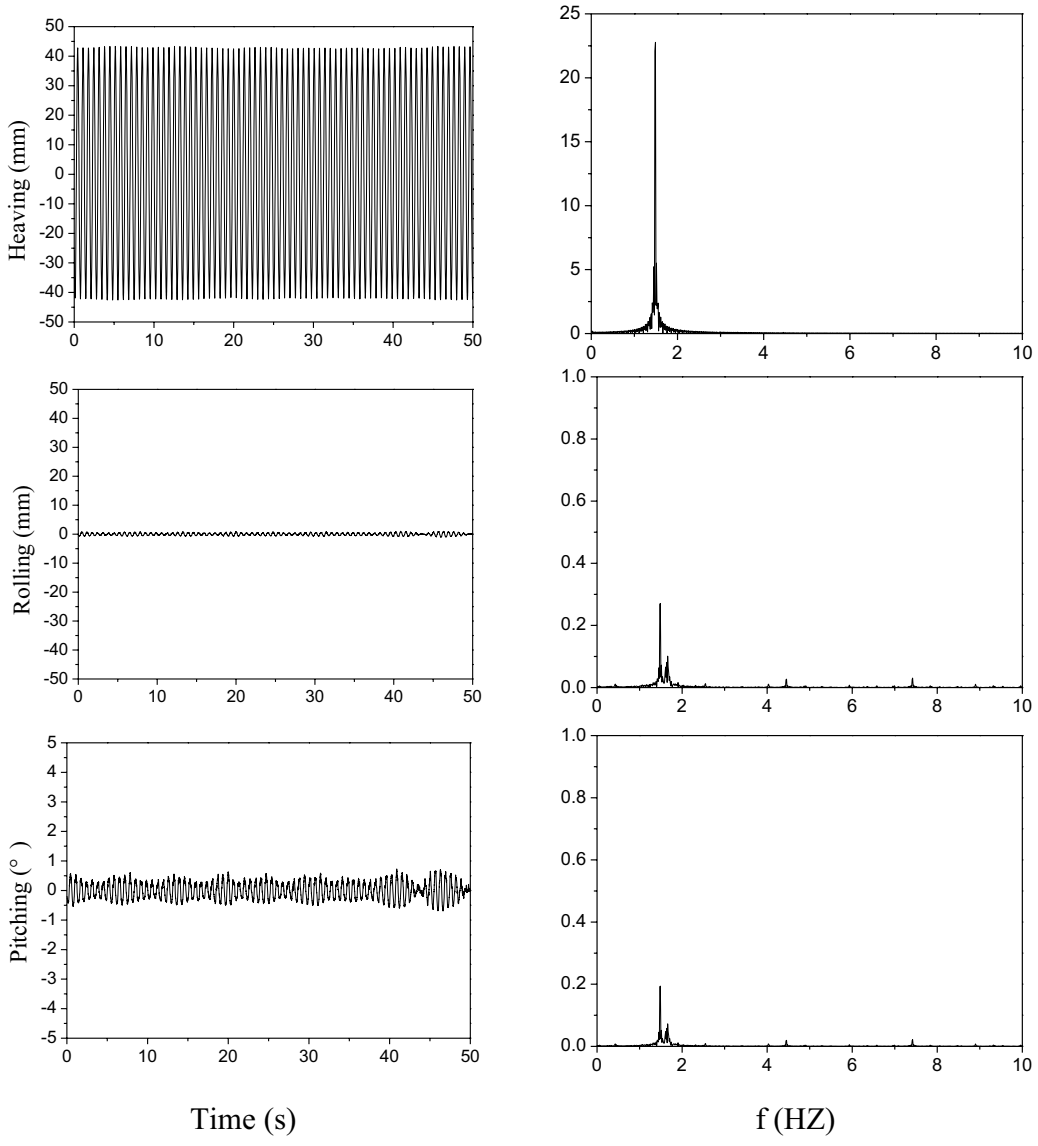

Fig.5. Tests example of Group 3: the section model anti-wind with short edge, at U/fD=23.97, which is related to the measured maximum point of galloping instability .The first row is the time series and corresponding frequency spectrum by FFT of heaving mode; the second row is for rolling mode and the third row is for pitching mode.

Let's take the group 3 as an example to illustrate the data analysis. Just as shown in Fig.5, these are vibration details of group 3 (short edge facing the flow), at the normalized wind velocity of U/fD=23.97. It can be clearly observed from the comparison of three different modes that the

pitching and rolling modes are about 10 times smaller (and therefore negligible) with respect to the heaving mode. Despite the vibration amplitude up to A/D=0.5, the heaving mode still vibrates at the identical frequency to the natural frequency f=1.51HZ and maintains the continuously steady amplitude.

While, for the cases of model anti-wind with long edge of group 3, normalized wind velocity at U/fD=8.89, the vibration details are shown in Fig.6. The peak amplitude of VIV lock-in range was selected. Very similar to Fig.5, in this case, the mode vibrates dominantly at the heaving mode and at the single natural frequency; more importantly, time series also show the steady amplitude vibration.

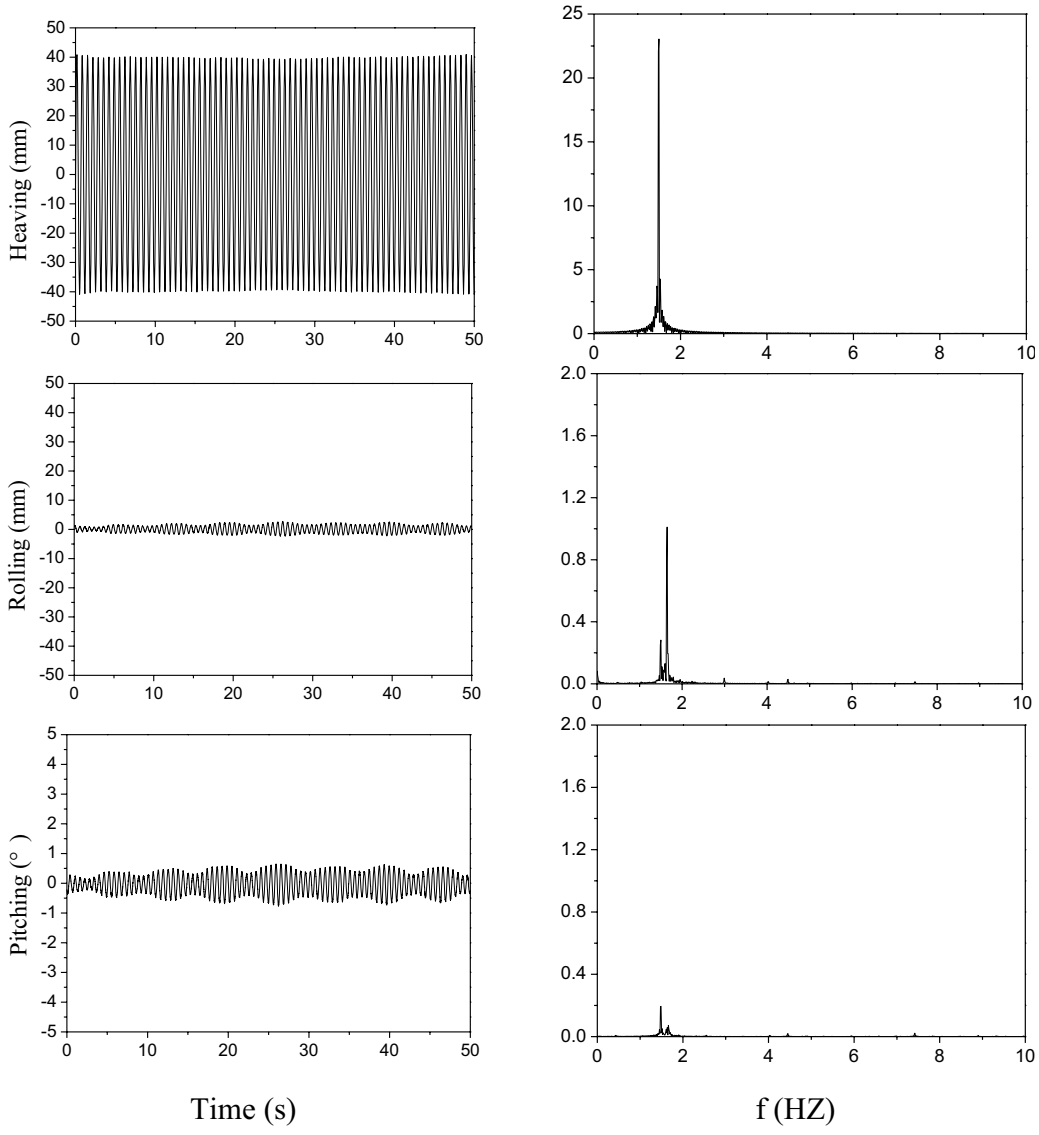

Fig.6. Tests example of Group 3: the section model anti-wind with long edge, at U/fD=8.89, which is related to the maximum point of VIV lock-in range .The first row is the time series and corresponding frequency spectrum of heaving mode; the second row is for rolling mode and the third row is for pitching mode.

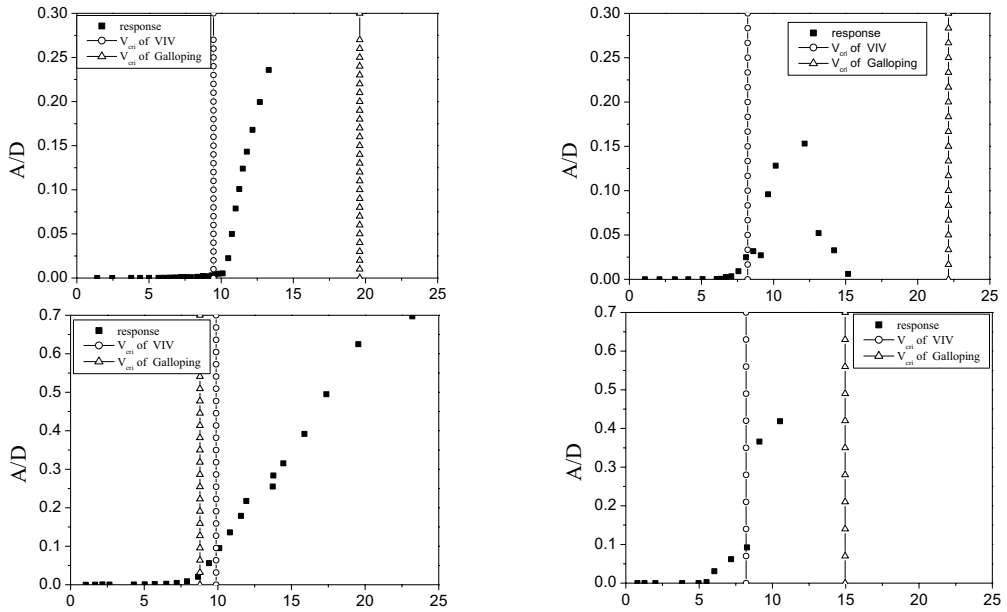
The conclusive experimental measured vibration curves of group 1~group 4 are shown in Fig.7, together with the predicted critical wind velocity of VIV and galloping. Unfortunately, the experimental data of group 1and group 4 were not enough when the vibration curves were straightly increasing with the increased wind velocity. Nevertheless, it can be clearly seen from other curves that the measured maximum normalized amplitudes are very large although the Scruton number of each model are over 10.

For the cases of group 2 and group 3, which the estimated critical wind velocity of VIV and galloping are within the range of 1.5 times, an interesting vibration phenomenon occurred. There is neither self-limited VIV lock-in nor divergent type galloping appearing, whereas the vibration amplitude consistently increases with the increasing wind velocity. It can be obviously observed that there with still no indications of trend of the response amplitude to stop increasing even the normalized amplitude A/D rising up to 0.7. Moreover, the vibration time series of each wind velocity component, especially for the large amplitude ones, were very similar to the form of Fig.5. Recorded vibration time series always maintain the astonishing steady amplitude, and vibrated at the natural frequencies. In particular, the factor of 1.5 times between predicted critical wind velocity of VIV and galloping is also recommended by the Eurocode at which the specific research should be undertaken.

However, for the cases of group 1 and group 3, the section models facing wind with their long edges, the estimated critical wind velocity of VIV and galloping were deviated significantly. The separated VIV lock-in range and divergent type galloping phenomenon were observed separately. Meanwhile, it is worth noting that the measured peak amplitudes of VIV lock-in are extraordinary large. The Scruton numbers of these two groups are 12.83, 19.83 respectively, and the experimental measured non dimensional amplitude reach 0.15, 0.29 respectively. In contrast to wind induced vibrations of circular section structures, it is very uncommon for these rectangular section models to oscillate up to such large amplitudes with the relatively large Scruton number. Therefore, one can reasonably assume that the negative aerodynamic damping of galloping instability contributes to the large amplitude VIV to some degree.



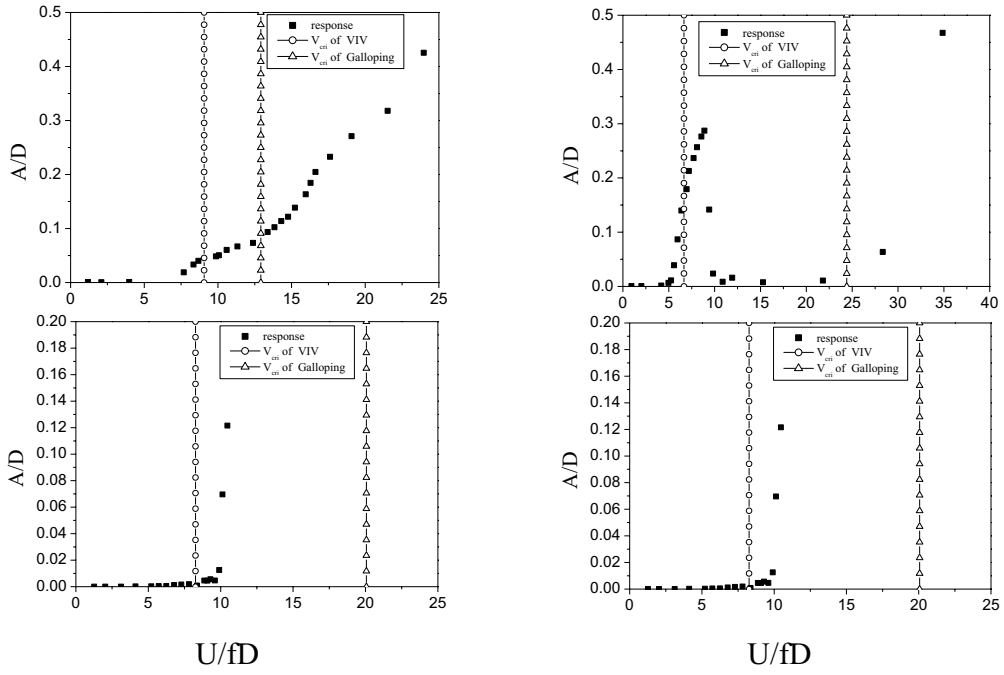


Fig.7. Conclusive test results: non dimensional vibration displacement A/D vs. normalized wind velocity. The first row to the fourth row represent the wind induced vibration curves of group 1~ group 4 respectively. And the entire first column is with respect to the condition of section model of each group anti-wind with short edge, while the whole second column is for the conditions of section models anti-wind with long edge.

5 CONCLUDING REMARKS

Four groups of tests on rectangular section model were performed in wind tunnel, each group of models are varied in aspect ratio and Scruton number. The critical wind velocity of VIV and galloping were also predicted with the beforehand identified aerodynamic coefficients. Main characteristics of result curves allow following remarks.

With respect to the circumstance that estimated critical wind velocity of VIV and galloping are very close, e.g. within the range of 1.5 times, an interesting experimental phenomenon occurs. The interaction of VIV and galloping aerodynamic forces creates a new oscillation type: it shows neither lock-in VIV nor divergent type galloping characteristics. The cross flow vibration amplitudes consistently increases with the increased wind velocity, moreover, the vibration time series of each steady wind velocity always maintains constant amplitude. The VIV aerodynamic force seemed to suppress the occurrence of divergent type galloping.

When the predicted critical wind velocity of VIV and galloping diverge significantly to each other, the fully measured VIV lock-in range demonstrates the relatively large non dimensional amplitude which the circular section structures cannot achieve at the same Scruton number. According to the quasi-steady galloping theory, the circular section will never attain the galloping instability negative damping; whereas the rectangular models investigated in the present work always being the models differentiated in aspect ratio and Scruton number (B/D, Scr, Table 1~4). Hence, it is reasonable to assume that the interaction of VIV and galloping contribute to the distinctively large VIV amplitude.

Numerical Simulation with PCA analysis of flow around 1:5 rectangular cylinder

Shining Zhang[a], Zhiwen Zhu[a]

([a]*Center of Wind Engineering, Hunan University, Changsha, China*)

ABSTRACT: The unsteady flow field around a two-dimensional rectangular prism with aspect ratio of 5 is studied by using Unsteady Reynolds-Averaged Navier-Stokes (URNS) equations. Fundamental flow characteristics are provided with numerical simulation and compared with the experiment, satisfactory agreement is obtained consequently. The aim of this paper is to find the nature of the fluctuating pressure on the surface of the rectangular cylinder indicated by the Principal Component Analysis. To better understand the vortex shedding phenomenon, flow visualization is provided. At last, effects of Reynolds number ranged from 1.03×10^4 to 1.03×10^6 on the flow characteristics are discussed.

KEYWORDS: Rectangular cylinder, CFD, PCA, vortex shedding, Reynolds number effects.

1 INTRODUCTION

In bridge engineering, rectangular shape are commonly employed as the cross section of bridge components, such as the plate girder, tower, pier, etc. The infamous bridge destroyed by the wind-induced vibration and shocking the civil engineers is old Tacoma Narrows Crossing, with its H-shaped stiffening girder at chord-to-thickness ratio very close to 5. Therefore investigation of the flow past such kind of cross section is of great concern. As a benchmark problem, rectangular cylinder had been studied by many researchers over the years through wind tunnel test, numerical simulation method and site measurement.

The aerodynamics of a rectangular cylinder with the aspect ratio of 5 as a benchmark problem has been studied for many years. Both the two-dimensional (2-D) and three-dimensional (3-D) features of the flow characteristics around rectangular cylinders have been clarified in several studies, e.g. in Claudio Mannini(2010), Luca Bruno(2009), Gunter Schewe(2009). Most of what they explored was the mean pressure coefficient distributions, nevertheless, usually it is the fluctuating pressure that mainly affects the variation of aerodynamic forces, therefore fluctuating pressure should be well considered and analyzed when dealing with aerodynamics.

This paper deals with the two-dimensional (2-D) numerical simulation of flow past a rectangular cylinder with a chord-to-thickness ratio B/D=5 at zero flow incidence. The reattachment which significantly relates to the pressure recovery is calculated, some other natures of flow characteristics is analyzed, mainly including principal component of pressure distribution around the upper surface and periodic vortex shedding. The Principal Component Analysis which is recognized an effective method to represent the unsteady flow is employed to deal with the fluctuating pressure. Finally, the effects of Reynolds number on those flow characteristics have been investigated. Through those flow characteristics, we can better understand the fluctuation of aerodynamic forces and find the main factors leading to those variations.

Although the resulting flow field is known to be three dimensional, the current two-dimensional calculation is able to predict important flow properties (D. K. Tafti and S. P. Vanka,

1991). The current 2-D numerical simulation is adopted to explore its capacity and advantages through comparison with the experimental results and three-dimensional (3-D) calculations. Also, this paper will definitely lay a foundation for 3-D research and the results analyzed from 2-D are used to compare with latter 3-D study in order to find the indispensable role and improvement of 3-D effects.

2 FLOW MODEL AND PCA THEORY

2.1 Governing equation and turbulent model

The unsteady, incompressible, 2D viscous fluid flow around the rectangular cylinder is modeled by means of the time-averaged Navier-Stokes equations as follows:

$$\frac{\partial \overline{u_i}}{\partial x_i} = 0 \tag{1}$$

$$\frac{\partial}{\partial t}\left(\rho \overline{u_i}\right) + \frac{\partial}{\partial x_j}\left(\rho \overline{u_i}\,\overline{u_j}\right) = -\frac{\partial \overline{p}}{\partial x_i} + \frac{\partial}{\partial x_j}\left(\mu \frac{\partial \overline{u_i}}{\partial x_j} - \rho \overline{u_i' u_j'}\right) \tag{2}$$

Where x and t are the space and time coordinates, $\overline{u}$ and $\overline{p}$ are the time-averaged velocity and pressure, μ is the turbulent viscosity and ρ is the fluid density. $\rho u_i' u_j'$ is the Reynolds stress.

The Boussinesq hypothesis to relate the Reynolds stresses to the mean velocity gradients:

$$-\rho \overline{u_i' u_j'} = \mu_t \left(\frac{\partial \overline{u_i}}{\partial x_j} + \frac{\partial \overline{u_j}}{\partial x_i}\right) - \frac{2}{3}\left(\rho k + \frac{\partial \overline{u_i}}{\partial x_i}\right)\delta_{ij} \tag{3}$$

In consideration of complex flow near the wall of rectangular cylinder, the shear-stress transport (SST) $k-\omega$ model is employed in present simulation, since $k-\omega$ model effectively blend the robust and accurate formulation of the $k-\varepsilon$ model in the near-wall region with the free-stream independence of the $k-\varepsilon$ model in the far field.

2.2 Principal Component Analysis (PCA) theory

In the study of the pressure fluctuation around bluff bodies using PCA, Holmes(1990) pointed out that the covariance matrix of the pressure fluctuation contains information on the magnitude and distribution of the underlying fundamental modes of the pressure distribution around a body. Studies show that these modes are represented by the eigenvectors of the corresponding covariance matrix of the pressure distribution on the body's surface.

Mathematically, to perform PCA on a data set x, the eigenvalues, λ_i and the eigenvector, e_i of a covariance matrix C_x can be evaluated from the solution of :

$$C_x e_i = \lambda_i e_i \tag{4}$$

The eigenvalues is calculated as the roots of ,

$$\left|C_x - \lambda_i I\right| = 0 \tag{5}$$

Where $i = 1,2,\ldots,n$, n is the total number of the input data and I is the identity matrix.

The eigenvalues are associated with the variance of each of the components. Each eigenvalue is accompanied by an eigenvector, the nonzero vector e_i that satisfies Eq. 4.

The principal components of PCA are made up of columns of eigenvectors of the covariance matrix C_x. By arranging the eigenvectors in the order of descending eigenvalue($\lambda_i > \lambda_{i+1...}$), one gets the most significant changes of the variables in the data in the first principal component.

In PCA, the variables x are decomposed in the process of the eigenanalysis. It is possible to regenerate the variables x using the PCA results as follows:

$$x = A^T Y + \mu_x \tag{6}$$

Where A^T is the transpose matrix whose columns are given by the eigenvector of the covariance matrix and Y is the coefficients of the principal components. μ_x is the mean value of the data set x.

From Eq. 6, the original data can be reconstructed from the terms on the right hand side of the equation to see how well the original data can be represented from the few principal components in the analysis.

3 COMPUTATIONAL MESHES

As we all know that the quality of the computation mesh plays a crucial role in the reliability of numerical simulation. For this reason, a simple grid-convergence study is outlined in order to choose a reasonable grid for the following computations. In this paper the stationary rectangular cylinder at zero-degree angle of attack ($\alpha = 0^\circ$) and Reynolds number Re=$U_\infty B / \nu = 3.42 \times 10^5$ (B is the width of the cylinder and ν the air kinematic viscosity) is chosen as test case.

Three 2-D hybrid grids were investigated, whose main characteristics are listed in Table 1. The fine grid is display in Fig.1 (left). In order to guarantee the accuracy of numerical simulation, the grid along the surface is generated by structured grid. Additionally, the only difference among those three grids is the level of grid refinement in structured grid zone close to the body surface.

The Dirichlet condition on the velocity field and sub-grid kinetic energy is imposed on the inlet boundary. Neumann conditions on the normal component of the stress tensor $\boldsymbol{T}$, as well as the same Dirichlet conditions on turbulence kinetic energy k, are imposed at the outlet boundary. Symmetry conditions are imposed on the both upper and lower boundary of the computational domain, while the no-slip boundary condition is imposed on the body surface, as indicated in Fig.1 (right). In order to represent the imposed physical boundary and reduce the influence from outside boundary, the distance between outside boundaries of the computational domain and the center of the body has also been meticulously selected, as shown in Fig.1 (right).

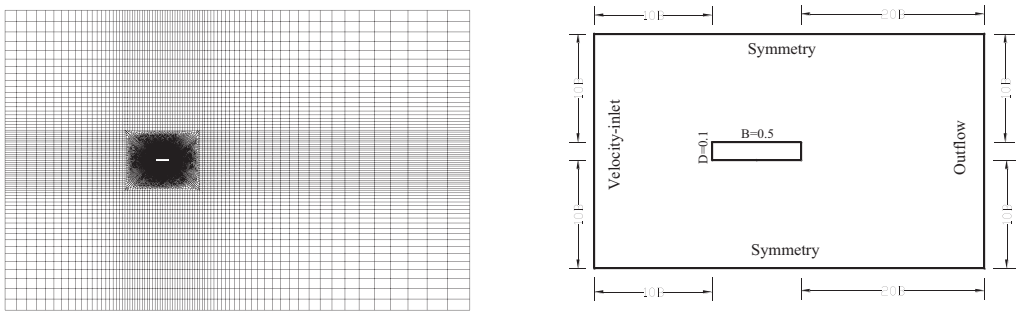

Fig.1. Fine grid and whole computational zone.(units: m)

Table 1. Main properties of grid system. The parameter δ and $\Delta y_{j+1} / \Delta y_j$ is the height and stretching factor of the first structured layer closest to the body surface respectively.

Grid	δ / B	$\Delta y_{j+1} / \Delta y_j$	Total cells	Structured cells	Unstructured cells	Good mesh
Coarse	2.5E-6	1.1	60,883	38,300	22,583	91.7%
Fine	6.0E-6	1.1	94,483	71,900	22,583	89.3%
Finest	6.0E-6	1.03	139,283	116,335	22,948	88.0%

Table 2. Present results of different grid arrangement in comparison with other literature (α =0°)

Grid	Reynolds number	max y^+	St	C_D	$C_L^{'}$	$C_D^{'}$
Coarse	3.42×10^5	4	0.114	1.05	0.1	0.006
Fine	3.42×10^5	0.1	0.113	1.09	0.16	0.009
Finest	3.42×10^5	0.1	0.116	1.08	0.1	0.004
Experiments(Schewe,2009)	2.64×10^5	-	0.111	1.029	0.4	-
Okajima(1983) I=0.4%	0.42×10^5	-	0.110	-	0.15	-
K. Snimada and T. Ishihara ($k-\varepsilon$ model)	-	-	0.118	1.0	0.05	-

After a series of trial calculation with several time-step size (dt), dt=0.0005s is eventually verified small enough, even conservative to resolve the dominant unsteady flow phenomena. Table 2 shows the computed St, the mean drag coefficient C_D and the standard deviation of lift and drag coefficients, $C_L^{'}$ and $C_D^{'}$. The table also reports the maximum value of the maximum value of the computed first-layer non-dimensional distance from the wall, defined as Yplus, y^+, which is recommended around 1 for the higher Reynolds number when utilizing the SST $k-\omega$ turbulent model. Considering the results obtained, the fine grid is found to be a reasonable compromise between accuracy and computational time cost. Therefore this grid will be employed in the following simulations.

4 FLOW RESULTS

4.1 Fundamental flow characteristics

Fig.2 displays the mean and standard-deviation values of the pressure coefficient on the body surface with several wind tunnel results reported for comparison. Usually, since the pressure fluctuation at some points (x/D=0 and 5) is thought to be sensitively affected by the approaching flow, those points have been excluded from the following discussion. The mean pressure coefficient C_P is defined as

$$C_P = (p - p_\infty) / 0.5\rho U^2 \tag{7}$$

Obviously, the mean C_P computed with 2-D SST $k-\omega$ model agrees well with the numerical simulation conducted by T. Ishihara (2001) and the experiment performed by Matsumoto (2005) at higher Reynolds number of 200,000, while a small discrepancy exists near leading edge at Re=100,000. The mean pressure coefficient distribution on the upper surface of rectangular cylinder exhibits a pressure increase toward the rear end. This is the inclination of reattachment of the flow which leads to pressure recovery toward the trailing edge, and this reattachment can be confirmed by streamlines in flow visualization. As for the standard deviation of the pressure coefficient, $C_P^{'}$, the wind tunnel data present a significant dispersion. This is probably due to the fact that the distribution of $C_P^{'}$ is more sensitive to the experimental boundary conditions than the mean values of pressures. Also, from the experiment results (Matsumoto,2005) we can con-

clude that $C_P^{'}$ is relevant to the Reynolds number to some extent. Although the present result of $C_P^{'}$ also distinct from the experiment, it predicts nearly the same position of the peak of $C_P^{'}$, which is a crucial parameter indicating the existence of vortex in this region. As a result, the experimental data provided the position at about x/D=3.7, while this present simulation give the location at x/D=3.85. From the mean friction coefficient distribution on the upper surface of the rectangular cylinder, the present calculation gives a value of x_R/B=0.903, which is slightly larger (3.2%) than the experiment estimated by Matsumoto et al. (2002) based on the distribution of the time-averaged pressure coefficient C_P and RMS value $C_P^{'}$ (x_R/B=7/8).

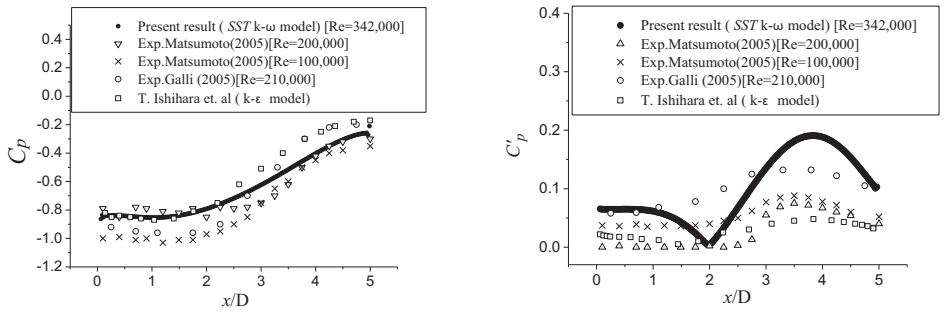

Fig.2. Comparison of pressure coefficient distribution with experiments (Matsumoto,2005 and Galli,2005), left: mean, right: standard deviation.

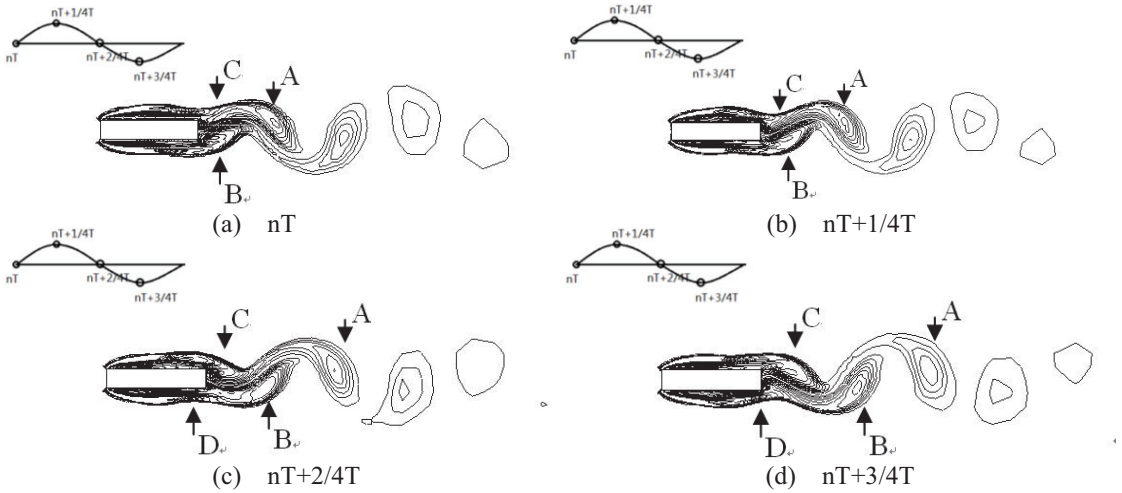

Fig.3. Snapshots of vorticity magnitude in flow field.

Fig.3 clearly describes the shedding of vortices from the rectangular cylinder. In (a), the total lift force on the bluff body is zero, and three vortices are labeled by A, B and C behind the cylinder. A is already shed, preparing to exit into the wake. B was originally from the lower side of the cylinder and is still attached to the rear side of the cylinder. In (b), A moves further towards the wake, while C moves to the center of the rear side surface. In (c), half a cycle of the lift force is completed, and it may be concluded that the vorticity close to the cylinder in (c) is similar to those in (a), but only reversed. In (c), B is completely shed off the rear side surface while a new vortex D is formed at the lower side behind the cylinder.

4.2 Principal Component Analysis results

In this section, the PCA theory is utilized to identify the fluctuating pressure. The analysis is carried out based on the procedures outlined in the previous section (section 2.2). As mentioned

above, the first principal component corresponds to the eigenvalues with the highest values, which quantifies the largest variation of pressure with respect to the total pressure changes in the flow within the time series considered in the analysis.

The principal components represent the fluctuating nature of the flow. Fig.4 depicts the first and second principal component of the pressure distribution on upper surface of the cylinder. It is found that the largest pressure fluctuation is appeared near the trailing edge of the section (upper surface). This indicates the presence of vortex structures at these regions and the peak of the first principal is located at x/D=3.85, which agrees well with the RMS values of C_P' distribution shown in Fig.2. Compared to the first principal component, the second one owns a more even pressure distribution (comparing total area on both sides of the *x*-axis in the graphs).

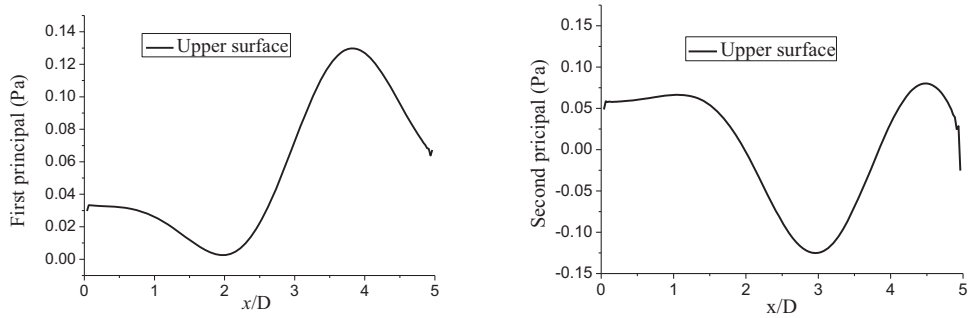

Fig.4. First and second principal component of pressure distribution on upper surface.

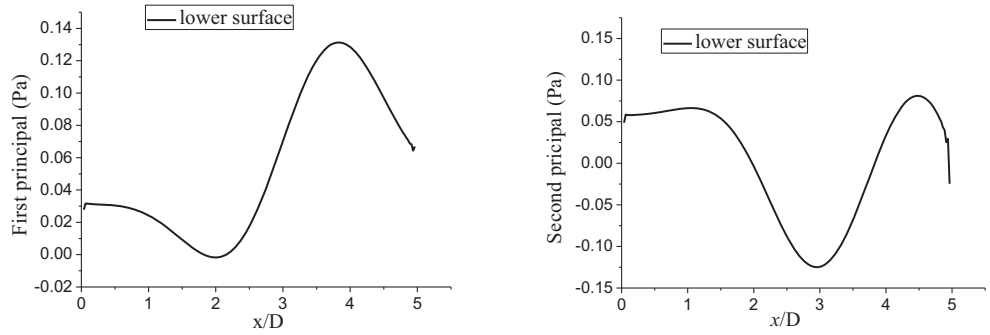

Fig.5. First and second principal component of pressure distribution on lower surface.

Fig.5 displays the first and second principal component of the pressure distribution around lower surface of the cylinder. Notice that the pressure distribution on the upper and lower surfaces of the cylinder shows different trends in the first principal component compared to the second principal component. A large amplitude pressure distribution appears near the trailing edge of the cylinder in the first principal component, while it happens at the middle part of the cylinder in the second principal component (Fig.4-Fig.5). Physically, this indicates the movement of the vortex along the cylinder surface.

When discussing the principal component, the contribution rate reflects energy percentage of one principal component in all components. The contribution rate of *i*th principal component can be defined as

$$CR_i = \frac{\lambda_i}{\sum_1^n \lambda_i} \tag{8}$$

Where λ_i is the value of the *i*th eigenvalue mentioned in section 2.2 and $\sum_1^n \lambda_i$ is the sum of all the eigenvalues.

Fig.6 depicts the contribution rate of the first fifteen eigenvalues. The first and second principal components of the pressure changes account for more than 99.8% of the total changes on the cylinder surface, which suggests that the first and second principal components of the pressure distribution around the cylinder account for most of the total variance of the pressure field without losing much information.

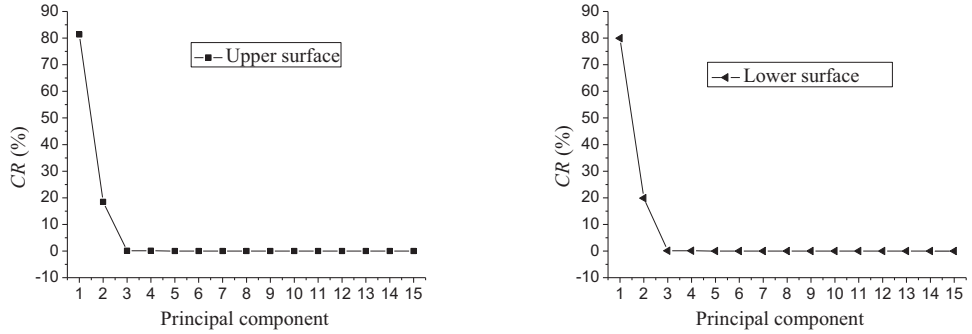

Fig.6. Contribution rate of the principal component on upper and lower surface.

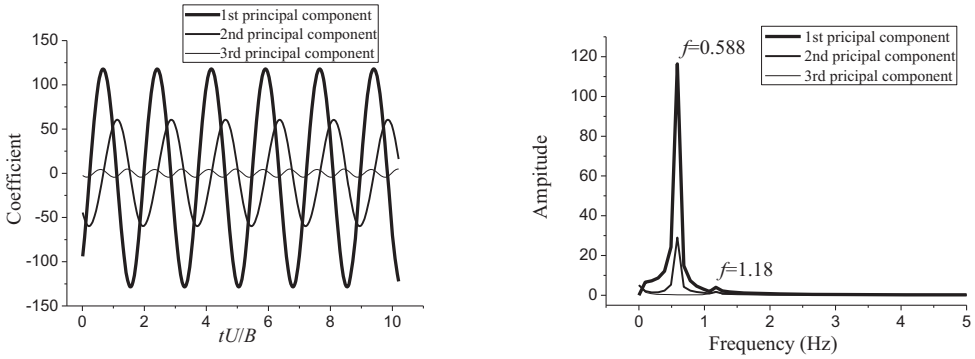

Fig.7. Coefficients and FFT analysis of first 3 principal components on upper surface.

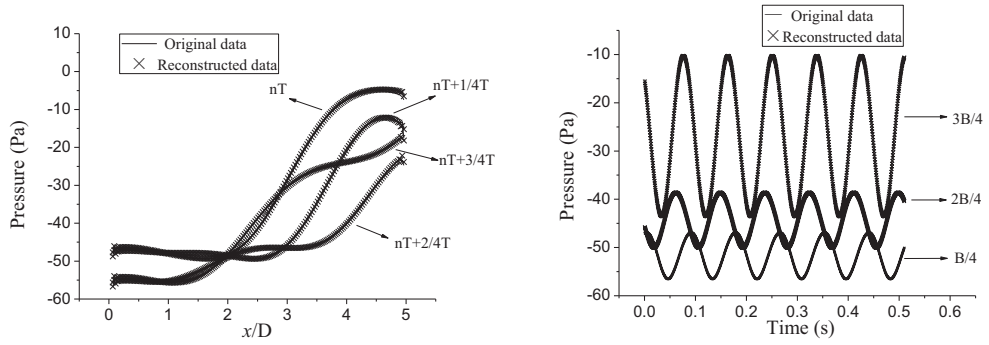

Fig.8. Reconstruction of fluctuating pressure on upper surface (B is width of cylinder).

As mentioned in section 2.2, the coefficients fluctuation of the principal component can be calculated, as shown in Fig.7. From the FFT analysis of the coefficients, one can find that a dominant frequency has been observed from both of the coefficients, with the first and second principal components showing the same frequency. Comparison shows that this frequency agrees well with the Strouhal number. Thus, the frequency feature of the coefficients can be related to the vortex shedding of the flow. A small peak also appears on the spectrum of the third principal component (right in Fig.7). Physically, this is related to smaller eddies and scales in the flow accompanying the main vortex mentioned above. Fig.7 also verifies that the first and second principal component contain most of the variable information, corresponding to the main vortex shedding.

Now that the first two principal components are responsible for the main fluctuation of pressure fluctuation along the surfaces, then we can reconstruct the time-dependent pressure on the surface of cylinder based on the Eq.6. Fig.8 shows the original and reconstructed transient pressure data (left) and time history of pressure at prescribed positions (right) on upper surface. Obviously, the reconstructed data agrees well with the computed data which indicates that the first principal component is enough to reconstruct the fluctuating pressure data along the surface. From Fig.8 (right) we can find that maximum pressure fluctuation occurs at x/D=3B/4, which can also be seen from RMS values of pressure in Fig.2.

From all mentioned above, PCA is proved to be useful and efficient for dealing with the nature of pressure distribution along the surface and original data can be easily reconstructed with few principal components without losing much information.

4.3 Effects of Reynolds number

In this section, effects of Reynolds number on flow characteristics are simulated and discussed. Table.3 lists the several cases performed in this paper, Reynolds number ranges from 1.03×10^4 to 1.03×10^6.

Fig.9 shows the Strouhal number and drag coefficient is insensitive to the variation of the Reynolds number in the range investigated, which has been verified in wind tunnel test. The tendency of 2-D $SST\ \ k-\omega$ model to underestimate the base pressure may be responsible for the overestimation of drag coefficient. From Table.3 one can find the standard deviation of lift and drag coefficient $C_L^{'}$ and $C_D^{'}$ decrease intensely with the increase of Reynolds number.

Table.3. Effects of Re number on aerodynamic parameters

Case	Reynolds number	Velocity (m/s)	max y^+	Time step	St	C_D	$C_L^{'}$	$C_D^{'}$
1	1.03×10^4	0.3	6.0E-03	0.010	0.117	1.14	0.22	0.035
2	3.42×10^4	1.0	1.5E-02	0.001	0.120	1.14	0.20	0.022
3	5.13×10^4	1.5	2.0E-02	0.002	0.119	1.13	0.19	0.017
4	1.03×10^5	3.0	3.5E-02	0.0015	0.113	1.11	0.18	0.013
5	3.42×10^5	10	0.8E-01	0.0005	0.113	1.09	0.16	0.009
6	6.84×10^5	20	1.5E-01	0.0002	0.112	1.10	0.15	0.008
7	1.03×10^6	30	2.3E-01	0.0001	0.113	1.11	0.16	0.009

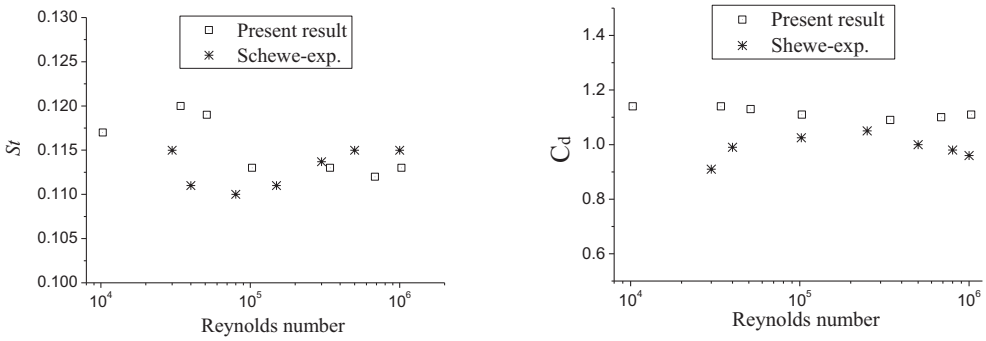

Fig.9. Strouhal number and drag coefficient as function of varying Reynolds number: comparison of current numerical results and experimental result from Schewe (2009).

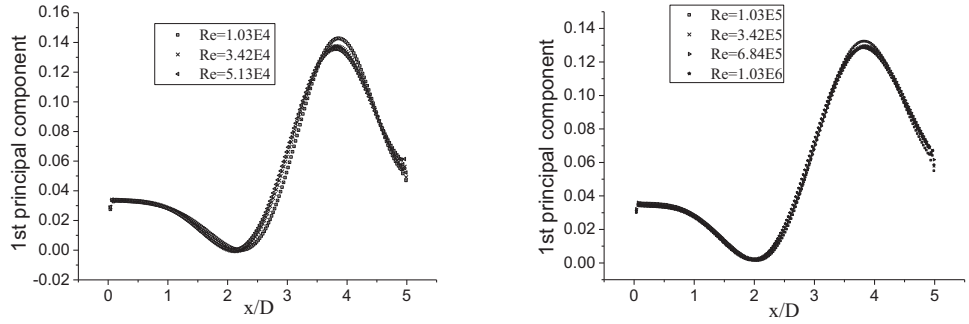

Fig.10. First principal component on the upper surface as functions of varying Reynolds number.

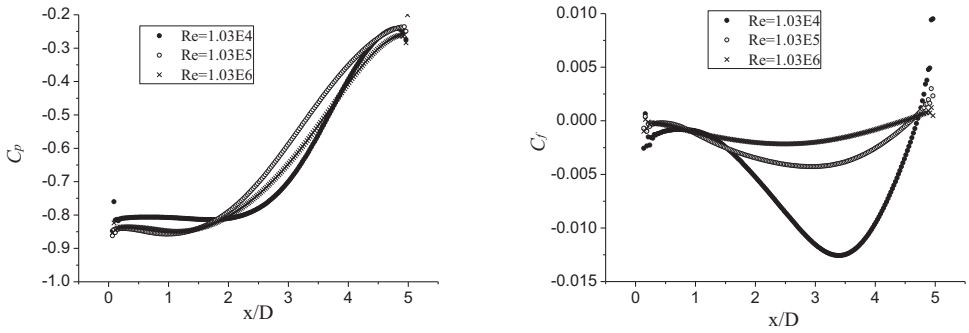

Fig.11. The mean pressure and friction coefficient on the upper surface as functions of varying Reynolds number.

The distribution of the first principal component on upper surface with the varying Reynolds number is depicted in Fig.10. It is found that similar mode is found when the Reynolds number exceeds 1.03×10^5, while less than it the peak of the first principal component will close to the trailing edge as the Reynolds number decreases. Fig.18 displays the mean pressure and friction coefficient on the upper surface as functions of Reynolds number. Similarly, mean pressure coefficient exhibit the same tendency at Re number larger than 1.03×10^5, while Re number is under 1.03×10^4 the position of pressure recovery lag behind the location in case of Re number larger than 1.03×10^5 on the upper surface. This phenomenon can be analyzed from the position of bubble vortices on the surface as shown in Fig.11 (right). The local valley in mean friction coefficient distribution is considered to be the position of the centre of the time-averaged bubble vortices. It is clear that when Re is smaller than 1.03×10^5 the position is closer to trailing edge which impedes the flow reattachment on former portion.

5 CONCLUSIONS

This paper provides the fundamental flow characteristics around the 1:5 rectangle cylinder, and compares the resuts with the experiments.

Main conclusions are included as following:

(1) Consequently, good agreement with the experiment is obtained. According to the numerical result of *St* and force coefficient, 2-D numerical simulation is proved efficient and reliable, which indicates that 2-D numerical simulation can satisfy the engineering requirement.

(2) Based on the distribution of the RMS values of pressure fluctuation, mean vortex shedding position is considered at x/D=3.85 and the fluctuating pressure distribution is considered to 3-D effects. Moreover the numerical flow visualization is provided to better understand the change of aerodynamic force on the side surface of the rectangular cylinder.

(3) Based on the PCA method, the nature of the pressure fluctuation is analyzed in this paper. It is found that the first two principal components are enough to contain the pressure fluctuation information. Furthermore, the pressure is reconstructed with few principal components, verifying the reliability of PCA and providing a feasible method to save the countless data extracted from experiment or numerical simulation. Analysis from the PCA also indicates that the first two modes are mainly responsible for the variations of the pressure on the side surface of this bluff body.

(4) At last, effects of Reynolds number on those flow characteristics are discussed. Changes of *St*, C_D, C_L', C_D', C_P, C_f and principal components varying as the function of Reynolds number are included. Generally, the *St* and C_D are insensitive to the changes of Reynolds number in present Re number range research while C_L' and C_D' both exhibit intensive decline as the Reynolds number increases. As for the C_P, C_f and the principal components, Re=1.03×10^5 is considered to be a critical values for the remarkable changes of those flow characteristics.

Further studies are required to explore the nature of the pressure distribution on the surface of the bluff body based on 3-D numerical simulation and to confirm the present assertion about the effects of Re number on C_P, C_f.

Shear effects on flow past a rectangular cylinder with side ratio B/D=5

Qiang Zhou, Shuyang Cao*, Zhiyong Zhou

State Key Laboratory of Disaster Reduction in Civil Engineering, Tongji University, Shanghai 200092, P. R. China

ABSTRACT: Large Eddy Simulation (LES) is carried out to investigate shear effects on flow past a rectangular cylinder with side ratio *B/D*=5 at Reynolds number Re=22,000 (based on the thickness of the cylinder). Simulation results showed that the Strouhal number has no significant variation with oncoming velocity shear, while the peak fluctuation frequency of the drag coefficient becomes identical to that of the lift coefficient with increase in velocity shear. The intermittently-reattached flow that features the aerodynamics of the 5:1 rectangular cylinder in non-shear flow becomes more stably-reattached on the high-velocity side and more stably-separated on the low-velocity side. The mean of the drag force was found to have little variation while its standard-deviation increases with increase in velocity shear. The mean and standard-deviation of the lift and moment forces vary almost linearly with the velocity shear. The lift force acts from the high-velocity side to low-velocity side, which is similar to that of a circular cylinder but opposite to that of a square cylinder under the same oncoming shear flow condition.

KEYWORDS: A Rectangular cylinder, Shear parameter, Large eddy simulation, Aerodynamic forces, Vortex shedding, Flow reattachment

1 INTRODUCTION

Rectangular cylinders are common configurations in many structures, such as bridges, tall buildings and so on, thus the flow past a bluff body with a rectangular cross section is of direct relevance to the structural problems in which wind-induced vibration is one of the most important issues to consider. So far, the majority of studies on this issue have been conducted under uniform oncoming flow conditions in which vortices with equal strength alternately shed from each side of the cylinder. However, in many practical applications, a cylindrical structure is immersed in a non-uniform flow. A bridge deck in the atmospheric boundary layer is an example, in which the vertical mean wind profile is one factor to determine the wind load on bridge deck. The influence of velocity profile or velocity shear in the oncoming flow becomes more significant at the situation of non-synoptic wind like a downburst, where the wind speed increases rapidly near the ground and reaches its maximum at the height about 80-100m, and then decreases with increase in height resulting in a stronger velocity shear than in synoptic winds. Strong velocity shear may also be created in complex topography. Therefore, the variation of aerodynamic behaviors of a rectangular cylinder with the velocity shear needs to be studied in detail. In this study, a dimensionless shear parameter $\beta = G \times D / Uc = (dU / dy) \times (D / Uc)$ is defined to express the extent of velocity shear, where U_C is the mean velocity at the center plane, and D is the thickness of the rectangular cylinder and G is the velocity gradient, as illustrated in Fig. 1. The magnitude of the shear parameter implies the velocity difference between the up and down surfaces of the rectangular cylinder.

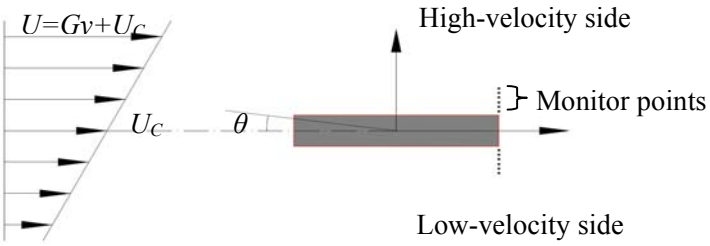

Fig.1. Schematic of shear flow configuration

Although the number of published papers is few, we are still able to find some studies about the shear flow past bluff bodies. Kiya et al. (1980) investigated the vortex shedding from a circular cylinder in shear flow and reported that the critical Reynolds number for the occurrence of vortex shedding becomes larger than in non-shear flow. Kiya's work was followed by many studies on the circular cylinder (e.g. Sumner and Akosile, 2003; Cao et al., 2010), and on the square cylinder (e.g. Cao et al., 2012). However, the common points of interest of these investigations were focused on how the Strouhal number varies with shear parameter and Reynolds number. Little attention was devoted to the shear effects on the aerodynamic forces and underlying background. In addition, there is no other reported study on the shear effects on a rectangular cylinder, expect for the experimental study of Onirsuka et al. (2000). The insufficient study on the shear effect over a rectangular cylinder partly motivates present study.

In this paper, aerodynamic characteristics of a rectangular cylinder with side ratio B/D=5 in shear flows are investigated at Re=22,000, where the Reynolds number Re is based on the thickness of the rectangular cylinder D and the centerline velocity U_C. The side ratio 5:1 is chosen as the study objective because this kind of rectangular cylinder has often been adopted as a reference for investigations of the aerodynamics and aeroelasticity of a bridge deck and other structural members (Matsumoto, 1996; Bartoli and Righi, 2006). In addition, a B/D=5 rectangular cylinder has very delicate dynamic behaviors of vortex shedding that is characterized by massive flow separation due to the sharp leading edges and intermittent-reattachment on side surfaces forming unsteady separating bubbles, and deserves to be studied from the view points of fundamental study of bluff body aerodynamics.

With the occurrence of shear parameter, i.e. an asymmetry in the oncoming flow, the separated flow must differ on the two sides of the rectangular cylinder, resulting in different aerodynamic behaviors with those in non-shear flow. Non-zero-mean lift and moment forces, which are important factors in determining the behavior of flow-structure coupling, must appear. However, there is no reported research on the flow around 5:1 rectangular cylinder in shear flows. Onirsuka et al. (2000) studied experimentally the Strouhal number of rectangular cylinders in linear shear flows at Re=3.2-9.7×10^4 at B/D=0.2-3. But the separated shear layer did not reattach on the side surface when B/D=0.2-3. The side ratio B/D=5 considered in this study involves intermittent flow reattachment, which makes the flow more sensitive to the oncoming velocity shear that brings separated shear layers with different strength and depth at the high and low velocity sides.

In this study, we investigated the vortex shedding and the aerodynamic forces on a rectangular cylinder in shear flows by Large Eddy Simulation (LES). We employed a structured grid mesh system for finite volume approximation of incompressible Navier-Stokes equations. The Fluent© package is used as a solver of the governing equations, but the options offered by Fluent© for simulation were carefully selected in order to achieve a good simulation. The numerical method and details applied in this study are described and validated by presenting the aerodynamic behaviors of a circular cylinder at Re=3,900. The aerodynamic characteristics of the 5:1 rectangular cylinder in shear flows at Re=22,000 are presented by comparison with available experimental and numerical results. Time-mean and unsteady flow patterns around the cylinder are

studied to enhance the understanding of the effects of velocity shear. In addition, the obtained results are compared with those of a circular cylinder (Cao et al. 2010) and a square cylinder (Cao et al. 2012) to achieve a comprehensive understanding of the shear flow around bluff bodies.

2 PROBLEM FORMATION AND NUMERICAL DETAILS

2.1 *Problem formulation*

The numerical model for the flow around a 5:1 rectangular cylinder is formulated using the Cartesian coordinate system. Eqs. (1) and (2) show the filtered continuity and Navier-Stokes equations for Large Eddy Simulation, in which the grid-scale turbulence is solved while the sub-grid-scale turbulence is modeled.

$$\frac{\partial \overline{u_i}}{\partial x_i} = 0 \tag{1}$$

$$\frac{\partial(\overline{u_i})}{\partial t} + \frac{\partial(\overline{u_i u_j})}{\partial x_j} = -\frac{1}{\rho}\frac{\partial \overline{P}}{\partial x_i} + \frac{\partial}{\partial x_j}\left(\nu \frac{\partial \overline{u_i}}{\partial x_j}\right) - \frac{1}{\rho}\frac{\partial \tau_{ij}}{\partial x_j} \tag{2}$$

where all the variables with the upper-marking are filtered components. The subgrid scale stresses (SGS stress), $\tau_{ij} = \overline{u_i u_j} - \overline{u}_i \overline{u}_j$, are expressed as $\tau_{ij} = -\frac{1}{3}\delta_{ij}\tau_{kk} + 2\nu_\tau \overline{S}_{ij}$

$\overline{S}_{ij} = \frac{1}{2}(\frac{\partial \overline{u}_i}{\partial x_j} + \frac{\partial \overline{u}_j}{\partial x_i})$, and $\nu_\tau = l^2 \left|\overline{S}\right|$ where $l = C_s \overline{\Delta}$ ($\overline{\Delta}$ is the size of grid filter).

We studied the flow around the 5:1 rectangular cylinder by performing three-dimensional unsteady simulation of the incompressible governing equations shown above with the aid of Fluent package. The options offered by Fluent© for simulation were carefully selected under the following considerations.

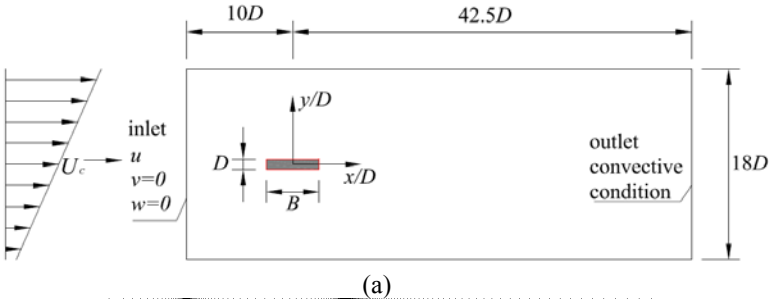
The velocity and the pressure are defined at the center of a control volume, while the volume fluxes are defined at the midpoint of their corresponding cell surfaces. In order to avoid the oscillating problems, the momentum Interpolation Method (MIM) developed by Rhie and Chow (1983) is used. The SIMPLE (Semi-Implicit Method for Pressure-Linked Equations) algorithm proposed by Patankar and Spalding (1972) is utilized, in which governing equations are solved sequentially because of their non-linearity and coupling characteristics and the solution loop is carried out iteratively in order to obtain a converged numerical solution. The pressure field is extracted by solving a pressure correction equation that is obtained by manipulating continuity and momentum equations, while the velocity field is obtained from the momentum equations. In addition, the convergence criterion of the iterative calculation is set to be 10^{-6}, and it takes about 30 iterations to satisfy this criterion in the simulation.

In order to avoid instability caused by central-differencing schemes and non-physical wiggles, the bounded central differencing scheme is applied to spatial differencing of convection term, which is a composite normalized variable diagram (NVD, Leonard, 1991) scheme that consists of a pure central differencing, a blended scheme of the central differencing and the second-order upwind scheme, and the first-order upwind scheme. Meanwhile, a fully-implicit second-

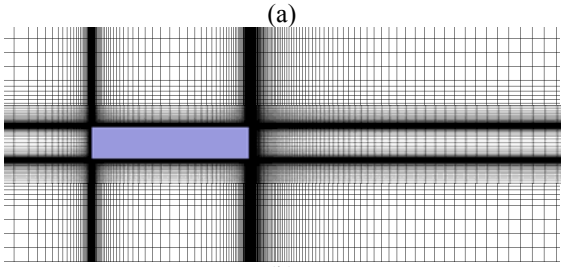
order time-advancement scheme is chosen for temporal discretization to obtain stable and accurate simulation.

2.2 *Numerical model and boundary conditions*

As shown in Fig. 2 (a), the computational domain is 52.5*D* in *x*-direction, 18*D* in *y*-direction and 5*D* in *z*-direction. The blockage ratio is 5.55% that is smaller than the suggestion (6.4%) of Sohankar et al. (2000). The ratio of spanwise length *L* to chord length *B* is set to be *L/B*=1 in order to achieve a good simulation of the mean and RMS of aerodynamic forces (Tamura et al. , 1998). *L/B* was utility also in the simulation of Mannini et al. (2010) and Bruno et al. (2010) . A structured grid system with the number of 325(*x*)×164(*y*)×24(*z*) is used to adequately resolve the flow (see Fig.2) with the first grid Δd near the body surface given empirically as $0.1/\sqrt{\mathrm{Re}}$ ($\Delta d / D = 6.5\times10^{-4}$). For the spatial discretization in spanwise direction, 24 cells are uniformly distributed with a grid length $\Delta z / B = 0.042$ that is smaller than the minimum requirement $\Delta z / B = 0.1$ recommended by Tamura et al. (1998). The non-dimensional time-step, Δt^* is $\Delta t^* = \Delta t U / D = 5\times10^{-3}$ which maintained the Courant number *CL*<1.



(a)



(b)

Fig.2 (a) Computational domain in x-y plane and boundary conditions, (b) Grid example near the cylinder

The boundary conditions for simulation are as follows:

Cylinder body surface: A no-slip condition for u_i=0 and a Neumann condition for pseudo-pressure ϕ are imposed.

Inlet: An UDF (User-Defined Function) condition, i.e., $U = 1 + Gy$, v=0 and w=0, and a Neumann condition of pseudo-pressure ϕ are imposed at the inlet boundary.

Outflow boundary: A convective boundary condition ($\partial\phi/\partial t + \bar{u}\cdot\partial\phi/\partial x = 0$) is applied for pseudo-pressure.

Spanwise: A periodic condition for velocity and pseudo-pressure are applied.

3 NUMERICAL VALIDATION

The flow over a circular cylinder at Re=3900 is often considered as a benchmark test model to check or confirm the accuracy of numerical simulation because there is plenty of reliable experimental and numerical data. Thus, in this study the numerical method is validated by comparing the mean and turbulence statistics of the flow around a circular cylinder at Re=3,900. Fig. 3(a) shows that the mean pressure coefficient distribution obtained by present numerical

shows that the mean pressure coefficient distribution obtained by present numerical method agrees well with other studies, while Fig. 3(b) shows that the streamwise mean velocity on the center line exhibits reasonable agreement also, especially at the near wake. Fig. 4 compares the turbulence statistics obtained at several downstream locations. Although the values deviate somewhat at several points, similar trendy of the variation of $u'u'$ and $u'v'$ in y direction is obtained. In short, the numerical method of present simulation produced reasonably good results, so it may be considered appropriate to simulation the flow over a bluff body with large scale vortex shedding.

4 NUMERICAL RESULTS AND DISCUSSIONS

4.1 *Vortex shedding*

The Strouhal number $St=fD/U$ is calculated from the FFT analysis of the lift coefficient for the flow around the 5:1 rectangular cylinder at non-shear and shear flows at Re=22,000, where f is the dominant vortex shedding frequency. The result obtained in present study are St=0.118 at β=0, St=0.117 at β=0.05 and St=0.118 at β=0.1, which is almost unchanged with shear parame-

ter. In addition, the Strouhal number obtained in non-shear flow is compared with other studies at Fig. 5, which exhibits the variation of the Strouhal number with side ratio. The present result St=0.118 at non-shear flow is very close to the numerical results of Yu and Kareem (1996) with St=0.114, Bruno et al. (2010) with St=0.115, and the experimental result of Schewe (2009) with St=0.111. In addition, the result that Strouhal number does not vary significantly with shear parameter were also observed at other studies of Cao et al. (2010) on a circular cylinder and Cao et al. (2012) on a square cylinder. It seems reasonably to conclude that the shear parameter does not bring significant change to the Strouhal number although it creates asymmetry into the wake structure as shown later.

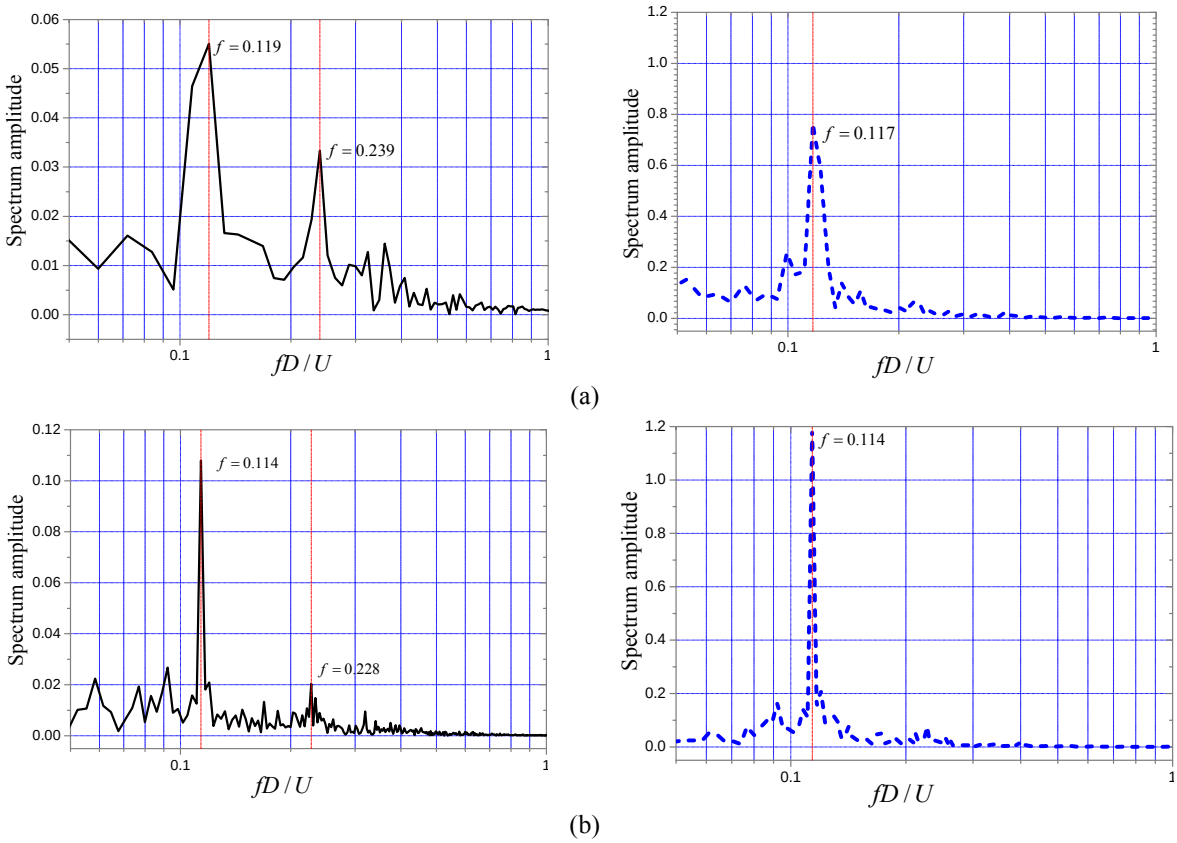

Fig. 6 Spectra of drag and lift coefficients at (a): β=0.05 and (b): β=0.1 (left: drag; right:lift)

Fig. 6 compares the power spectra of the instantaneous drag and lift coefficients at different shear parameters, β=0.05 and 0.1 at Re=22,000 for the 5:1 rectangular cylinder. The solid line shows the spectrum of drag coefficient C_D and the broken line shows that of lift coefficient C_L. Although the fluctuating lift coefficient still has one harmonic, a subharmonic has entered into the fluctuation of C_D. The strength of the subharmonic increases as the shear rate increases and it becomes dominant, resulting in the peak fluctuation frequencies of C_L and C_D becoming identical at β=0.1. A similar phenomenon was also reported in the case of a square cylinder (Cao et al. 2012).

Fig. 7 compares the instantaneous iso-vorticity surface of primary Karman vortex between no-shear and shear flows, where dashed and solid lines represents clockwise and counterclockwise vortices respectively. All the figures correspond to the moment when the lift coefficient is maximum. The vortices appears alternatively in the wake when β=0. However, with an increase in shear parameter, the counterclockwise vortices on the low-velocity side become weaker, and disappear in the far wake at β=0.1. The Karman Vortex Street is broken as result of the shear ef-

fect, but the counterclockwise vortex on the low-velocity still exists at the near wake and vortex shedding never disappears. This complicated phenomenon is also noticed by Saha et al (1999) from their two dimensional simulations on a square cylinder and Cao et al (2010, 2012) on a circular cylinder and a square cylinder. Therefore, it can be concluded that similar wake flow pattern exists for circular, square and rectangular cylinders in shear flows.

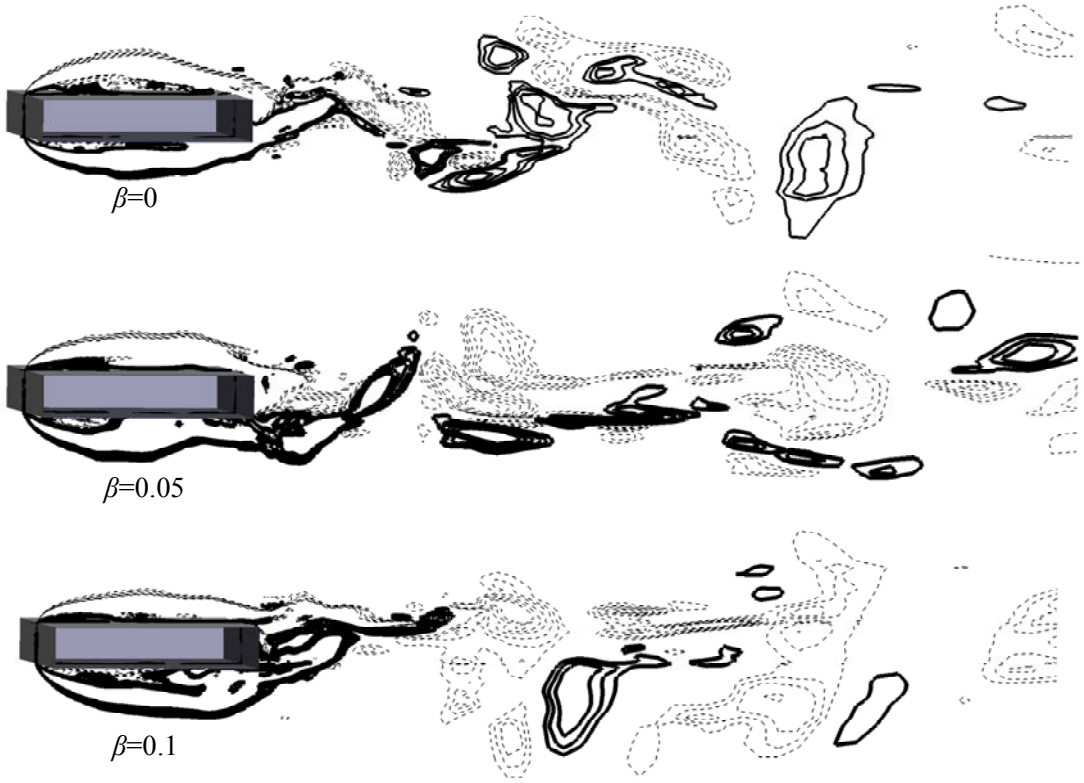

Fig. 7 Instantaneous wake structure with different shear parameters, $\omega_Z=\pm 2$

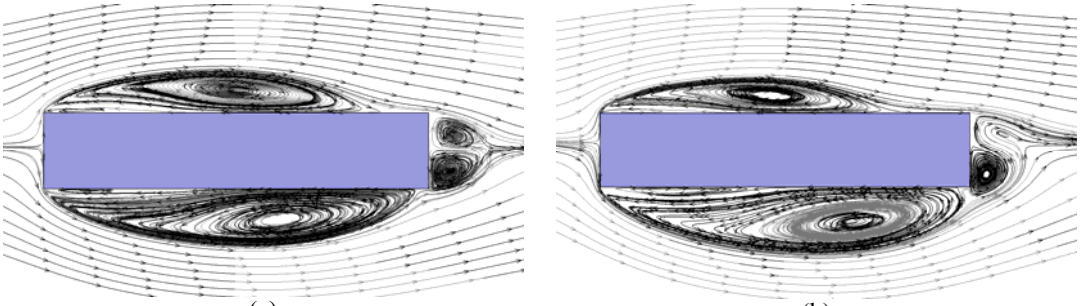
4.2 *Flow structures and Aerodynamic Forces*

The time-averaged streamlines of flow field around the rectangular cylinder with different shear parameters are compared in Fig. 8. As in the non-shear flow, the first vortex (the main vortex) and the second vortex (the bubble) can be observed both on the upper and lower sides of the rectangular cylinder in shear flow. However, they are no longer symmetric as in non-shear flow. With increase of shear parameter, the center position of the first vortex moves upstream on high-velocity side and downstream on low-velocity side respectively. Meanwhile, the first vortex on the high-velocity side becomes thinner while its counterpart on the low-velocity side becomes thicker. The mean recirculation region was not formed after the trailing edge of the cylinder at β=0.1. These complicated flow phenomena influence the aerodynamic forces on the 5:1 rectangular cylinder directly.

Fig. 9 compares the mean friction coefficient distribution around the rectangular cylinder between in shear and non-shear flows. The distribution of mean friction coefficient distribution becomes asymmetrical in the shear flow. With the increase in shear parameter, the mean reattachment length L_r on the low-velocity side increases from $L_r / D = 4.632$ （β=0） to $L_r / D = 4.850$（β=0.05）and $L_r / D = 4.868$（β=0.1），while it decreases from $L_r / D = 4.632$ （β=0）to $L_r / D = 4.469$（β=0.05）and $L_r / D = 4.073$ (β=0.1), which implies that the flow

will reattach more steadily on the high-velocity side and separate more steadily on the low-velocity side when the shear parameter is large enough.



(a) (b)

Fig. 8 Streamlines of the time-averaged flow field around the cylinder, (a) β=0.05; (b) β=0.1

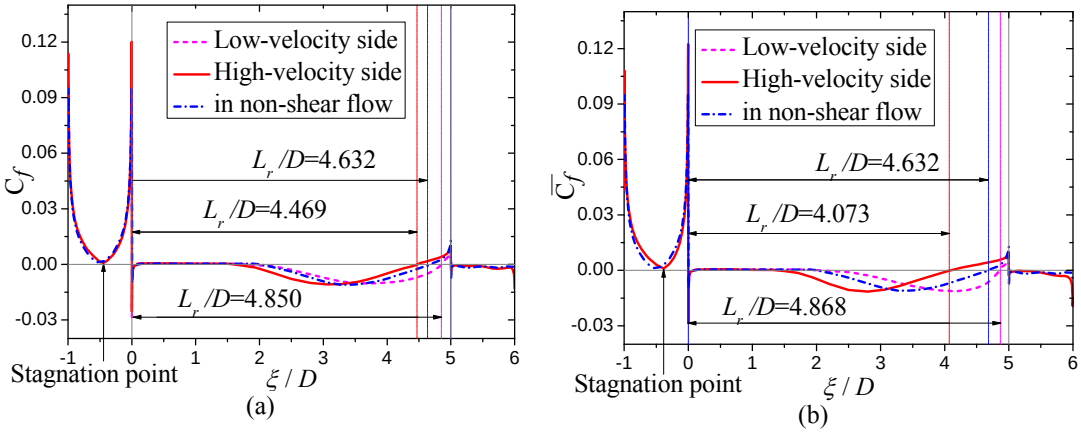


Fig. 9 Comparison on the distribution of the mean friction coefficient in shear flow and non-shear flow; (a) β=0.05; (b) β=0.1

Fig. 10 compares the mean pressure coefficient distribution around the rectangular cylinder surface in non-shear and shear flows. By the comparison in the region of $-1<\xi/D<0$ (the leading surface), it can be evidently observed that the stagnation point moves to the high-velocity side in shear flows.

As shown in Fig. 10, the value of mean pressure coefficients on the upper and lower sides in shear flows is almost the same in the region of $0<\xi/D<2.5$, in which the second vortex (the separate bubble) is formed. Thus it implies that the shear effects have little influence on determining the strength of separate bubble. However, for the region of $2.5<\xi/D<5$ where the first vortex (the main vortex) was formed, a significant deviation exists in the mean pressure distributions on high- and low-velocity sides as a result of the shear effects. Moreover, this deviation increases with the increase in shear parameter. The reason for this deviation is that the main vortex is quite different on the high- and low-velocity sides in shear flows as mentioned previously, and it suggests that the main role of shear effect plays on the large scale vortex.

For the region of $5<\xi/D<6$ (the trailing side), the mean base pressure coefficient increases with increase in shear parameter. This is similar to the finding of Onitsuka et al. (2000) in experimental study of the shear flow around rectangular cylinders with side ratio from 0.1 to 3.0.

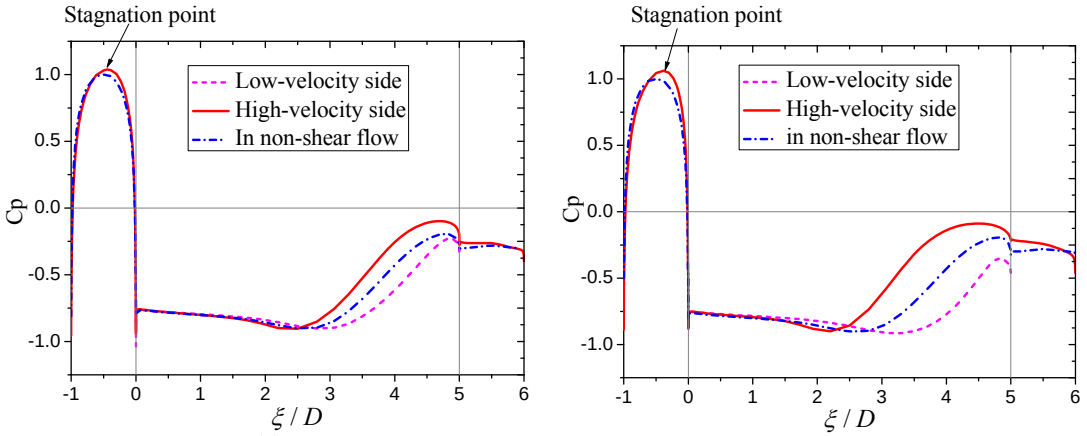

Fig. 10 Comparison of mean pressure coefficient over the rectangular cylinder surface in non-shear and shear flows, (a) β=0.05; (b) β=0.1.

Table 1 Comparison of mean and standard deviation values of aerodynamic force coefficients (normalized with respect to the body thickness D) with different shear parameters.

β	C_D	C_D'	C_L	C_L'	C_M	C_M'	T^*
0	1.100	0.082	--	0.890	--	0.773	279.5
0.05	1.128	0.090	-0.480	0.927	-0.717	0.817	213.4
0.1	1.142	0.111	-1.119	1.011	-1.405	0.867	262.1

As shown in Table 1, the direction of the lift force on a rectangular cylinder is the same to that on a circular cylinder, but opposite to that on a square cylinder. In the case of a circular cylinder, the movement of stagnation point generates a lift force from the high-velocity side to low-velocity side, while the velocity difference of the two sides has a contrary effect. The studies of Cao et al. (2007, 2010) showed that the contribution of the movement of stagnation point is dominant, and thus the lift force on a circular cylinder acts from the high-velocity side to low-velocity side. For the case of a square cylinder, the flow separates completely from leading side without flow reattachment, and the movement of stagnation point does not contribute to the lift force as shown in the simulation of Cao et al. (2012). Thus lift force direction is determined by the velocity difference and accompanying vortices with different strengths on two sides. For a rectangular cylinder with a side ratio B/D=5, the movement of stagnation point still has little influence on determining the direction of lift force. However for this kind of rectangular cylinder, the different movements of mean reattachment points on high- and low-velocity sides result in mean pressure distributions differing on two sides as shown in Fig. 15. Thus the lift force of a 5:1 rectangular cylinder acts from the high-velocity side to low-velocity side in shear flow.

5 CONCLUSIONS

In this paper, we carried out numerical simulations to investigate the aerodynamic characteristics of a 5:1 rectangular cylinder in shear flows at Reynolds numbers Re=22,000. The vortex shedding and aerodynamic forces accompanying with the complicated flow structures are studied.

The Strouhal number was found to have no significant variation in the shear parameter range of 0-0.1 at Re=22,000, which is similar to that in the case of a square cylinder and a circular cylinder. With increasing of shear parameter, the peak frequency of the drag coefficient becomes more identical to that of the lift coefficient due to the change of vortices forming behind

the back side. Although the Karmen vortex is not completely suppressed in the investigated ranges of shear parameter at Re=22,000, the Karmen vortex street in the wake is broken as a result of shear effects.

The intermittently-reattached flow becomes more stably-reattached and results in that the mean reattachment point moves upstream on the high-velocity side in shear flow, whereas it becomes more stably-separated on the low-velocity side. The stagnation point moves to the high-velocity side in shear flow, and the stagnation angle increases almost linearly with increasing of shear parameter.

Due to the movements of mean reattachment point, the mean pressure coefficient distribution over the rectangular cylinder surface is no longer symmetric. In the investigated range of shear parameter at Re=22,000, the mean value of drag force was observed to have unchanged while its standard-deviation increases with an increase in shear parameter. The mean lift force is no longer closing to zero resulting from the difference of the strength and location of the main vortices on two sides. Unlike the case of a square cylinder in a shear flow, the lift acts from high-velocity side to the low-velocity side for a 5:1 rectangular cylinder which is similar to that of a circular cylinder. However, the physical mechanism of the lift force direction of the rectangular cylinder, in which the movement of the mean reattachment point plays a dominating role to the lift force and the separation point is fixed, differs from that of the circular cylinder.

1 INTRODUCTION

Slender high rise structures are exposed to aerodynamic problems connected to the wind-structure interaction, for example vortex shedding or dynamic instability (e.g. galloping). Generally the design of these structures requires the aid of wind tunnel tests on scaled models. The paper investigates the aerodynamic behavior of a bluff body and the shape is adopted for section of the tower of a cable-stayed bridge (Fossati et al. 2011). The problem is investigated by wind tunnel tests using a rigid sectional model with particular attention on the effects related to the turbulence intensity of the incoming flow. The present paper shows the results obtained in terms of aerodynamic forces and pressure distributions for two level of turbulence, I_u=0.2 % and I_u=2 %. Vortex shedding phenomenon in these two conditions will be also discussed.

2 EXPERIMENTAL SET-UP

The sectional model has been realized scaling the reference section of the real bridge tower (1:18 scaled model). Figure 1 shows the section geometry that is characterized by two curved surfaces and cut edges. The distance D between the two plane sides represents the characteristic dimension of the model and it is equal to 0.446 m. The model has an aspect-ratio L/D equal to 8. It is manufactured using an internal structural beam covered by an external shell that reproduces the required geometry.

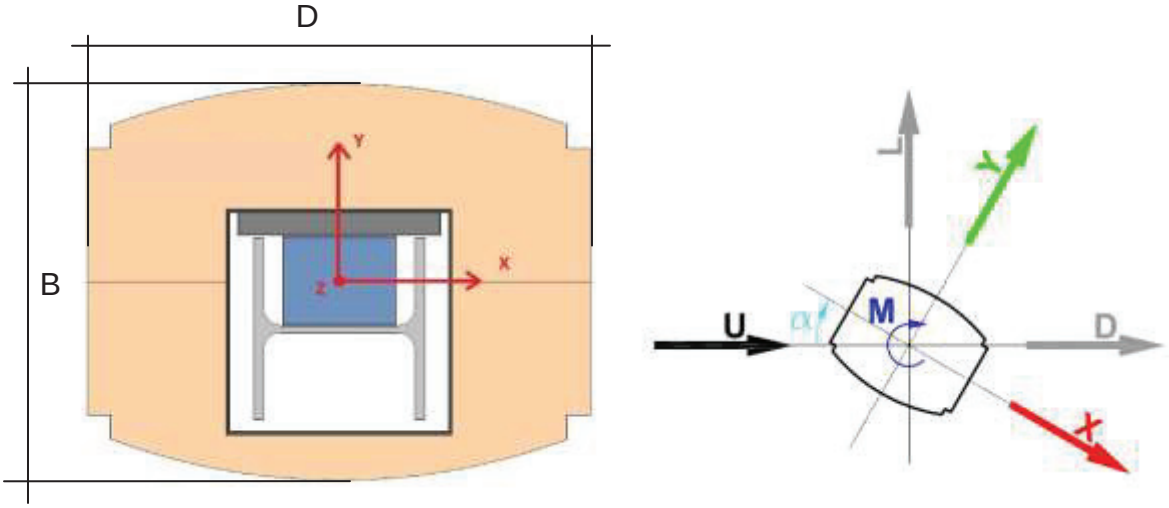

Figure 1 Section geometry: wind exposures and reference system

The external is divided in a dynamometric part, connected to the beam through a six component balance and a non-dynamometric part rigidly connected to the beam to correctly reproduce the boundary conditions for the aerodynamic forces measurements. In particular, drag

and lift forces have been considered, defined in agreement with the sketch reported in Figure 1.
Pressure taps have been placed on different sections of the non-dynamometric part in order to define surface pressure distribution. The taps were connected to high sample-rate scanners allowing high-resolution measurements of the pressure field distribution in time domain. The pressure scanners have been installed inside the model with short pneumatic connections to the pressure taps. This solution guarantees a high frequency response of the tubing system.
A total number of 96 pressure taps distributed on three different sections has been placed on the model: this configuration permit to define pressure distributions in three positions of the sectional model in order to control how the flow evolves in the axial direction. Aerodynamic forces have been obtained integrating pressure distribution along one section, and compared with the forces measured by the balance.
Experimental tests were performed in the Politecnico di Milano wind tunnel, using two different tests sections to obtain the different turbulence intensity conditions.

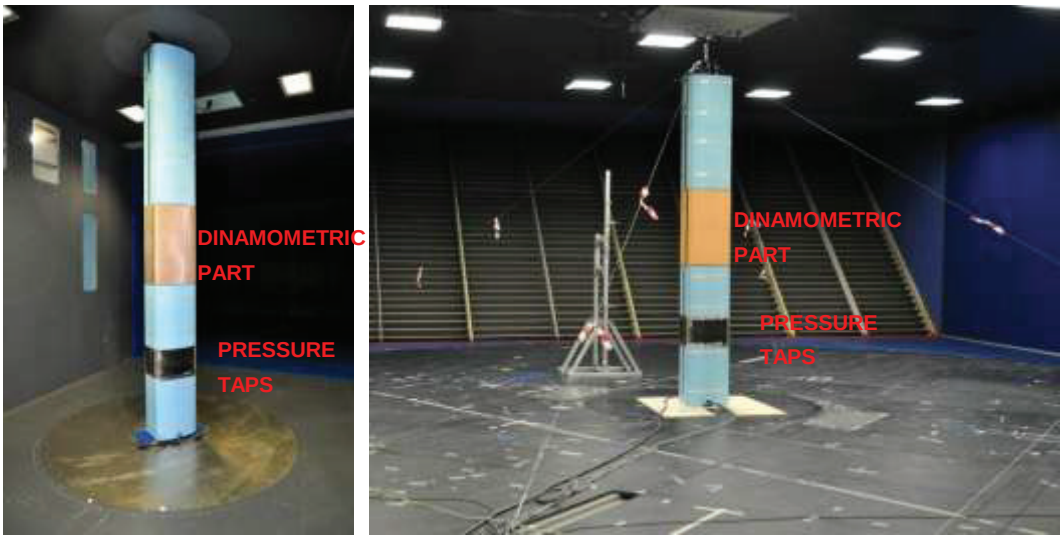

Figure 2. Wind tunnel model setup. (left) 0.2% turbulence condition (right) 2% turbulence condition

Figure 2 shows the model placed in the low turbulence tests section (left) and in the boundary layer tests section (right). Each test section is characterized by a natural value of turbulence intensity, 0.2 % and of the integral length scale L_u^x=0.01 m for the first one and 2 %, L_u^x=0.2 m for the second one. In both cases the model has been fixed on the ground obtaining a stiff structure with high structural frequencies (the lowest natural frequencies of the model are equal to 20 Hz in the low turbulence tests section and 7 Hz in the boundary layer tests section). The dynamic behavior of the model has been checked by means of two accelerometers. The model has been tested for different angles of attack as showed in Figure 1.

3 EXPERIMENTAL RESULTS

Tower sectional model has been tested for different wind exposure (0°–90°) and for different wind velocity (up to 50 m/s in the high speed/low turbulence tests section and up to 15 m/s in the boundary layer tests section). The tests highlight that no significant dependence to the wind velocity can be observed in the tower aerodynamic behavior for the studied velocity range: for this reason the results will be presented only for one wind velocity (V=15 m/s, Re=4.5 10^5). The forces have been obtained from the balance signals and they are in good agreement with the forces obtained integrating pressure distributions. Figure 3 shows the mean drag coefficient as a function of the wind exposure, measured both by the balance and by the pressure system.

Figure 4 compares the drag force coefficient measured in different turbulence intensity conditions as a function of the exposure angle. It is possible to notice that the aerodynamic behavior of the model is very sensitive to this parameter: a small increase in turbulence intensity completely changes the forces. In particular at I_u=0.2 % the drag coefficient is quite high and it become smaller increasing the turbulence intensity. A spectral analysis of the aerodynamic forces points out that the high drag condition is characterized by a well defined vortex shedding, on the other hand the low drag condition do not highlight vortex shedding phenomenon.

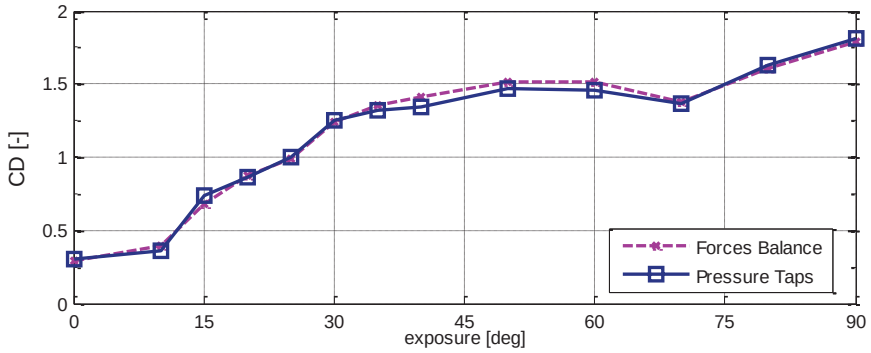

Figure 3. Comparison between drag coefficient measured by balance and pressure systems: I_u=0.2 %, Re=4.5 10^5

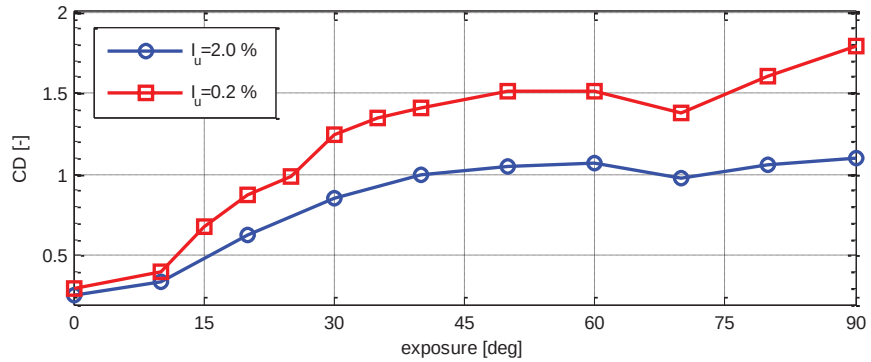

Figure 4. Drag force coefficient at Re=4.5 10^5 as a function of the angle of attack and for the two tested turbulence intensity conditions

Vortex shedding is clearly identified for exposure angles higher than 20° in I_u=2% condition, while for lower angles and lower level of turbulence no significant periodic vortex shedding can be observed.

In order to better understand the phenomenon a deeper analysis has been made for each exposure angle and in particular pressure distributions and harmonic content of aerodynamic forces have been considered. In the following the results relative to 0° and 90° of angle of attack will be presented: these two cases can be considered representative of the different phenomena observed during the tests. Moreover they can also easily related to literature data concerning the aerodynamics of rectangular prisms with different aspect ratio (Holmes. 2007). In particular at 0° the tower section is characterized by an aspect ratio B/D=1.27, while at 90° the ratio is equal to B/D=0.78. Only the case at Re=4.5 10^5 will be reported: similar results have been obtained also for different wind velocities. Only the pressure distributions measured along one section will be presented, others sections show similar results.

3.1 *Exposure angle: 0°*

The tower section at 0° does not show significant vortex shedding in both the wind turbulence conditions. Figure 5, Figure 6 and Figure 7 concern the test performed in low turbulence condition (I_u=0.2%) and they report respectively the aerodynamic coefficients time histories, the

pressure distributions at four different times and the PSD of the aerodynamic coefficients. It is possible to notice that the typical narrow band related to vortex shedding phenomenon is not visible in the time histories and in the PSD of drag and lift coefficients. The absence of a periodic vortex shedding is confirmed by the pressure distributions shown in Figure 6 in terms of pressure coefficients: four different instants have been reported in order to observe how the distribution evolves in the time. The pressure distribution does not change and especially downstream large oscillations in pressure signals have not been found.

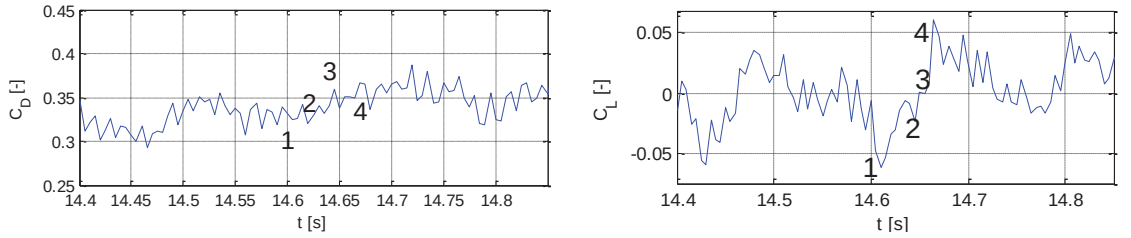

Figure 5. Drag and lift coefficients time histories zoom (I_u=0.2%, Re=4.5 10^5, exposure 0°)

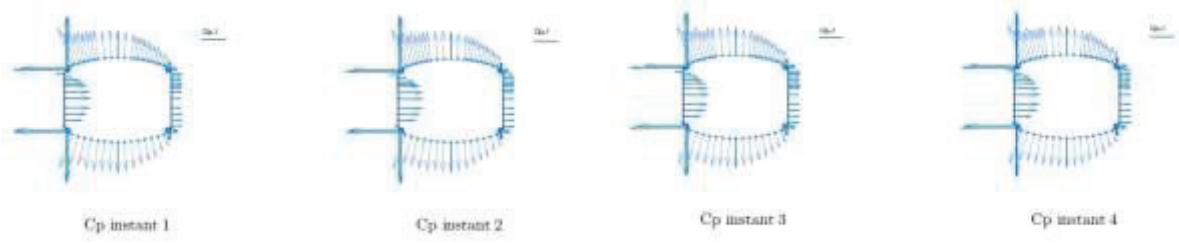

Figure 6. Instantaneous pressure coefficient on the section for the four instants identified in Figure 5 (I_u=0.2%, Re=4.5 10^5, exposure 0°)

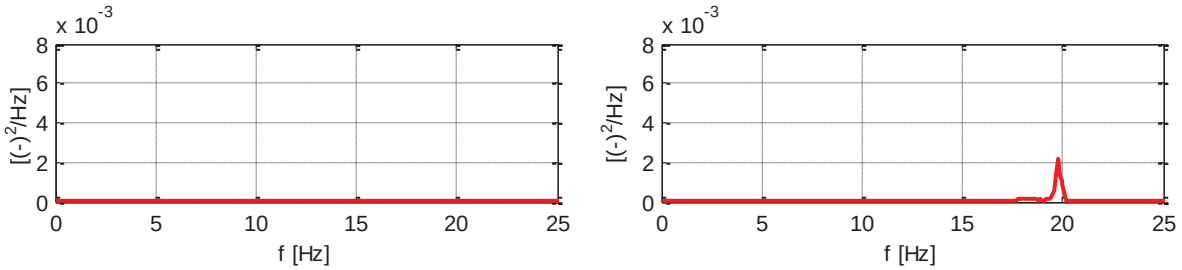

Figure 7. PSD of drag and lift coefficients (I_u=0.2%, Re=4.5 10^5, exposure 0°)

The tower section in higher wind turbulence condition shows a similar behavior compared to the one observed at I_u=0.2 % without a clear vortex shedding. In particular the pressure distributions reported in Figure 9 are comparable with the distributions reported in Figure 6 and they do not change significantly with the time. The small peaks identified in the PSD of the aerodynamic coefficients (Figure 8) and the sinusoidal shape of the drag time history (Figure 10) can be related to a buffeting excitation in correspondence of the two first natural frequencies of the model. This excitation produces small inertial forces on the dynamometric part that were measured by the balance. These peaks are not present in the forces obtained from the pressure system and they are fixed by changing wind velocity, for these reasons they cannot be considered related to vortex shedding phenomenon.

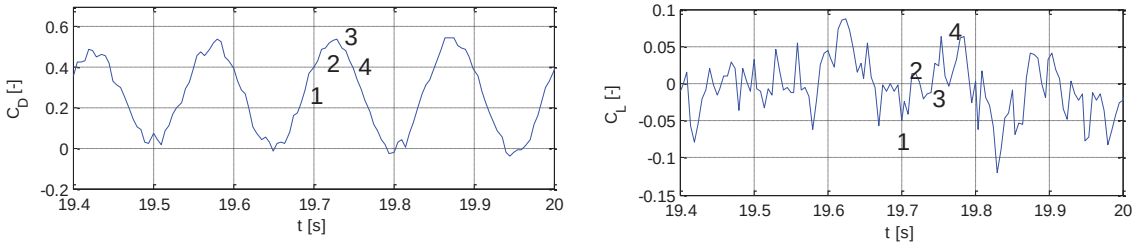

Figure 8. Drag and lift coefficients time histories zoom (I_u=2%, Re=4.5 10^5, exposure 0°)

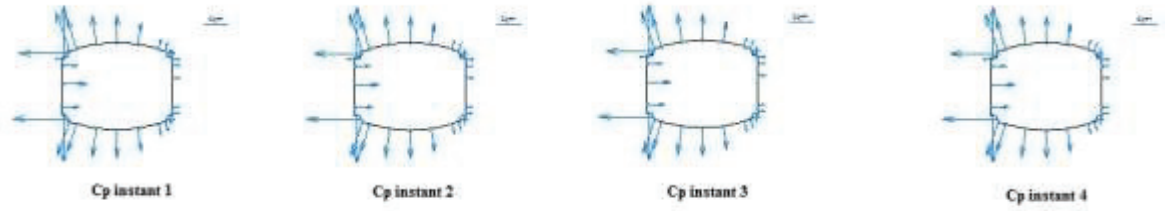

Figure 9. Instantaneous pressure coefficient on the section for the four instants identified in Figure 8(Iu=0.2%, Re=4.5 105, exposure 0°)

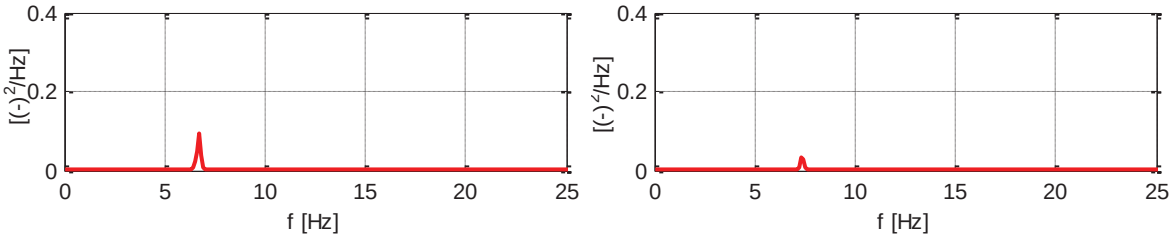

Figure 10. PSD of drag and lift coefficients (I_u=0.2%, Re=4.5 10^5, exposure 0°)

It is possible to note that there are small differences in the standard deviation of the pressure coefficients. The pressure coefficients have been represented as a function of the position along the section for the two wind turbulence conditions in Figure 11. In particular, the turbulence of the incoming wind increases the level of the fluctuating part of the pressures. Similar results have been found also in literature data (Nakamura & Ozono, 1987; Li & Melbourne, 1999; Albin wt al., 1998) considering rectangular prism: an increase in the wind turbulence move downstream the separation point reducing the wake dimension and the drag coefficient (in the presented case C_D=0.25 for I_u=0.2% and C_D=0.29 for I_u=2%).

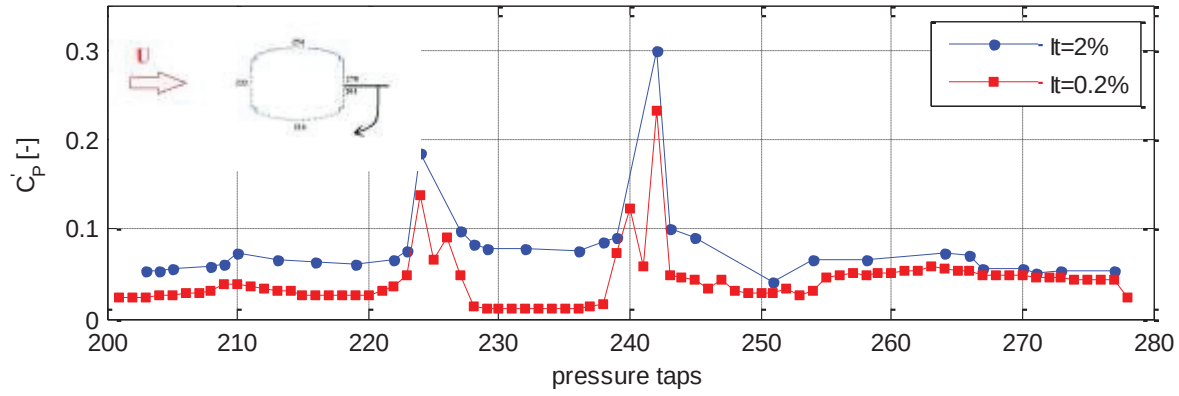

Figure 11.Pressure coefficients standard deviation Re=4.5 10^5 as a function the pressure taps for the two tested turbulence intensity conditions (exposure 0°)

3.2 *Exposure angle: 90°*

Exposure 90° is representative of the behavior experienced by the tower with and without turbulence. The tests performed in the low turbulence test section highlight a clear vortex shedding (Figure 12, Figure 13, Figure 14) while a small increase in the wind turbulence intensity completely suppress vortex shedding (Figure 15, Figure 16, Figure 17)
In particular, in low turbulence condition the lift force coefficient is characterized by a sinusoidal trend observable both in the time history (Figure 12) and in the spectrum (Figure 14). The peak is in correspondence of a frequency equal to 5.4 Hz resulting in a Strouhal number of 0.17 and the peak moves with the velocity. Also the pressure distributions (Figure 13), relative to different points of the lift coefficient cycle, are characterized by strong oscillations: the oscillation in the pressures measured along the horizontal edges are related to the oscillation of the lift force; whereas pressures measured on the downwind curved surface change in the time due to the vortex shedding.

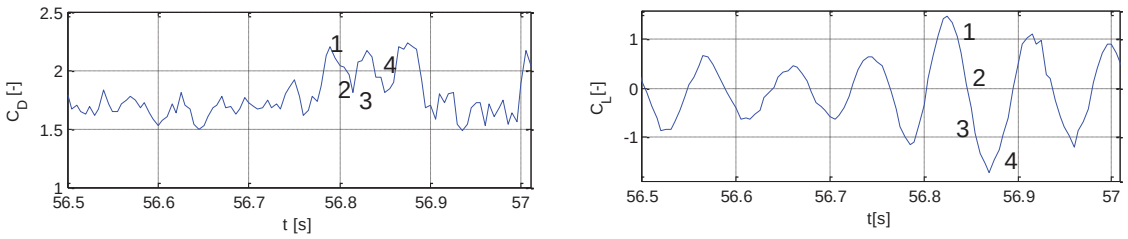

Figure 12. Drag and lift coefficients time histories zoom (I_u=0.2%, Re=4.5 10^5, exposure 90°)

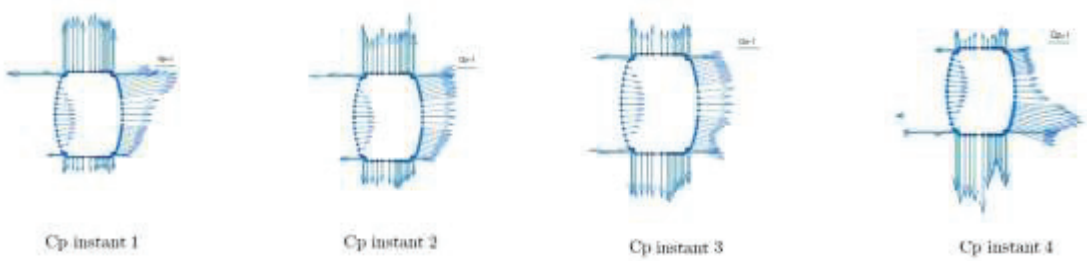

Figure 13. Ins Instantaneous pressure coefficient on the section for the four instants identified in Figure 8(Iu=0.2%, Re=4.5 105, exposure 90°)

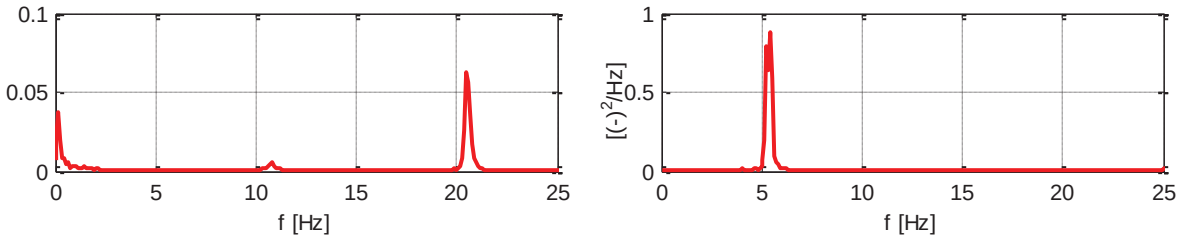

Figure 14. PSD of drag and lift coefficients (I_u=0.2%, Re=4.5 10^5, exposure 90°)

In the higher turbulence condition vortex shedding cannot be observed. The only oscillations observable are in drag and lift coefficients and they are referable to the forcing excitation that excites the first two natural frequencies of the model itself (Figure 15, Figure 17). In fact the pressure distributions do not highlight any vortex shedding phenomena with a constant trend with the time. The absence of vortex shedding also affects the wake dimension resulting in a lower drag compared to the one measured at I_u=0.2%. However, in both the turbulence condi-

tions the mean drag coefficient is higher than the one measured at 0°: this is in agreement with the trend found for rectangular prism as a function of the aspect ratio (Holmes. 2007).

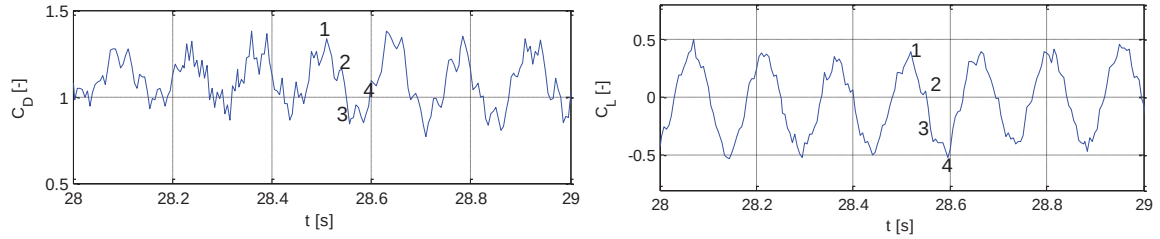

Figure 15. Drag and lift coefficients time histories zoom (I_u=2%, Re=4.5 10^5, exposure 90°)

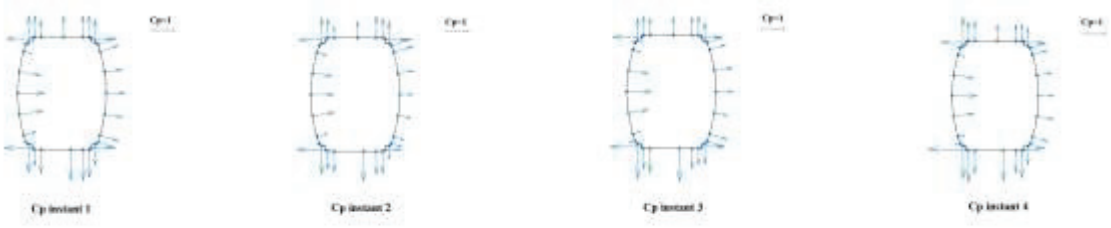

Figure 16. Instantaneous pressure coefficient on the section for the four instants identified in Figure 8(Iu=2%, Re=4.5 105, exposure 90°)

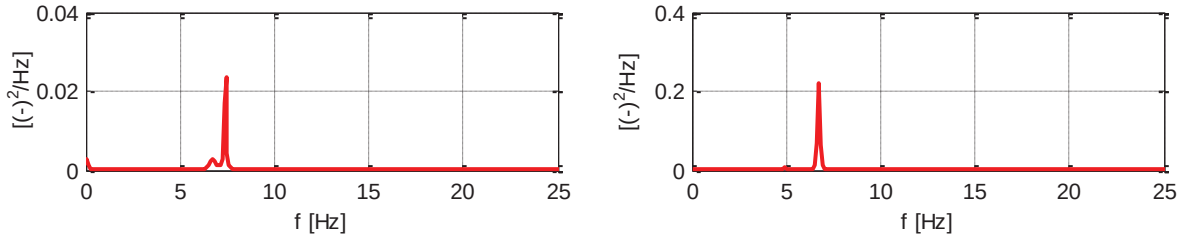

Figure 17. PSD of drag and lift coefficients (I_u=2%, Re=4.5 10^5, exposure 90°)

4 CONCLUSION

Traditionally studying bluff bodies, a dependence of the drag coefficient from Reynolds number is observed. During the experimental campaign performed on a section of a cable stayed bridge tower a wide wind velocity range has been investigated but no significant Reynolds number effects have been observed. On the other hand a strong dependence on the small scale turbulence of the incoming flow has been highlighted. In particular for some tested exposure angles it has been observed that a small increase in the turbulence intensity can completely suppress vortex shedding phenomenon.
Moreover it is author's opinion that not only the turbulence intensity influences the aerodynamic behavior of the model but also the length scale of the turbulence referred to the characteristic dimension of the considered section.

The pressure distribution characteristics of a typical bluff-section model

Banghu Qian [a], Xiaohong Hu [a], Chuanxin Hu[a]

[a]*Department of Bridge Engineering, Tongji University, Shanghai, China*

ABSTRACT: Typical bluff-section model pressure distributions are measured in the condition of fixed model as well as fluttering model with and without stabilizer in this paper. Firstly, surface pressure fluctuation characteristics of the bluff-section model during flutter are analyzed. Then, surface pressure distribution characteristics are analyzed based on proper orthogonal decomposition (POD). In the end, pressure distributions are compared between fixed model and fluttering model with and without stabilizer.

KEYWORDS: Pressure distribution, POD analysis , intrinsic mode , principal coordinate, amplitude spectrums, stabilizer

1 INTRODUCTION

Bridge flutter is one of diverging self-excited vibration. During flutter, vibrating decks are constantly absorbing energy from flowing air, which is greater than that dissipated by structural damping [1]. At present, three main methods are used in researching bridge flutter mechanism. They are flutter driving mechanism analysis method based on aerodynamic derivatives [2], flutter analysis method based on computational fluid dynamics (CFD) [3] and particle image velocimetry (PIV) analysis method[4].

In the process of long-span bridge design, it has to be ensured that structural flutter critical velocity is higher than the flutter checking velocity in order to avoid the occurrence of fatal flutter instability phenomena. Three main measures are used to improve bridge flutter critical velocity, which are: structural measures[5], mechanical measures [6] and aerodynamic measures[7] .

Aerodynamic measures improve bridge flutter critical velocity by changing aerodynamic shape. Central stabilizer is one of the common used aerodynamic measures. The control effects of central stabilizer to flutter have a great relationship with its position. For example, stabilizer control located in upstream has better effect than the downstream one. Meanwhile, control effects of the central stabilizer are strongly affected by the wind attack angle. The most unfavorable attack angles of the stabilizers with different heights are not the same. As the most unfavorable flutter critical velocity first increases and then decreases with the increasing of stabilizer height, there exists a “optimal height”[8].

After the old Tacoma Narrow Bridge was destroyed under wind in November 7th 1940, researches on structural vibration has been carried out from the aspect of the driving effect of vortex. Allan[9] and Green[10] explained the wind-damage reason from the aspect of vortex distribution and the effect on structure in the form of physical model and numerical simulation respectively. In China, Wei Zhang[4] described the vortex driving effect more clearly by obtaining vortex and its moving law around the bridge section by PIV equipments.

POD (Proper Orthogonal Decomposition) technology provides a statistical method of describing structural surface wind pressure field. It decomposes wind pressure field into intrinsic mode only relying on space covariance and principle coordinates only relying on time. POD method can find the hidden characteristics behind the known data of a series of random processes. The most advantage of this method is that it can describe a process only using a few intrinsic mod-

es, while a strong relevance lies in main mode and phenomena's mechanism[11]. Armitt[12] firstly applied POD technology to wind engineering. Zhiyong Zhou [13]applied POD technology to analyze flutter pressure distribution characteristics of box-section with inclined web. He find that one of intrinsic modes obtained from POD method has strong relevance with flutter torsional divergent motion. Its principle coordinate has the same detergency with the irrational displacement and has a predominate frequency as the flutter divergence's frequency.

In this paper typical bluff-section model pressure distributions are measured in the condition of fixed model as well as fluttering model with and without stabilizer. Firstly, analyzing primary model fluttering pressure distribution and comparing model fluttering pressure distribution's intrinsic modes with fixed model's intrinsic modes, the intrinsic modes correlated with fluttering divergent motion can be found. Then, comparing the primary model fluttering pressure distribution's intrinsic modes with barrier model fluttering pressure distribution's intrinsic modes, fluttering pressure distribution's common points and differences can be found.
rief reference to previous work on the subject.

2 BASIC MATHEMATICAL FORMAT OF POD METHOD

$p(x,y,t)$ is assumed as the function of random fluctuation wind pressure ,then, the covariance function $C(x_i,y_i,x_j,y_j)$ can be written as

$$C(x_i,y_i,x_j,y_j)=\overline{p(x_i,y_i,t)\,p(x_j,y_j,t)} \tag{1}$$

The eigenvalue problem of wind pressure covariance matrix is expressed as follows:

$$\int C(x_i,y_i,x_j,y_j)\phi_n(x_j,y_j)dx_jdy_j=\lambda_n\phi_n(x_i,y_i) \tag{2}$$

Calculated in the form of rectangular integration rule, the discrete expression of Eq.(2) can be shown as,

$$\sum_{j=1}^{N}C(x_i,y_i,x_j,y_j)\phi_n(x_j,y_j)\Delta A_j=\lambda_n\phi_n(x_i,y_i) \tag{3}$$

where ΔA_j indicates area of the jth pressure tap, Eq.(3) can be replaced by a matrix equation:

$$[C][\Delta A][\Phi]=[\Lambda][\Phi] \tag{4}$$

where $[\Delta A]=diag(\Delta A_1,\Delta A_2,\ldots\Delta A_N)$, $[\Phi]=[\phi_1,\phi_2,\ldots,\phi_N]$, $[\Lambda]=diag(\lambda_1,\lambda_2,\ldots\lambda_N)$.

As every principal minor of area matrix $[\Delta A]$ is greater than zero, $[\Delta A]$ is a positive definite matrix [14].Therefore there must be a nonsingular matrix $[T]$ meeting the following equation

$$[\Delta A]=[T]^T[T] \tag{5}$$

where $[T]=[\Delta A]^{1/2}=diag[(\Delta A_1)^{1/2},(\Delta A_2)^{1/2},\ldots,(\Delta A_N)^{1/2}]$.

Eq.(4) is substituted into Eq.(5), then Eq.(5) is left multiplied by matrix $[T]$, we can get,

$$[T][C][T]^T[T][\Phi]=[T][\Lambda][\Phi] \tag{6}$$

If assumed that

$$[D]=[T][C][T]^T,[\Phi]_D=[T][\Phi] \tag{7}$$

Eq.(6) can be reformed into

$$[D][\Phi]_D=[\Lambda][\Phi]_D \tag{8}$$

Matrix $[D]$ is a symmetric matrix, because matrix $[D]$ and $[C]$ are congruent transformation and matrix $[C]$ is symmetric

$$[D]=[T][C][T]^T=[T][C][T]^T[T][T]^{-1}=[T]([C][\Delta A])[T]^{-1} \tag{9}$$

From the deduction above, it can be seen that matrix $[D]$ and $[C][\Delta A]$ have the same eigenvalue $[\Lambda]$. The eigenvector of matrix $[C][\Delta A]$ can be represented as $[\Phi] = [T]^{-1}[\Phi]_D$.

The normalized eigenvalue can be obtained by normalizing every eigenvalue

$$\phi_n = \frac{\phi_n}{(\phi_n{}^T \phi_n)^{1/2}} \tag{10}$$

The principal coordinate corresponding relevant eigenvector can be expressed as follow

$$a_n(t) = \int \mathrm{p}(x,y,t)\phi_n(x,y)dxdy = \sum_{n=1}^{N} p(x,y,t)\phi_n(x,y)\Delta A_n \tag{11}$$

3 PRESSURE FLUCTUATION CHARACTERISTICS OF TYPICAL BLUFF-SECTION MODEL WHEN FLUTTERING

Surface pressure distributions of typical bluff-section model with and without stabilizer are measured in this paper. The cross section and pressure taps location are shown in Fig.1. The experimental study is carried out in uniform flow. The sampling rate of surface pressures is 312.5Hz, while the recorded time length is 38.4s.

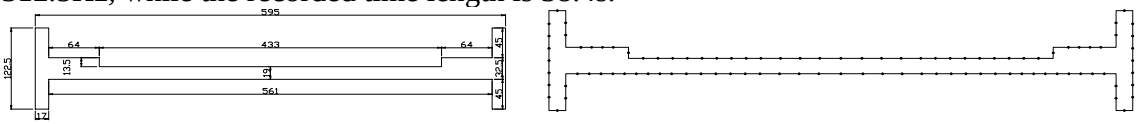

Fig.1 the cross section and pressure taps location of typical bluff-section

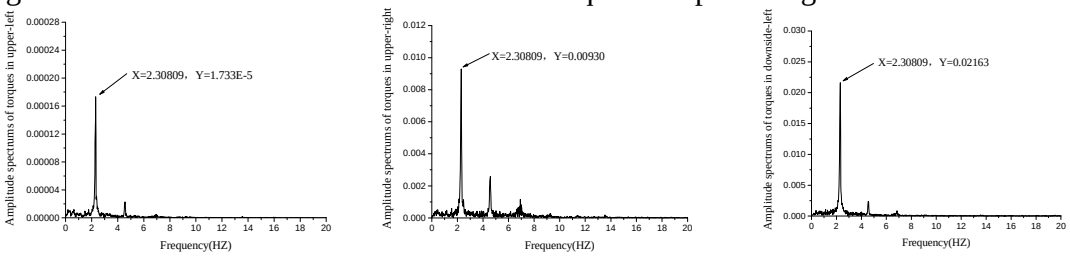
The structural bending and torsional frequencies of the bluff-section model are tested at zero wind speed, which are 1.332Hz and 2.339Hz. The flutter critical velocities of primary model with and without stabilizer are 7m/s and 8.5m/s, while the flutter frequencies are 2.308Hz and 2.310Hz correspondingly. The flutter frequency is very close to structural torsional frequency which is the typical feature of separated flow flutter.

In order to make clear pressure fluctuation characteristics of each part of fluttering model, model's surface contour is divided into six part, which are upperside-left, upperside-right,downside-left,downside-right , left -web and right-web. When bluff-section model is fluttering, the contributions to torque of each part are shown in Tab.1. The amplitude spectrums of torques in each part are shown in Fig.2. It clearly shows in Tab.1 and Fig.2 that: upperside-right and downside-left contribute most to torque. The percentage is about 90%.



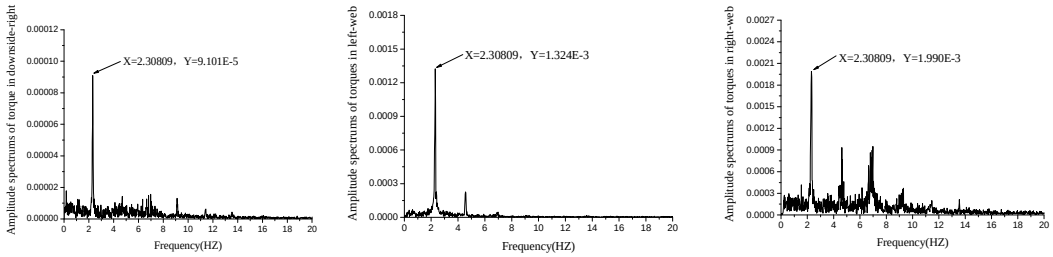


Fig.2 the bluff-section model amplitude spectrums of torques in each part

Table.1 the bluff-section model contribution to the torque of each part

Position	Contribution to torque （%）	Position	Contribution to torque （%）
Upperside-left	0.05	Downside-right	0.26
Upperside-right	27.07	Left -web	3.85
Downside-left	62.97	Right-web	5.79

4 ANALYSIS ON BLUFF-SECTION MODEL SURFACE PRESSURE BY POD

4.1 *Analysis on primary fluttering model surface pressure POD*

As 98 pressure taps are located on the cross section of the section model, covariance matrix is real symmetric matrix of 98 by 98. 98 intrinsic modes can be obtained. Flutter mechanism can be investigated by studying pressure distribution from the aspect of space and time. Because intrinsic mode represents spatial characteristics of pressure distribution and principal coordinate represents time characteristics of pressure distribution. As flutter is the movement of a single frequency, there is only one or a few surface pressure intrinsic modes which have close correlation with fluttering movement when performing POD. Considering that higher modes contain a little energy and have little effect on fluttering motion, the first 8 intrinsic modes are chosen to be analyzed.

The first 8 intrinsic modes $\phi_n(x_i, y_i)$ with their principal coordinates $a_n(t)$ and amplitude spectrums are shown in Fig.3. It can be found that principal coordinates of the 2rd to 7th surface pressure intrinsic modes from POD method have the trend of divergence. But principal coordinate which is after the 3th one have a small amplitude spectrums and have no obvious predominant frequency. The 2rd principal coordinate have an obviously divergent trend, and its amplitude spectrum has an obvious predominant frequency and great amplitude. If eigenvector can be seen as a kind of force distribution, from the 2rd intrinsic mode it can easily figure out that: resultant force is great force but little torque, which causes separated-flow-flutter. Through the 3rd section analysis it can be found: upperside-right and downside-left pressure fluctuation contributes most to torque, a great eigenvector at those parts in the 2rd intrinsic mode. From above discussion, we can reasonably infer that the 2rd intrinsic mode has strong relevance with fluttering motion.

4.2 *Contrast analysis of surface pressure of fluttering and static primary model*

Fig.4 is a contrast figure of fluttering and fixed primary model surface pressure intrinsic modes. It can be seen in Fig.4 that: the 1st mode of fluttering model is close to the 1st mode of fixed model, the 4th mode of fluttering model is close to the 3rd mode of fixed model, the 5th mode of fluttering model is close to the 6th mode of fixed model, the 6th mode of fluttering model is close to the5th mode of fixed model, the 7th mode of fluttering model is close to the 4th mode of fixed model, the 8th mode of fluttering model is close to the 2nd mode of fixed model, the 2nd and 3rd intrinsic modes of fluttering primary model have not a close one in fixed model, and the other intrinsic modes all have a close one.

(a)The 1st mode of fluttering model (left) and the 1st mode of fixed model (right)

(b) The 4th mode of fluttering model (left) and the 3rd mode of fixed model (right)

(c) The 5th mode of fluttering model (left) and the 6th mode of fixed model (right)

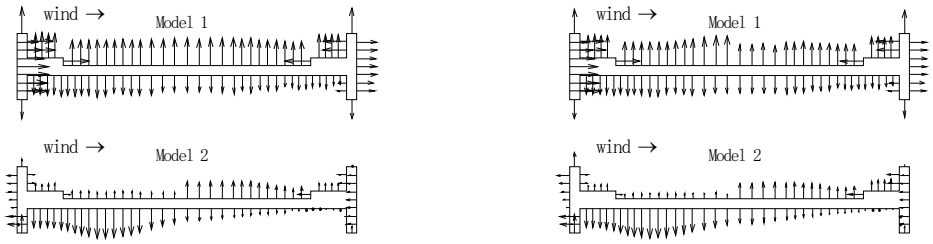
(d) The 6th mode of fluttering model (left) and the 5th mode of fixed model (right)

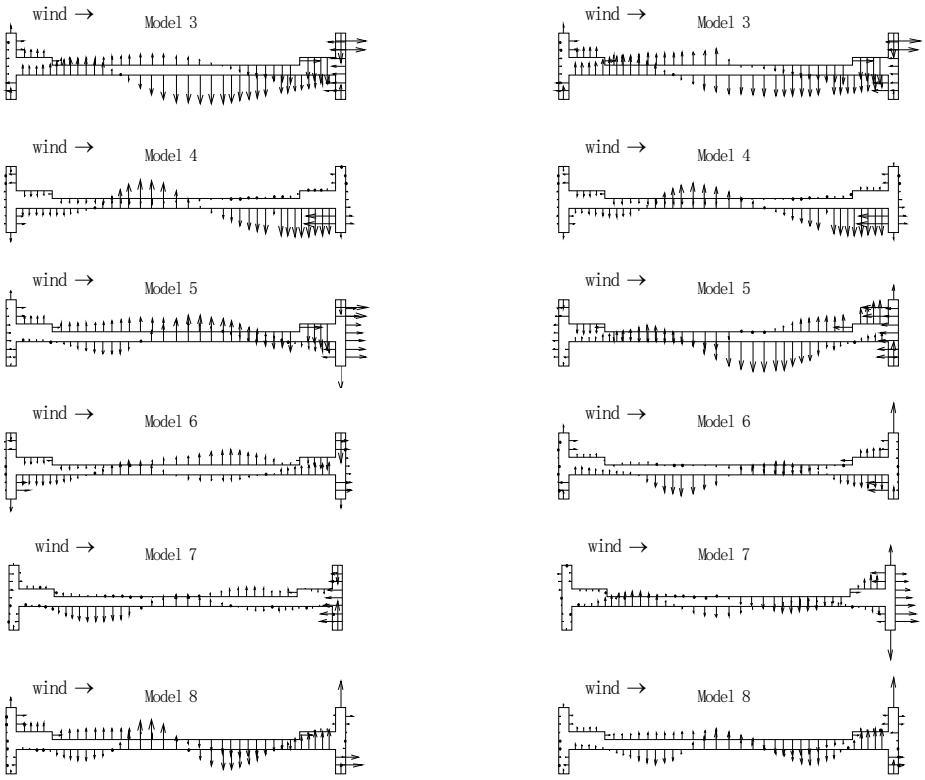
(e) The 7th mode of fluttering model (left) and the 4th mode of fixed model (right)

(f) The 8th mode of fluttering model (left) and the 2nd mode of fixed model (right)
Fig.4 contrast figure of fluttering and fixed primary model surface pressure intrinsic modes

4.3 *Contrast analysis of surface pressure of fluttering primary model with and without stabilizer*

Flutter critical velocity increases from 7m/s to 8.5m/s as 2.6cm (0.52m in actual bridge) height stabilizer is added to model's upper-middle. Fig.5 is a contrast figure of surface pressure intrinsic modes of fluttering primary model with and without stabilizer. It is shown in Fig.5 that, there is faint difference between two model's the 1st intrinsic mode, with the influence of stabilizer, the eigenvector before stabilizer is greater and after stabilizer is smaller. The 2nd to 8th intrinsic modes of both models are close to each other. Reference[13] shows that the 1st intrinsic mode represents normalized mean pressure distribution, so we can reasonably infer that stabilizer changes the mean pressure distribution as it changes model's outside shape, that is to say stabilizer have some effect on the 1st intrinsic mode while it have no effect on the other intrinsic modes.





First 8 intrinsic modes of fluttering model without stabilizer First 8 intrinsic modes of fluttering model with stabilizer

Fig.5 contrast figure of surface pressure intrinsic modes of fluttering primary model with and without stabilizer

5 CONCLUSIONS

Through surface pressure acquisition and POD analysis of typical bluff-section model with and without stabilizer, the mechanism of fluttering divergence is investigated from the aspect of pressure distribution. Some conclusions can be made, which are,

(1) Upperside-right and downside-left pressure fluctuations of bluff-section fluttering model contribute most to torque.

(2) The 2rd principal coordinate of fluttering primary model have an obviously divergent trend, and its amplitude spectrum have an obvious predominant frequency and great amplitude.

(3) The 2nd and 3rd intrinsic modes of fluttering primary model have no close ones in fixed model, the other intrinsic modes all have a close similar ones.

(4) Stabilizer only changes the mean pressure distribution by altering model's aerodynamic configuration. That is to say stabilizer has a effect on the 1st intrinsic mode while it has no effect on the other intrinsic modes.

Radial distribution of typhoon pressure fields measured by ground multi-point pressure distribution

L. Zhao, A.P. Lu, L.D. Zhu, S.Y. Cao, Y.J. Ge

SLDRCE, Tongji University, Shanghai, China, zhaolin@tongji.edu.cn

ABSTRACT: It is common at international level to predict the extreme wind speed with mature typhoon numerical model. And it is necessary to analyze the radial wind-pressure field and radial wind-speed field of typhoon in numerical simulation before the prediction. The paper analyzes the analytic model, proposed by Holland, for the radial wind-pressure field and radial wind-speed field of typhoon and discusses what influence the different values of β , distribution coefficient of radial typhoon pressure (also referred to as Holland parameter β), introduced by Holland, will produce on radial distribution of typhoon pressure and speed and it also reviews and concludes existing formulas, which have been proposed by numerous scholars, for calculating wind-pressure distribution coefficient β. We have studied and compared the values of β, which had been computed by various formulas, and their impacts on calculating results of radial typhoon pressure distribution and also compared it with the data fitting conclusions of measured pressure from ground stations, according to the Holland empirical analytic model for wind-pressure field and wind-speed field of typhoon and by using the actual air pressure data from hundreds of ground stations in Zhejiang province, China. Since the maximum wind-speed radius, central pressure differential, latitude of typhoon center and surface temperature of the ocean, all of these can affect the value of wind-pressure distribution coefficient β, further study and verification are needed to figure out which method to calculate β will work out best fitting precision for radial wind-pressure distribution of typhoon.

KEYWORDS: Typhoon; Wind-pressure field; Maximum wind-speed radius; Central pressure differential

1 INTRODUCTION

Long-span and towering structures have sprung up in coastal areas in the past few years. All of these structures are sensitive to extreme wind speed within their service life. Therefore, it is really necessary to predict the extreme typhoon speed reasonably during the reoccurrence life of target structures and thus figure out reasonable basis for safety design and risk assessment of building structures. In addition, mature prediction for extreme typhoon speed with numerical modeling is commonly used at international level. In the numerical simulation process of typhoon, it is critically important to simulate and calculate the wind field of typhoon or the radial speed distribution of typhoon (also referred to as radial wind profile of typhoon). Research results [1, 2], which are based on the sensitivity analysis method, suggest that the typhoon pressure distribution coefficient β impacts the determination of the design wind speed during the recurrence interval at the engineering site. Therefore, we make use of the actual pressure data from the hundreds of ground stations in Zhejiang province, China, study and compare the values of the coefficient β, which have been figured out by different formulas, as well as their influence on the calculated results of radial typhoon pressure distribution, and we also compare it with the fitting results of measured data from ground stations.

An accurate calculation of the radial wind profile of typhoon plays a very important part in the prediction of the extreme typhoon speed and the evaluation of typhoon disasters. Thus, a

great number of scholars have proposed their models to calculate the radial typhoon profile. However, most of the previous scholars have based the statistical fitting on measured data. They usually present the empirical formulas, such as Schloemer [3] and Atkinson [4], to calculate the radial wind profile. In 1980, Holland [5] innovatively combined the empirical function for typhoon pressure distribution, which had been obtained by Atkinsonand, Holliday and Dvorak [6], with the equilibrium equation of radial pressure gradient of typhoon cyclone, and thus figured out the analytic function model of radial typhoon speed distribution. The analytic model is better by having only one parameter, namely the typhoon radial wind pressure distribution coefficient β. But it also relies on measured data to estimate the value of β. In conclusion, the fitting results, from the numerical simulation calculation of typhoon in the Atlantic and Australia by Holland analytic model, are more accurate than those of empirical function models.

2 HOLLAND ANALYTIC MODEL

A great deal of actual measurement for radial wind pressure distribution of typhoon has been made and many measured data and information have been obtained in early years. The measured data of typhoon pressure is standardized, to remove the influence from different typhoon centers and different air pressures on the variability of measured results, shown as below:

$$\mathrm{P_{st}} = \left(P_r - P_c\right)/\left(P_a - P_c\right) \tag{1}$$

In which, P_r means wind pressure at the distance of r away from the typhoon center; P_c is central pressure of typhoon; P_a is natural air pressure, it is theoretically the pressure where r is infinitely great.

On the basis of measured data, many scholars, such as Depperman [7] and Schloemer [3], have used researches to suggest that the radial wind pressure distribution of typhoon complies with the negative exponent relationship. Holland presents them all in the following functional expression:

$$\mathrm{P_{st}} = \frac{\left(P_r - P_c\right)}{\left(P_a - P_c\right)} = \exp\left[-\left(\frac{R_{\max}}{r}\right)^{\beta}\right] \tag{2}$$

In the above formula, P_a-P_c is low pressure differential ΔP; R_{max} is maximum radius of wind speed; β wind pressure distribution coefficient, also named as Holland parameter. Eq. (2) can be transferred to Schloemer equation when $\beta = 1$.

Equilibrium equation of radial pressure gradient of typhoon cyclone:

$$\frac{1}{\rho_A}\cdot\frac{\partial P_r}{\partial r} = \frac{V^2}{r} + fV \tag{3}$$

In the equation, ρ_A = air density, kg/m^3; P_r = wind field pressure distribution function, hPa; r = radius from typhoon center, km; V = average tangential wind speed of air micelle, r away from typhoon center, m/s; f is Coriolis coefficient, $f = 2\Omega\sin\Psi$, in which Ω (radian/ s) represents the revolving speed of the earth and Ψ is the latitude of the air micelle.

It can be learned from equation (3):

$$V = \sqrt{\frac{r}{\rho_A}\cdot\frac{\partial P_r}{\partial r} + \frac{1}{4}f^2r^2} - \frac{1}{2}fr \tag{4}$$

$$V = \sqrt{\frac{\beta}{\rho_A} \cdot (\frac{R_{\max}}{r})^B \cdot [100] \cdot (P_r - P_c)} \quad (5)$$

$$V_{\max} = \sqrt{\frac{\beta \Delta P}{e \rho_A}} \quad (6)$$

Coriolis strength is much smaller than the gradient pressure of cyclone and its centrifugal force in the maximum speed region of typhoon, so the Coriolis strength is ignored. The functional expression for average tangential wind speed V at r away from typhoon center is worked out from equation (2) and (4). When r=R_{max} is obtained from $\partial V / \partial r = 0$, the average tangential wind speed reaches the maximum value.

In the equation, e = 2.71828, it is the base number of natural logarithm. [100] = hPa is converted into Pa.

Thus it can be seen that if typhoon central pressure P_c = 950 hPa, natural air pressure P_a = 1010 hPa, maximum wind speed radius R_{max} = 20 km, radial air pressure distribution and radial wind speed distribution of typhoon vary to the coefficient β, as is shown in Fig. 1 a) and b). According to Fig. 1 a), when the value of β is enlarged, the eye of typhoon becomes bigger and the wind distribution curves intersect at the maximum wind speed radius. According to Fig. 1 b), as the value of β is enlarged, horrizontal wind profile changes a lot and the wind speed becomes larger within the maximum wind speed radius but smaller beyond it. On the basis of measured data and the upper limit of the air boundary layer, Holland determined that the wind pressure distribution coefficient β be between 1.0 and 2.5. Since the wind pressure distribution coefficient β introduced by Holland numerical model takes many values, Holland numerical model applies to a larger field. It can simulate different typhoons to such a good degree that most scholars accept it.

Figure 1. The variation of radial pressure and wind speed distribution with various value of β.

3 COMPUTING METHOD OF WIND PRESSURE DISTRIBUTION COEFFICIENT

The value of wind pressure distribution coefficient β influences the computing accuracy of numerical simulation of typhoon, so scholars have made a lot of researches on it. But such researches are still few in China. There are mainly two methods to estimate the wind pressure distribution coefficient β: one is to make regression analysis on the data of ground air pressure and then to estimate the values of parameters; the other is to get the gradient velocity from the equilibrium equation of barometric gradient and then to compare it with the data of wind speed of the upper frictional layer. Vickery and others [8] compared the two methods. In the first method, the parameter β changes in different phases of typhoon and at different sites of wind field. Thus the value of Holland parameter β is hard to determine. However, this method demonstrates the varying pattern of Holland parameter β to some degree. And in the other method, Holland parameter β can be expressed by the function of central air pressure differential and maximum wind speed radius. The formulas to calculate typhoon pressure distribution coefficient β, suggested by various scholars, are introduced briefly as follows.

3.1 *Love & Murphy*

Love & Murphy [9], according to measured data of typhoon pressure from northern Australia, suggested:

$$\beta = 0.25 + 0.3\ln(\Delta P) \tag{7}$$

In the formula, $\triangle P$ is the central pressure differential.

3.2 *Hubbert and etc.*

When they analyzed the typhoon that attacked Australian coasts, Hubbert and others [10] proposed that wind pressure distribution coefficient parameter β and the smallest central pressure of typhoon P_c comply with linear relation. The expression is shown below:

$$\beta = 1.5 + (980 - P_c)/120 \tag{8}$$

3.3 *Holland & Harper*

Holland & Harper [11] suggested that, as to Australian tropical cyclone, parameter β is a liner function of central pressure differential. They also proposed an empirical equation:

$$\beta = 2.0 - (P_c - 900)/160 \tag{9}$$

3.4 *Jakobsen*

By using the empirical relationship between the maximum wind speed and the central pressure differential as well as the equation of motion, Jakobsen [12] considered the function of Coriolis force and thus put forward a formula to calculate the Holland parameter β:

$$\beta = \frac{e}{r_2^2}\frac{\rho_A}{[100]\Delta P}\left(V_{\max}\right)^2 \quad (10)$$

$$V_{\max} = [\frac{1}{3.6}]K_p(\Delta P)^{\gamma} \quad (11)$$

In the formula, e = 2.71828, it is the base number of natural logarithm; r_2 = 1.05; ρ_A = 1.15 kg/m^3; $\triangle P$ = central pressure differential, hPa; [100] = the value of central pressure differential when it is changed from hPa to Pa; V_{max} = the maximum wind speed within one minute at 500 m above sea level; K_p and γ are regression parameters, K_p = 12.36, γ = 0.73.

3.5 *FEMA*

The technical manual, in the Hazus typhoon disaster analysis software of the American Federal Emergency Management Agency (FEMA), also suggested a computing method of parameter β. This is a linear relational expression of central pressure differential and maximum wind speed radius.

$$\beta = 1.38 + 0.00184\Delta P - 0.00309R_{\max} \quad (12)$$

3.6 *Holland*

In 2008, Holland [14] proposed a new formula to calculate the wind pressure distribution coefficient β. He said that many factors, such as central pressure of typhoon and its variation to time, its moving speed, its wind speed profile and the longitude and latitude of typhoon center. The computing expression is as follows:

$$\beta = b_s(v_{mg}/v_m)^2 \rightarrow 1.6b_s \quad (13)$$

$$b_s = -4.4\times10^{-5}(\Delta P)^2 + 0.01\Delta P + 0.03\partial p_c/\partial t - 0.014\psi + 0.15V_T^{\,x} + 1.0 \quad (14)$$

$$x = 0.6(1 - \Delta P/215) \quad (15)$$

In the formula, $\partial p_c/\partial t$ = variation of central pressure strength, hPa/ h; ψ = absolute value of the central latitude of typhoon; V_T = moving speed of cyclone, m/s; V_{mg}/V_m = conversion factor from gradient wind to surface wind.

4 COMPARISON OF METHODS BASED ON AIR PRESSURE OBSERVATION

4.1 *Introduction to Air Pressure Data from Observation Stations in Zhejiang Province*

To study and verify the analytic model for radial typhoon pressure and speed distribution proposed by Holland, we compare the mentioned functional expressions for computing the typhoon

pressure distribution coefficient β, study the influence from different methods on computing results of radial typhoon pressure distribution and compare them with the fitting results of air pressure data from ground stations. A good deal of data on typhoon pressure is needed. Now we have collected a lot of measured data on wind pressure of the No.8 tropical storm Morakot from ground stations in 2009. It is demonstrated briefly as follows.

The No. 8 tropical storm Morakot was born at approximately 1,000 km away from the eastern Philippines on August 2, 2009. Its minimum central pressure was 945 hPa and the maximum average speed was 43.1 m/ s (in 10 minutes). And few typhoons in the history had had such strength. Typhoon Morakot pass through Zhejiang province from south to north. It is tracked in Graph 2. The abundant air pressure data, which has been measured by observation stations, is typical. Additionally, there are 1,000 and more ground observation stations in Zhejiang province and 270 and more stations at most recorded the landing process of Typhoon Morakot completely. Graph 3 shows the locations of these stations. Each station recorded from 21:00 on August 8 to 20:00 on August 11 and produced every hour a group of data, which includes: date, time, serial number of station, name of station, latitude (°), longitude (°), altitude (0.1 m, -9,999 means the altitude has not been measured.), average wind direction in 10 minutes (0 ~ 359), average wind speed (m/ s) within 10 minutes, maximum wind speed (m/ s) in one hour, extreme wind speed (m/s) in one hour, and air pressure of this station (-9,999 means the altitude has not been measured). The yearbooks [15] of tropical cyclones present the longitude and latitude and pressure of the center of Typhoon Morakot in every hour from 11:00 on August 6 to 20:00 on August 11.

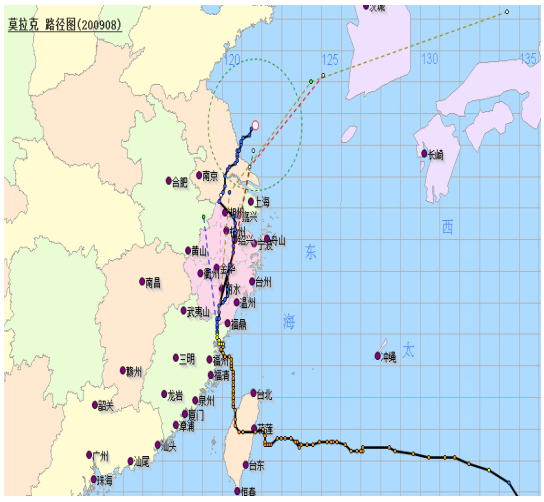

Figure 2. Path of typhoon Morakot.

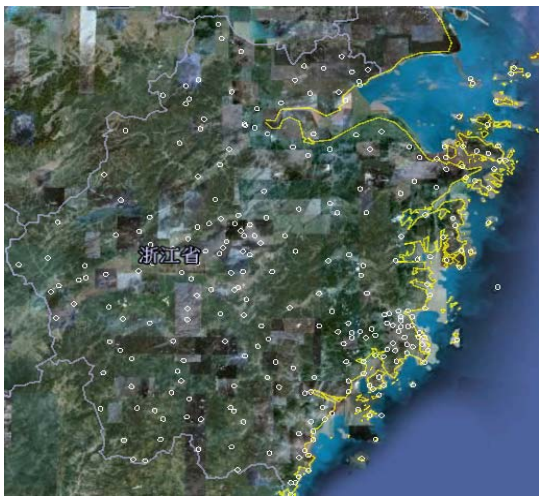

Figure 3. Locations of observation stations in Zhejiang.

4.2 *Values of Coefficient β Calculated by Various Methods and Their Comparison*

As is known, the maximum wind speed radius Rmax is needed when we calculate the typhoon pressure distribution coefficient β with different methods and study their influence on the computing results of radial wind pressure distribution of typhoon. But measured data and yearbooks for tropical cyclones do not record the measured value of the maximum wind speed radius Rmax. Therefore, the value of Rmax can be determined by the empirical functional relation, which has been obtained by Yasui [16] through fitting of measured records, between central pressure differential and maximum wind speed radius of typhoon. The following is the conditions for this relation:

(1) Central pressure of typhoon shall be smaller than 980 hPa;
(2) Distance from the center of typhoon to the engineering site shall be between 100 km and 500 km;
(3) Ground air pressure in the engineering site shall be smaller than 1,000 hPa.

$$E(R_{\max}) = 2.06\times10^{4}\,\Delta P^{-1.27} \tag{16}$$

$$\sigma(R_{\max}) = 4.4\times10^{4}\,\Delta P^{-1.76} \tag{17}$$

In the formula, E() represents the average value of R_{max} and σ() the variance.

On the basis of Holland distribution function for typhoon speed and pressure, the empirical function for Rmax determined by Yasui and yearbooks of tropical cyclones, we use calculate the value of the typhoon pressure distribution coefficient β by various functional expressions and compare the values of β. Fig. 4 shows the values of the wind pressure distribution coefficient β, which have been computed by various methods, throughout the process of Typhoon Morakot. As is seen is the graph, the values of β computed by two methods of Jakobsen and Holland change intensely while those computed by the four methods of Love & Murphy, Hubbert and etc., Holland & Harper and FEMA are relatively stable; the central pressure differentials differ a lot before 3:00 on August 10. The value of β computed by Jakobsen's method is largest and that computed by FEMA's method is smallest and the former is almost twice the value of the latter; as strength of typhoon and central differential reduces in the process, all of the values of β computed by the six methods tend to decrease.

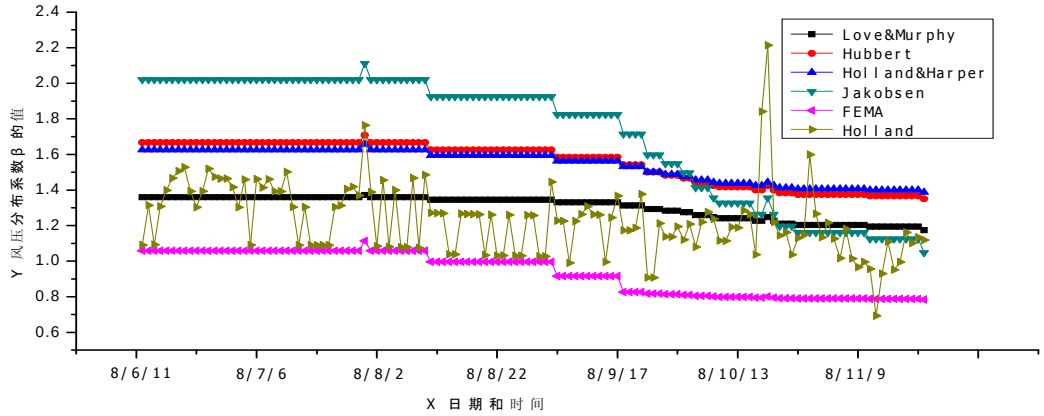

Figure 4. Values of wind pressure distribution calculated by various methods throughout typhoon Morakot.

4.3 *Influence from Different Computing Methods on Radial Typhoon Pressure Distribution*

Radial wind pressure and speed distributions of typhoon refer to the functional relationship between the wind pressure and wind speed on some profile in the center of typhoon and their distance to the center of typhoon. Fig. 5 presents the two-dimensional wind field and the radial wind speed profile of typhoon. Actually, ground observation stations cannot distribute or gather on a radial profile in the special structure of typhoon and the radius of the round vortex is usually from 500 km to 1,000 km. Typhoon can usually reach the lapse limit (15 ~ 20 km) vertically at most. The ration between the vertical and horizontal dimensions is around 1:50. Typhoon is a flat, cyclone and vertical air mass. Therefore it is considered that the wind pressure data of observation stations in two close plane regions is as same as that on a radial profile. On Fig. 6, a real point is a ground observation station; the two dotted oblique lines refer to two special planes;

the full oblique lie between the two dotted lines mean the radial wind profile of typhoon; the dots between the two oblique lines are selected ground observation stations; the quadrant box in the center refers to the center of typhoon; the wind pressure data from ground stations corresponding to these dots is exactly that of the radial wind profile; the two dotted curves represent stations furthest away from the center of typhoon and also the circle that takes the distance as its radius. In the disposal and calculation of wind pressure data from ground observation stations, we take 15 km as the distance between two planes and also between two straight lines. In consideration of landing of typhoon, its central pressure and its intense, we study the radial wind pressure distribution of typhoon at 00:00 on August 9 (before landing), 16:00 on August 9 (landing) and 16:00 on August 10 (after landing). And we reject abnormal wind pressure data from ground stations, in consideration that typhoon pressure shall be not smaller than central pressure and not bigger than barometric pressure.

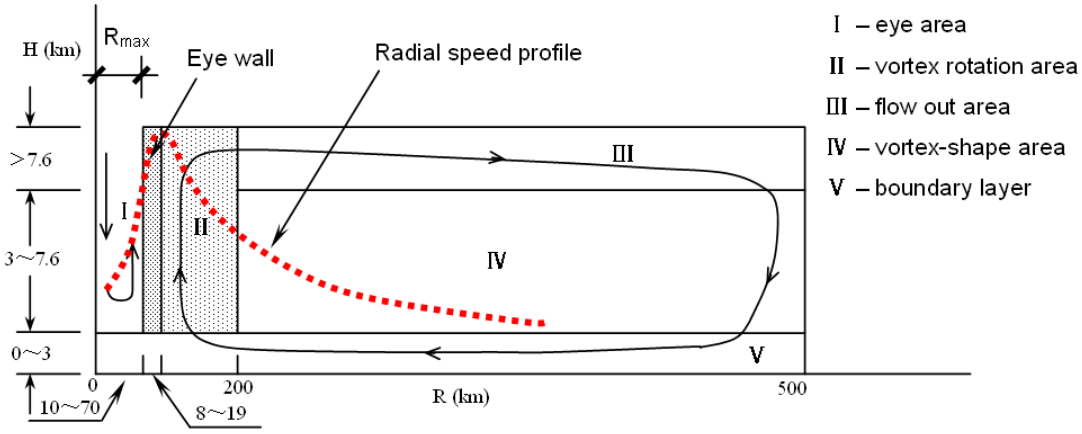

Figure 5. Wind Field Profile of Typhoon.

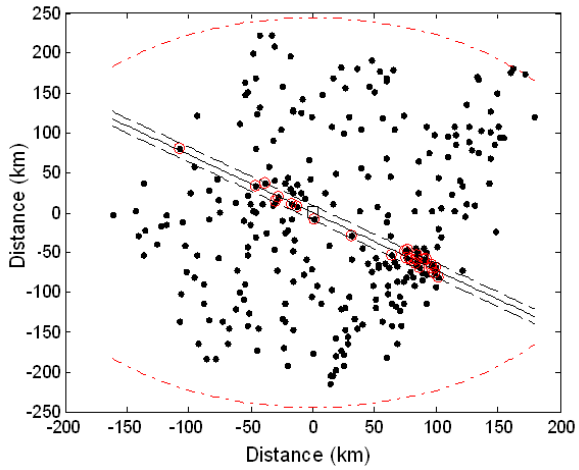

Figure 6. Selection and Disposal of Station Locations.

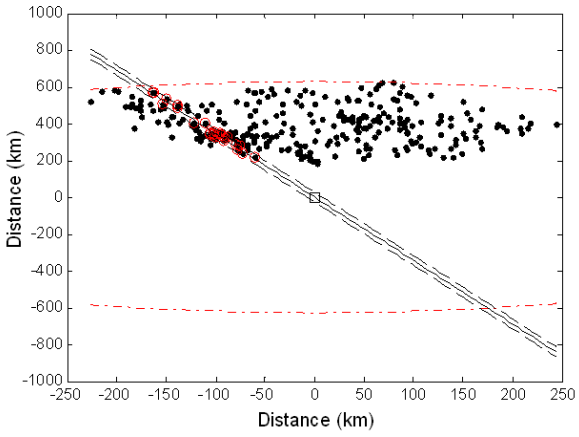
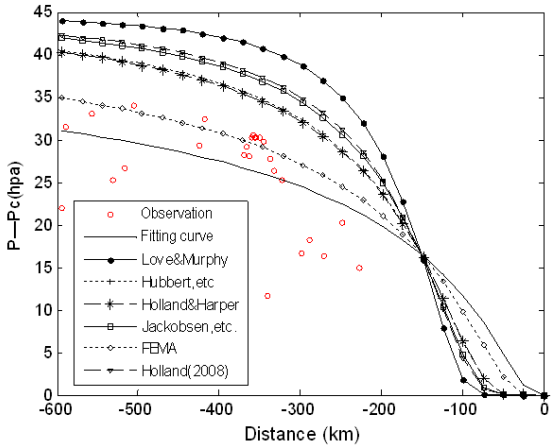
At 00:00, August 9, Typhoon Morakot did not land. Its center was 25.5° at northern latitude and 120.5° at eastern longitude. Its central pressure P_c was 965 hPa. At that time, 278 stations recorded it completely. Natural air pressure P_a was 1,010 hPa. Therefore, computing results are shown by Fig. 7a) and 7b). At the same time, the distance between two planes is considered

to be 15 km, covering 26 ground stations at most. Abnormal data is removed. And the wind pressure coefficient β is computed as 0.72 through fitting. It can be seen in Fig. 7b) that the wind pressure distribution curve, which is calculated according to Holland typhoon pressure distribution function and Yasui's empirical function of R_{max} and functional expressions of wind pressure distribution coefficient β of various scholars, differs a lot from that obtained through removal of abnormal points and fitting of measured wind pressure data. The wind pressure distribution coefficient of typhoon β=1.93, which is calculated by Jakobsen's method, is the largest one. In this method, the radius of typhoon's eye is biggest and the typhoon pressure is smallest within the region of the biggest speed but it is largest beyond this region; in FEMA method, coefficient β = 1.0, is the smallest one; radius of typhoon eye is smallest; the pressure is biggest in the region of the largest speed but smallest beyond the region. These are more similar to the measured data.

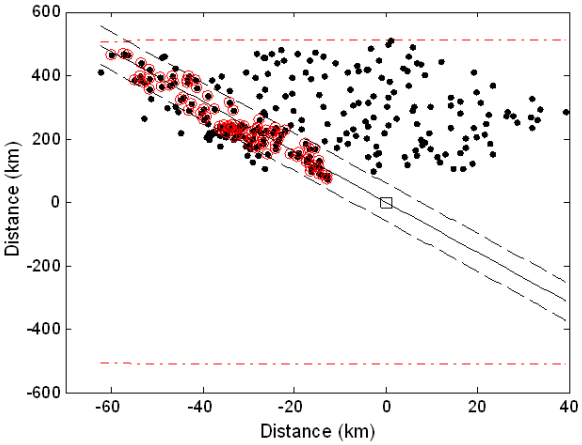


a) Selection of Station Locations

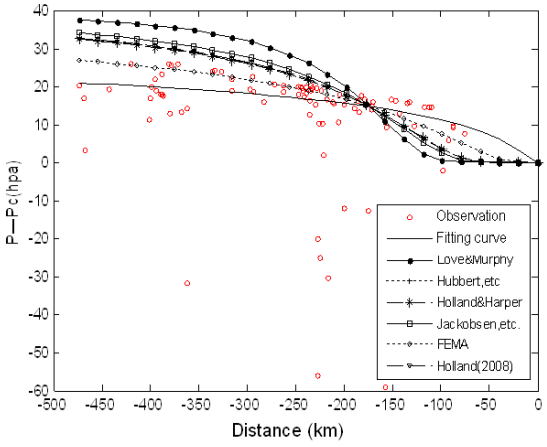


b) Radial Wind Pressure Distribution from Different Calculating Methods

Figure 7. The selection of stations and fitting process of pressure distribution (Before landfall)



a) Selection of Station Locations.



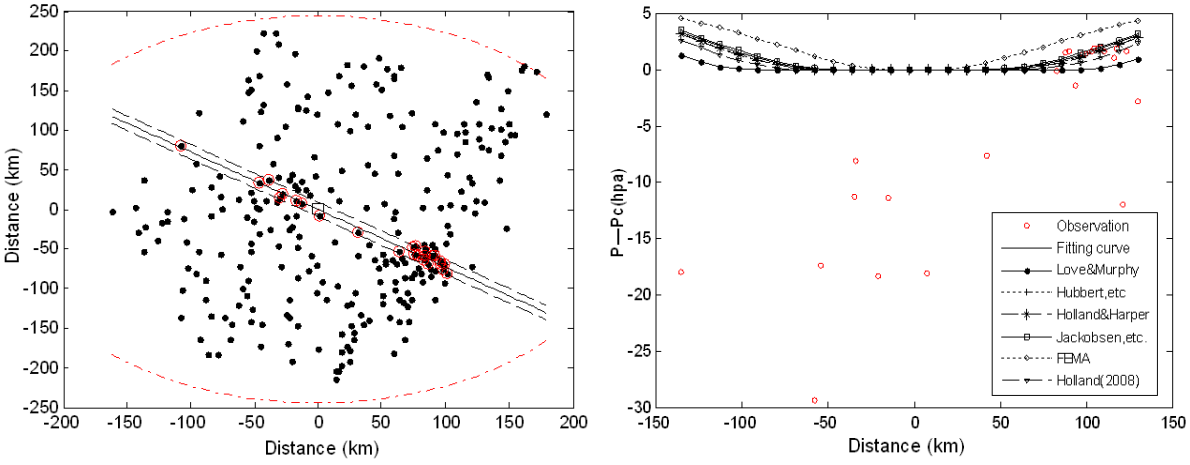
b) Radial Wind Pressure Distribution from Different Calculating Methods.

Figure 8. The selection of stations and fitting process of pressure distribution (While Landing)

When Typhoon Morakot was landing at 16:00 on August 9, the center was 26.5° at northern latitude, 119.9° eastern longitude. The central pressure P_c = 970 hPa. At that time, 252 ground stations recorded it completely. And the natural air pressure Pa was considered as 1,010

hPa. As a result, the computing results are shown by Fig. 8a) and 8b). At the same time, the distance between two planes is considered to be 15 km, covering 90 measuring stations at most. Abnormal points are disposed and the wind pressure distribution coefficient β is calculated as 0.43 through fitting. Fig. 8b) shows that the wind pressure distribution curve, which is calculated according to Holland typhoon pressure distribution function and Yasui's empirical function of R_{max} and functional expressions of wind pressure distribution coefficient β of various scholars, differs a lot from that obtained through removal of abnormal points and fitting of measured wind pressure data, similar to the situation before landing. The wind pressure distribution coefficient of typhoon β=1.82, which is calculated by Jakobsen's method, is the largest one. In this method, the radius of typhoon's eye is biggest and the typhoon pressure is smallest within the region of the biggest speed but it is largest beyond this region; in FEMA method, coefficient β = 0.87, is the smallest one; radius of typhoon eye is smallest; the pressure is biggest in the region of the largest speed but smallest beyond the region. These are more similar to the measured data. However, it is still more than twice the value of the typhoon pressure distribution coefficient β computed by fitting measured data.

Typhoon Morakot has landed at 16:00 on August 10. Its center was 29.1° at northern latitude, 120.3° at eastern longitude, close to the center of Zhejiang province. Central pressure P_c was 992 hPa. At that time, Typhoon Morakot has decreased and become a tropical storm. 275 ground stations recorded it completely. The natural air pressure P_a was considered as 1,010 hPa. Thus the computing results are shown by Fig. 9a) and 9b). At the same time, the distance between two planes is considered to be 15 km, covering 25 measuring stations at most. Abnormal data is removed and the wind pressure distribution coefficient β is computed as 1.33. Among all the methods to calculate the wind pressure distribution coefficient β, Holland's method considered it as 1.66 and it is the largest one; while FEMA considered it as 0.80, the smallest one.



a) Selection of Station Locations

b) Radial Wind Pressure Distribution from Different Calculating Methods

Figure 9. The selection of stations and fitting process of pressure distribution (After landfall)

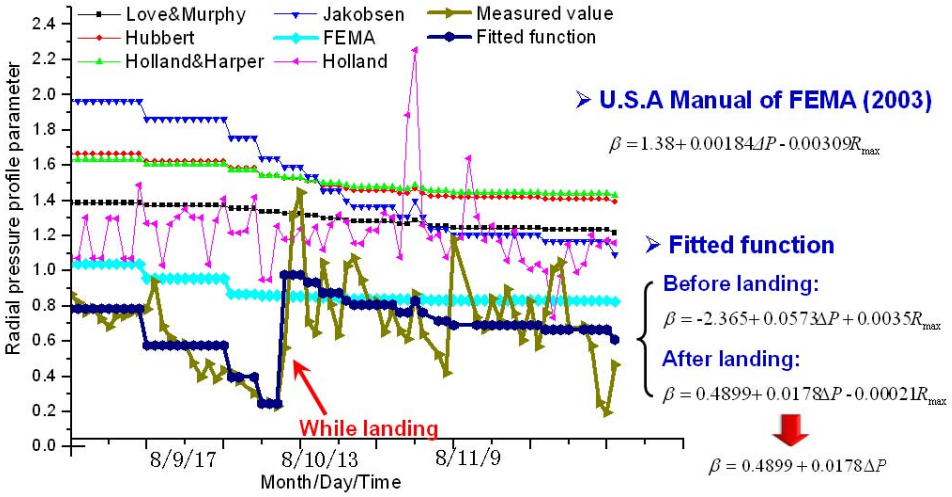


Figure 10. The variation of β with the state of typhoon landfall.

In Fig. 10, the general variation of β with the state of typhoon landfall are illustrated and compared with the other empirical results. Totally, the suggested curve from U.S.A. Manual of FEMA has the similar tendency with the observed curve, the fitted expressions of Eqs. (16) and (17) from the on-spot measurement can refinedly show the detailed change related to the state of typhoon landfall.

$$\beta = -2.365 + 0.0573\Delta P + 0.0035R_{max} \quad \text{(Before landfall)} \quad (16)$$

$$\beta = 0.4899 + 0.0178\Delta P \quad \text{(After landfall)} \quad (17)$$

5 CONLUCSIONS

For the reasons given above, by the analysis of Holland's functional model of radial wind speed and pressure distribution and on the basis of Holland's function of typhoon speed and pressure as well as Yasui's empirical function and measured data of R_{max} and through the comparison of the influence from various computing functional expressions for typhoon pressure distribution coefficient β, the following conclusions can be drawn:

1) The value of the typhoon pressure distribution coefficient β, which is introduced by Holland's functional model, influences the computing result to a large degree. It is necessary to analyze and determine the value of wind pressure distribution coefficient β at the engineering site on the basis of measured data.

2) The values of the coefficient β computed with different functional expressions differ a lot from each other. And the largest is likely to be twice the smallest one.

3) The wind pressure distribution curve, which is calculated according to Holland typhoon pressure distribution function and Yasui's empirical function of Rmax and functional expressions of wind pressure distribution coefficient β of various scholars, differs a lot from that obtained through removal of abnormal points and fitting of measured wind pressure data. It is necessary to work out a functional expression, which suits China's coast situation, to compute wind pressure distribution coefficient β.

4) Comparison between computing results and measured data shows that the computing method for the coefficient β, which is proposed by the technical manual of the Hazus typhoon disaster analysis software of the FEMA, can be used if the data of radial profile of air pressure is out of access. The wind pressure distribution curve obtained by this method is very similar to that obtained through fitting of measured data. But this conclusion needs studying and verifying further.

Evaluation of time history of design wind speeds and directions using typhoon model and empirical wind speed ratio

Masahiro MATSUI [a], Takeshi OHKUMA [b], Yukio TAMURA [a]

[a] *Tokyo Polytechnic University, 1583 Iiyama, Atsugi, Kanagawa, JAPAN*
[b] *Kanagawa University, 3-27-1 Rokkakubashi, Kanagawa-ku, Yokohama, JAPAN*

ABSTRACT: A modified method is proposed for calculating the temporal variation of wind speeds and directions during a typhoon to estimate wind load effects on energy-consuming structural devices and cumulative fatigue damage under an extreme typhoon event. This method is based on the concept of scenario-based design wind speed. It utilizes parameter scaling, and consists of selecting a seed typhoon that has affected the target site, identifying its parameters, modifying them and calculating the temporal change of wind speeds and directions of a virtual typhoon. A calculation example is shown. The calculated temporal wind speeds give the same maximum wind speed as the design wind speed and realistic temporal variations based on meteorological considerations. This method is an extension of what proposed by Matsui et. al. (2010).

KEYWORDS: scenario-based design wind, typhoon model, empirical wind characteristics

1 INTRODUCTION

Conventional wind resistant design consists of setting the design wind speed, calculating the maximum response under that wind speed, evaluating the wind load effects, and checking that they are within required criteria or allowable limits. The design wind speeds are prescribed in regulations or recommendations, and have been estimated from extreme value statistics obtained from historical observed records and special considerations of local wind climates. For example, in Japan, the recommendations for loadings on buildings take typhoon effects into account (AIJ, 2004). The estimated design wind speeds are annual maximum wind speeds under standard observed conditions. The standard conditions are 10-minute mean at 10m above flat and open terrain.

Maximum load effects, e.g. maximum stresses, maximum deformations and maximum accelerations, can be evaluated from maximum wind speeds only. However, for some structural devices these effects need to be evaluated from the viewpoint of energy consumption or cumulative damage. To evaluate these types of devices, the total wind application time or temporal variation of one extreme wind event is required. Existing references, recommendations and regulations do not provide this kind of information.

Matsui et. al. (2010) discussed the problem and proposed the method of how to estimate temporal variations of wind speeds whose maximum values are the same as the design wind speeds under extreme wind events by applying a typhoon model and scaling parameters. This is especially important because typhoons are the most predominant events in the north-west pacific area. The proposed method was based on the concept of a scenario-based design wind speed, so to speak. In this paper, calculation of wind directions is extended to the previous method. Estimations of used values of parameters were shown by comparing with the historical statistics of parameter distributions.

2 EVALUATION OF METHODOLOGY

2.1 *Outline of Procedure*

The proposed method follows a set procedure: selecting a seed typhoon that has affected the target site, identifying its parameters, modifying them, and calculating the temporal change of wind speeds of a virtual typhoon. The calculation utilizes parameter scaling.

2.2 *Original Typhoon Records and Identification of Pressure Parameters*

The first step of the procedure is to select as a seed a remarkable typhoon that has affected the site and to collect its observed records. This typhoon and its observed wind speeds are referred to as a seed typhoon (or an original typhoon) and seed wind records (or original records) hereafter.
The second step is to identify the typhoon's parameters: central pressure depth D_P, radius of maximum wind R_M, translation speed C, etc. These parameters are identified using observed atmospheric pressures around the typhoon's path and applying Schloemer's empirical formula (Schloemer, 1954),

$$P(r) = P_C + D_P \exp(-\frac{R_M}{r}) \tag{1}$$

to fit the distributed atmospheric pressure records.

2.3 *Calculating Temporal Variation of Virtual Typhoon Wind Speeds*

The virtual typhoon is assumed to move along the same path as the seed typhoon. The virtual typhoon's parameters are changed from their original values so that it shows the same maximum wind speed as the design wind speed.

Let $U_{s\text{-}obs}$ and U_{syn} be the wind speeds under the seed and virtual typhoons. These wind speeds are assumed to be those under concentric circle typhoon pressure fields (for seed and virtual typhoon winds, $U_{s\text{-}typ}$, and U_{typ}, respectively), large scale topographical effects and aerodynamic roughness effects of the ground surfaces. The large scale topographical effects and aerodynamic roughness effects of the ground surfaces on the wind speeds are assumed to be linear, and are indicated by E_{env}. These conditions are expressed as,

$$U_{s-obs} = U_{s-typ} \cdot E_{env} \quad , \tag{2}$$

$$U_{syn} = U_{typ} \cdot E_{env} \quad . \tag{3}$$

The wind speeds under concentric circle typhoon pressure fields are calculated from the typhoon model.

If the large scale topographical effects and aerodynamic roughness effects of the ground surfaces are assumed to be identical in equations (2) and (3), equation (2) is expressed as

$$U_{syn} = \left(U_{typ} / U_{s-typ}\right) \cdot U_{s-obs} \quad . \tag{4}$$

Assuming that the temporal variation, whose period is longer than that of the spectral gap pointed out by Van der Hoven (1957), is organized according to the pressure field's movement, the time scale of the seed record is transferred into the value of the virtual typhoon through the non-dimensional time τ.

$$\tau = T/(L/U) \quad , \tag{5}$$

where T, L and U are the reference values of time, length and velocity scales relevant to the typhoon pressure field.

In order to decide the combination of parameters, effects of parameters' perturbations give good references.

$$\begin{aligned} U_{syn} &= U_{typ}/U_{e-typ} \cdot U_{e-obs} \\ &\approx U_{e-obs} + \frac{\partial U_{e-typ}}{\partial D_P}(D_{P-typ} - D_{P-e}) + \frac{\partial U_{e-typ}}{\partial R_M}(R_{M-typ} - R_{M-e}) + \frac{\partial U_{e-typ}}{\partial C}(C_{typ} - C_e) \end{aligned} \tag{6}$$

2.4 *Evaluation of wind direction*

In the previous procedure, wind speed field $\boldsymbol{U}=(u, v)$ on the horizontal plane can be expressed as complex number $\boldsymbol{U}=u+v\mathrm{i}$, where $\mathrm{i}^2=-1$, the wind speed U in equations (1) to (4) is described as the following polar expressions, equation (7), and Φ in the same equation corresponds the wind direction.

$$\boldsymbol{U}=u+v\mathrm{i} = U\exp(\mathrm{i}\Phi), \tag{7}$$

where, $U = (u^2+v^2)^{1/2}$, $\Phi = \tan^{-1}v/u$.

Not only wind speeds (u, v), but also the factor E_{env} should be treated as complex number. The wind speeds and directions can be treated at once in equations (1) to (4) by this extension.

2.5 *Effect of averaging time*

As the averaging time of wind speed is fixed, e.g. 10 minutes, generally, the transformation of the temporal scale by equation (5) requires consideration on the averaging time of the synthesized wind speeds. In this study, the averaging time, 10 minutes, is assumed ranged in the "spectral gap", after Van der Hoven (1957).

If the averaging time of the original wind speed records is 10 minutes, in case that the temporal scale is prolonged, the temporal scale of the synthesized wind speed is more than 10 minutes. In this case, as the maximum wind speed is ensured by the given condition, the entire wind speeds tend to be estimated slightly higher values. In case that the temporal scale is shortened, on the other hand, the averaging time of the synthesized wind speed is less than 10 minutes. The wind speeds should be averaged by 10 minutes and the maximum would be reduced. It requires re-estimation of combination of parameters for higher wind speeds.

2.6 *Model of Typhoon Wind Field*

The typhoon wind field model employed here is Meng's model (Meng et.a al., 1997).

In a typhoon's boundary layer, the vertical wind speed and directional profiles (wind speed and direction, $u(z)$, $\theta(z)$) are given as

$$u(z) = u_G(z/z_G)^{\alpha_u} , \tag{8}$$

$$\theta(z) = \theta_G + \theta_S(1.0 - 0.4z/z_G)^{1.1}, \tag{9}$$

where u_G, θ_G are gradient wind speed and direction; α_u is the power law index; and z_G is the gradient height. The power law index α_u and the gradient height z_G are expressed as functions of the absolute vorticity f_λ and the surface Rosby number $\mathrm{Ro}_\lambda(=u_G/f_\lambda z_0)$. Inflow angle θ_S is a function of the homogeneity of vorticity ξ and the surface Rosby number.

$$\alpha_u = 0.27 + 0.09\log z_0 + 0.018\log^2 z_0 + 0.0016\log^3 z_0, \tag{10}$$

$$z_G = 0.06\frac{u_G}{f_\lambda}(\log R_{O_\lambda})^{-1.45}, \tag{11}$$

$$\theta_S = (69 + 100\,\xi)(\log R_{O_\lambda})^{-1.13}, \tag{12}$$

$$f_\lambda = \left(\frac{\partial u_G}{\partial r} + \frac{u_G}{r} + f\right)^{1/2}\left(\frac{2u_G}{r} + f\right)^{1/2}, \tag{13}$$

$$\xi = \left(\frac{2u_G}{r} + f\right)^{1/2} \Big/ \left(\frac{\partial u_G}{\partial r} + \frac{u_G}{r} + f\right)^{1/2}, \tag{14}$$

The gradient wind direction θ_G is assumed to be parallel to the isobar. The gradient wind speed u_G is evaluated by Meyers and Markin's formula (1961) as

$$u_G = \frac{C\sin\theta_r - fr}{2} + \sqrt{\left(\frac{C\sin\theta_r - fr}{2}\right)^2 + \frac{r}{\rho}\frac{\partial P(r)}{\partial r}}, \tag{15}$$

where C and θ_r are translation speed and direction of a typhoon and f is the Coriolis parameter.

3 EXAMPLE OF CALCULATION

3.1 *Calculation of Temporal Variation of Design Wind Speeds due to Virtual Typhoon at Haneda AMeDAS (Automated Meteorological Data Acquisition System) Site*

The historical records of maximum wind speeds at the site are listed in Table-1. Typhoon MA-ON(T0422) was selected as a seed typhoon, during which the highest wind speed was recorded at Haneda AMeDAS. The typhoon's path is shown in Figure-1.

Since the observation conditions at Haneda AMeDAS were the same as the standard conditions, i.e. observation height 10m and open terrain exposure (terrain category II in the AIJ recommendations), the target wind speed was the right value of the design wind speed 42.5 m/s. After repeated tunings of parameters, following conditions were found in which the maximum wind speed was identical to the design wind speed. The central pressure depth was 1.83 times and translation speed was 0.5 times the original typhoon's values.

The time histories of wind speeds and directions under these conditions are shown in Figure-2 a) and b). To decide the combination of parameters, the sensitivity maps shown in Figures-2 to 3 (Matsui et. al., 2010), are utilized.

Table-1 Historical daily maximum wind speed at Haneda AMeDAS (Automated Meteorological Data Acquisition System)

order	daily maximum wind speed (m/s)	wind direction	date	affecting typhoon
1	29	NNE	Oct. 09, 2004	T0422
2	27	SSE	Sept. 07, 2007	T0709
3	24	SW	Dec. 05, 2004	
4	24	W	Oct. 01, 2002	T0221
5	23	NE	April 18, 2008	
6	23	SSW	June 20, 1997	T9707
7	23	S	Dec. 05, 1996	
8	23	NNW	Sept. 22, 1996	T9617

Figure-4: Synthesized temporal wind speed and direction
Site: Haneda AMeDAS, original typhoon: T0422, MA-ON

3.2 *Estimation of typhoon pressure parameters in the calculation*

The typhoon pressure parameters used in the previous sections are estimated from the historical statistics of the parameters around observation site.

For historical typhoons passed inside 500 km from Tokyo for 40 years, their parameters, central pressure depth D_P, radius of maximum winds R_M and translation speed C were estimated and their distributions and correlations are shown in Fig.5. Their probability distributions can be fitted well by log-normal distributions. The correlations of them are not so high.

The values of parameters used in the calculations are also shown in Figure-5. The central depth is around 98% probability of non-exceedance and almost the maximum of all records. The used value of radius of maximum winds is smaller values in the distributions. The used value of translation speed is relatively low value among the distribution. As shown here, the procedure can show the estimation of the virtual typhoon for design wind speed.

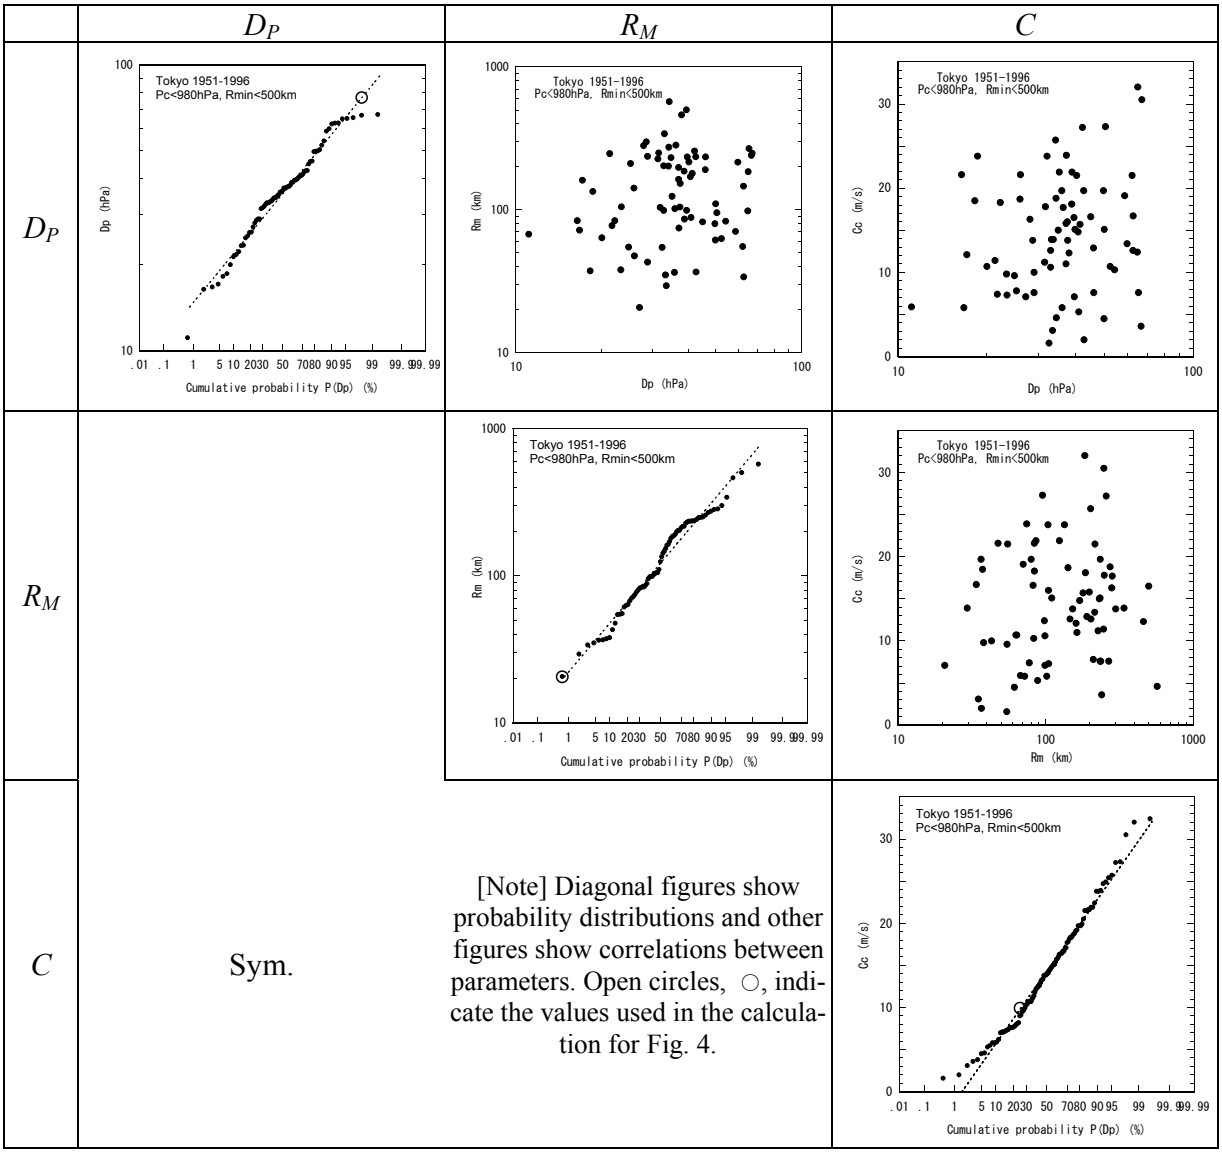

Figure-5: Statistical characteristics of historical typhoon pressure parameters, D_P, R_M and C for typhoons passing inside 500 km from Tokyo for 40 years.

4 CONCLUDING REMARKS

A method has been proposed for estimating the temporal variation of design wind speed and direction under typhoon conditions based on the concept of scenario-based design wind speed. This method utilizes parameter scaling, and consists of selecting a seed typhoon that has affected the target site, identifying its parameters, modifying its parameters and calculating the temporal change of wind speed of a virtual typhoon.

A calculation example has been shown and the effects of modifying the typhoon's pressure parameters have been studied. The calculated temporal wind speeds gave the same wind speeds as the design wind speeds and realistic temporal variations based on meteorological considerations.

The relationship between calculated maximum wind speeds and modification ratios of typhoon pressure parameters can be a useful guide for selection of parameter combinations.

The selected typhoon pressure parameters were estimated based on the statistical distributions of the historical typhoon parameters.

The proposed method can provide time histories of design wind speeds and directions with clear background on the physical image of the design typhoon models.

Statistics-based investigation on typhoon transition modeling

Shuoyun Zhang [a], Kazuyoshi Nishijima [b]

[a] *IBK, ETH Zurich, Zurich, Switzerland*
[b] *Department of Civil Engineering, Technical University of Denmark, Lyngby, Denmark*

ABSTRACT: The present study revisits the statistical modeling of typhoon transition. The objective of the study is to provide insights on plausible statistical typhoon transition models based on extensive statistical analysis. First, the correlation structures of the typhoon transition are estimated in terms of autocorrelation function (ACF) and partial autocorrelation function (PACF). This facilitates to specify a set of plausible models for further investigation. Then, the corrected Akaike Information Criterion (cAIC) is applied to investigate the relative goodness of fit of these models. The spatial inhomogeneity and the seasonality are taken into account by developing the models for different spatial grids and seasons separately. An appropriate size of spatial grids is investigated. The statistical characteristics of the random residual terms in the models are also examined. Finally, Monte Carlo simulations are performed to investigate the overall performance of the proposed model.

KEYWORDS: Typhoon transition, statistical analysis, spatial inhomogeneity, seasonality, non-normality, model selection.

1 INTRODUCTION

The methodology for probabilistic modeling of typhoon hazard and risks has experienced significant progress in the last few decades. Based on the methodology, probabilistic models have been developed. Presently, a spectrum of probabilistic models are available and widely utilized as a tool to quantify and manage typhoon risks in different contexts. Successful applications include the determination of design wind loads on structures and the pricing of re/insurance portfolio policies. More recently, the methodology and the probabilistic models have been applied beyond these classical applications: The methodology has been applied for quantifying the impact of the global climate change on wind risks due to typhoons, see e.g. Nishijima et al.[1]; a probabilistic model has been applied for real-time operational decision optimization in the face of an approaching typhoon, see Anders & Nishijima[2]. In these applications, among others, the modeling of typhoon transition plays the key role.

The modeling of typhoon transition from its genesis to dissipation, i.e. its whole life, has become the state-of-the-art in the modeling of the typhoon hazard and risks. This approach has several advantages over classical approaches. For example, a classical statistical approach for modeling the typhoon-induced wind hazard often encounters a lack of sufficient number of observations in reliably estimating the wind speeds of large return periods, whereas this approach alleviates the statistical problem by best utilizing the observations of historical typhoon tracks and by simulating sufficient number of typhoons by Monte Carlo techniques. It also facilitates to consider the spatial correlations of the hazard and risks, which are relevant for the estimation of the portfolio risks, while one of the classical approaches starts Monte Carlo simulations of typhoon events only at neighboring areas or at coastal lines of interest.

Vickery et al.[3] propose the first approach for modeling the transition of typhoon during its whole life, focusing on the Atlantic basin. They employ higher-order of Markov chains for modeling the changes of translation speed and angle as well as intensity of typhoons. Other modeling approaches are also proposed taking basis in different expressions for typhoon transition; see Powell et al.[4], James & Mason[5], Emanuel et al.[6], Rumpf et al.[7], Hall & Jewson[8], [9], Graf et al.[10], Yin et al.[11] and Yasuda et al.[12]. However, in spite of the proposals and their wide applications little attention has been paid on the relative performances of different transition models. Motivated by this and focusing on the Markov chain-based modeling, Graf & Nishijima[13] perform a systematic comparison of the performances of the different models; it is found that the performances are not too sensitive to the choices of the functional forms for the Markov chains and the way to deal with the spatial inhomogeneity (in terms of grid size) and seasonality, as long as the statistics on annual maximum wind speed is concerned. However, they do not investigate the plausibility of different models by extensive statistical analysis.

The present study aims at identifying plausible models by extensive statistical analysis; focusing on the translation speed and angle and the central pressure of typhoons, and restricting to the Markov-chain representation. First, by the statistical analysis, the order of Markov chains and the explanatory variables required in the modeling are investigated. Second, the appropriate size of the spatial grid in which the probabilistic characteristics of typhoons can be assumed to be stationary is examined. Third, the statistical characteristics of the residual terms in the Markov chain models are estimated. Thereby, a set of plausible typhoon transition models is identified. Selecting a proposed typhoon transition model, the performance of the model is compared to other competing models and the historical typhoons with respect to the statistics on the translation speed and angle and the central pressure of typhoons at several latitudes. For the statistical analysis and the modeling of the typhoon transition, the best track data provided by the Japan Meteorological Agency (JMA) in the period between 1951 and 2006 is utilized. In present paper, the term typhoon is employed for referring to tropical cyclones in general.

2 MODELING APPROACH

2.1 *Auto regression*

For the purpose to understand the basic statistical characteristics of the transition of historical typhoons, the successive translation speeds, successive translation angles and successive central pressures of the typhoons are plotted, see Figure 1. V_i, Γ_i and P_i represent the translation speed, translation angle, central pressure at time step i, respectively. These three variables are hereafter called the state variables of typhoons. Note the translation angle of a typhoon is 0^o when traveling north and positive clockwise. It is found that there are linear relationships with moderate randomness between successive translation speeds and translation angles, respectively. This is consistent with the observation made in Emanuel et al.[6], where the historical typhoons in the north Atlantic basin are examined. The similar relationship is observed between the successive central pressures. Furthermore, by developing these scatter plots for different areas and seasons, it is observed that the statistical characteristics of the state variables are different; implying the existence of the spatial inhomogeneity and the seasonality.

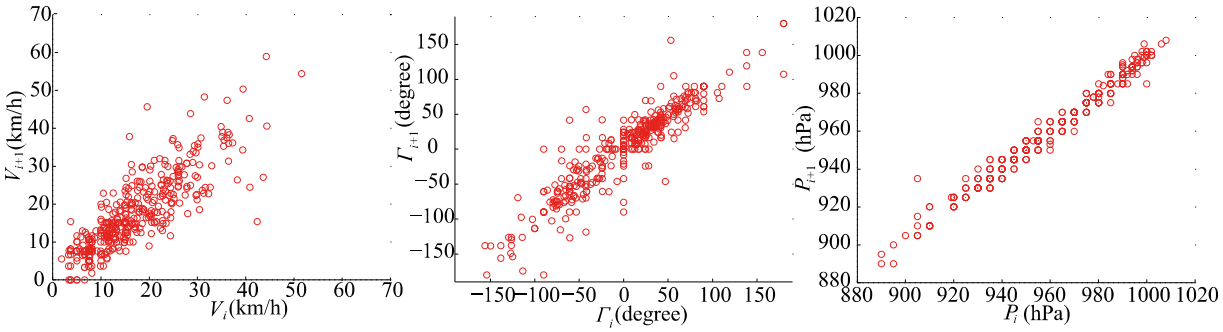

Figure 1. Scatter plots showing relationships between successive translation speeds, successive translation angles and successive central pressures. Track data utilized here to create the plots are on the typhoons travelling within the area bounded by the longitudes [124°E, 132°E] and the latitudes [24°N, 28°N] in September.

2.2 *Exploration of the regression form*

The relationships drawn in the scatter plots suggest that the autoregressive (AR) model can be appropriate to represent the transition of typhoons. Therefore, the autocorrelation coefficient function (ACF) and the partial autocorrelation coefficient function (PACF) are estimated in order to identify the necessary and sufficient orders of the AR models. Taking basis in the area bounded by the longitudes [124°E, 132°E] and the latitudes [24°N, 28°N] and the area bounded by the longitude [140°E, 148°E] and the latitude [28°N, 32°N] in September, and assuming the typhoon transition is stationary therein, ACF's and PACF's are estimated for the state variables as a function of the time lag, see Figure 2. Here, the unit of the time lag is 6 hours, at which interval the JMA best track data is available. Since the ACF's decay as a function of time lag and the PACF's show the cut off at around time lags of 2, it suggests the autoregressive models of the second orders, AR(2), can be plausible. Similar observations are made for other seasons and areas. Therefore, the first plausible transition models for the state variables are:

$$V_{i+1} = a_1 + a_2 V_i + a_3 V_{i-1} + \varepsilon_{V,i} \tag{1}$$

$$\Gamma_{i+1} = b_1 + b_2 \Gamma_i + b_3 \Gamma_{i-1} + \varepsilon_{\Gamma,i} \tag{2}$$

$$P_{i+1} = c_1 + c_2 P_i + c_3 P_{i-1} + \varepsilon_{P,i}\,. \tag{3}$$

Here, $\varepsilon_{V,i}$, $\varepsilon_{\Gamma,i}$ and $\varepsilon_{P,i}$ are the random residual terms for the state variables. Each of the residual term for different time steps is assumed to independently follow an identical distribution. For some seasons and areas the estimated PACF is significantly different from zero only at time lag of 1 for the translation speed and angle; hence, the autoregressive models of the first order, AR(1), are also plausible;

$$V_{i+1} = a_1 + a_2 V_i + \varepsilon_{V,i} \tag{4}$$

$$\Gamma_{i+1} = b_1 + b_2 \Gamma_i + \varepsilon_{\Gamma,i}\,. \tag{5}$$

As the third plausible models, regression models including the possible interrelations between the translation speed and the translation angle are assumed:

$$V_{i+1} = a_1 + a_2 V_i + a_3 V_{i-1} + a_4 \Gamma_i + \varepsilon_{V,i} \tag{6}$$

$$\Gamma_{i+1} = b_1 + b_2 \Gamma_i + b_3 \Gamma_{i-1} + b_4 V_i + \varepsilon_{\Gamma,i}\,. \tag{7}$$

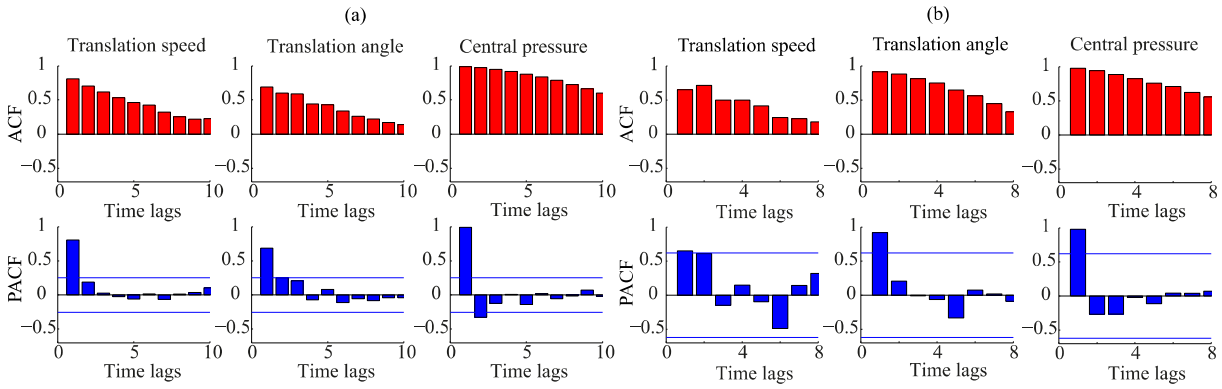

Figure 2. Illustration of the estimated ACF and PACF of the translation speed, the translation angle and central pressure as the function of lags. (a) is for the longitudes [124°E, 132°E] and the latitudes [24°N, 28°N] in September, and (b) is for the longitude [140°E,148°E] and the latitude [28°N,32°N] in September. The two lines in the figures of PACF's correspond to the 5%-significance level at which the PACF is considered to be different from zero.

Vickery et al.[3] indicate that the intensity of typhoon is subject to sea surface temperature (SST). Here, the following functional form is assumed as one of possible plausible models:

$$P_{i+1} = c_1 + c_2 P_i + c_3 P_{i-1} + c_4 T_i + \varepsilon_{P,i} \tag{8}$$

where T_i represents the SST at step i.

The goodness-of-fits of these plausible models is explored. The exploration is performed with respect to: AR(1) model vs. AR(2) model; whether or not the interrelation needs to be considered between the translation speed and the translation angle; whether the SST is necessarily included in the regression model. For this purpose, the corrected Akaike information criterion (cAIC) is employed. Note that the cAIC is capable of accounting for the non-normality of the residual terms, see e.g. Yanagihara[14]. It favors the model with a smaller value of cAIC. The cAIC is calculated for the model for each grid (latitude 4° × longitude 8°) for each month that contains at least 20 samples of the historical typhoon track record. Besides this, typhoons heading westward and eastward are separately treated in calculating the cAIC.

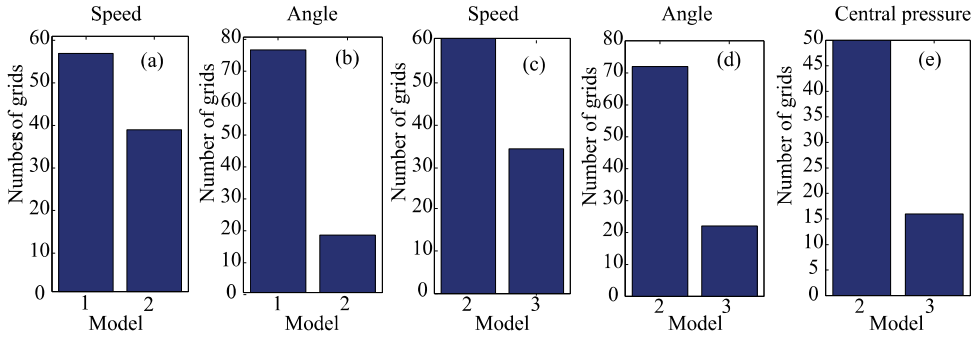

Figure 3. Histograms of the numbers of grids (and directions) with smaller cAIC values. The comparisons of these numbers are with respect to: (a) AR(1) vs. AR(2) for translation speed; (b) AR(1) vs. AR(2) for translation angle; (c) AR(2) for translation speed vs. interrelation model (Eq. (6)); (d) AR(2) for translation angle and interrelation model (Eq. (7)); (e) AR(2) for central pressure vs. model including SST (Eq. (8)). In the horizontal axis, AR(1) and AR(2) are indicated by 1 and 2, respectively, and 3 indicates the interrelation models for translation speed and translation angle and the model including SST for central pressure.

The numbers of the grids (and directions in case of the translation) with less cAIC are counted. In Figure 3, the histograms for these numbers are shown for the comparisons in those respects listed above, for September as an example. The results are: for all the months more grids favor AR(1) than AR(2), see (a) and (b) in the figure; more grids favor non-interrelation translation models, see (c) and (d) in the figure; more grids are in favor of not including SST in the model, see (e) in the figure.

2.3 *Estimation of the coefficients*

In order to reflect the spatial inhomogeneity and seasonality the regression models (Equations (1)-(8)) are developed separately for predefined spatial grids and time frames. The size of the grids must be determined by considering the balance between the numbers of samples available and the homogeneity of the characteristics of the samples in the grids. The average movements of the historical typhoons are approximately 0.4° in latitude and 0.8° in longitude in one time step (i.e. 6 hours). Considering that the set of the plausible models includes the second order of the (auto-) regression models, a grid size that can include two steps of typhoon transitions is required; hence, 0.8° in latitude and 1.6° in longitude at minimum. For the seasonality, it is postulated that the characteristics of typhoons do not significantly differ within one month period; hence, one month for the time frame. Furthermore, in order to taken into account the difference in the characteristics of the typhoon translation (speed and angle) eastward and westward, the models for the translation are developed separately for the two directions. These are the base line for estimating the coefficients of the regression models. However, in cases where sufficient number of samples is not available, the size of the spatial grid is expanded until the sufficient number of sample becomes available. The criteria for this are determined in accordance with the criteria on the validity of the regression analysis such as statistical power level and significance level, see Cohen[15], Cohen et al.[16].

2.4 *Modeling of residual terms*

Based on the functional forms of the plausible models, statistical characteristics of the residual terms are investigated. As shown in Figure 4, it is found that the residual terms for the state variables generally do not follow the normal distributions. This is consistent with the observation in Hall & Jewson[8]. In the figure, the normalized histograms of the frequencies of the residuals are shown together with the probability density functions of the two normal distributions that are fit to the histograms in two ways. One of the two normal distributions is obtained by considering all the data; the other normal distribution is obtained by neglecting both tails at quantiles larger than 1.5 times of the standard deviations. It either exaggerates the randomness if it is modeled by considering all the data (e.g. Graf et al.[10]) or underestimates the randomness if it is modeled by neglecting the tails (e.g. Emanuel et al.[6]).

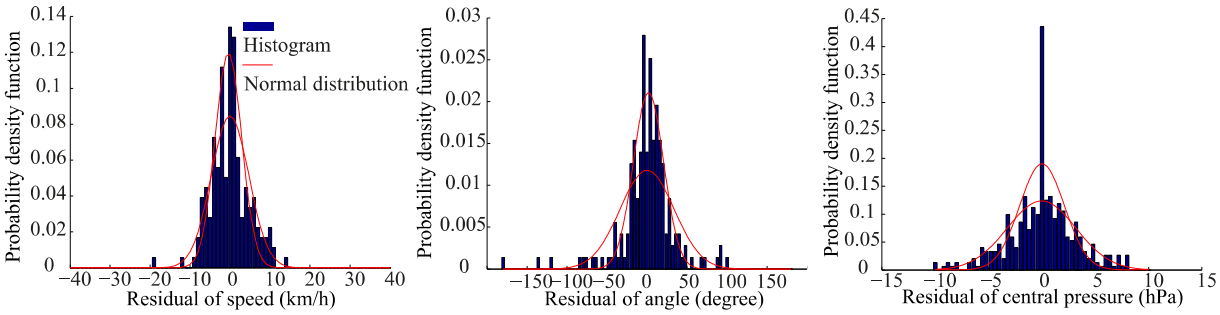

Figure 4. The normalized histograms of the frequencies of residuals for: (a) translation speed with model in Eq. (6); (b) translation angle with model in Eq. (7); (c) central pressure with model in Eq. (8). (a) and (b) are obtained by examining for typhoons in September travelling westward within the area bounded by the longitudes [124°E, 132°E] and the latitudes [24°N, 28°N].

The modeling of the residual terms becomes critical especially e.g. for the case when the typhoon transition model is utilized to predict the future transition of emerging typhoons. The consequences of the two ways of the approximations by the normal distributions on the simulated typhoon tracks are shown in the next section. It is not generally suggested to model the residual terms by the normal distributions; the empirical modeling of the residual terms, similar to the way by James & Mason[5], yet accounting for the spatial inhomogeneity and seasonality, or more flexible modeling such as mixture models are suggested.

3 PERFORMANCE OF MODELS

Based on the statistical investigation in the previous section, the following transition modeling is proposed: Eq. (6), (7) and (8) for modeling the state variables; the coefficients in the model are estimated by the method described in Section 2.3; the empirical distributions of the residual terms are employed. The performance of the proposed model is investigated by simulating typhoons by Monte Carlo techniques and then comparing several statistics of the typhoon transition with those of the historical typhoons. In the Monte Carlo simulation, the initial states of the typhoons are re-sampled from the initial states of the historical typhoons. Then, the transition of the typhoons is simulated using the transition model. Note that evolution of the typhoon intensity after landfall is simulated using a filling model, which takes basis in the modeling by Vickery et al.[17].

Figure 5a shows the tracks of the historical typhoons for the month September in the period between 1951 and 2006. Note that the other plots show the tracks of the simulated typhoons for September in the same period. Figure 5b illustrates the simulated typhoon tracks with the proposed model; Figure 5c with the modeling of the residual terms by the normal distribution considering all the data; Figure 5d with the modeling of the residual terms by the normal distribution considering the data only within the 1.5 times of the standard deviations. As can be clearly seen, two ways to model the residual terms by the normal distributions result in that the tracks are either overly fluctuated or overly smoothed. In contrast, it seems that the modeling of the residual terms by empirical distributions succeeds in reproducing the randomness in the historical typhoon tracks.

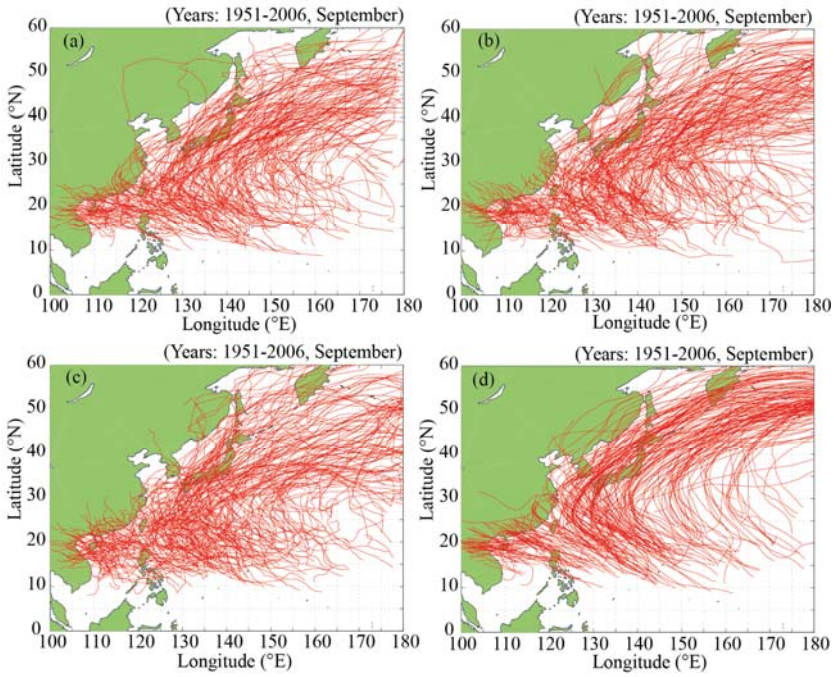

Figure 5. (a) Historical tracks occurred in September during 1951-2006; (b), (c) and (d) are the simulated tracks for the typhoon occurred in September over the same period. (b) is the result of proposed model; (c) is the result by modeling all the residual terms with normal distribution; (d) is the result by modeling the residual term with normal distribution disregarding both tails at quantiles larger than 1.5 times of standard deviation.

The statistics of the transitions of the typhoons simulated with the proposed model are calculated. These are compared to the statistics of the historical typhoons. Moreover, for comparison two competing (not recommended) models are developed and the statistics of the typhoons simulated by these models are also calculated. These competing models are, based on the proposed modeling, yet the ones whose coefficients of the regression models are estimated either by assuming the spatial homogeneity or by assuming no seasonality.

In Figure 6, cumulative annual average numbers (CAAN's) of typhoons are shown as the function of the translation speed, translation angle, and central pressure, respectively. These statistics are obtained by counting the typhoons traveling at the latitude 20°N or 35°N at the longitudes between 120°E and 160°E. CAAN's for translation angle and speed are the measures of the movements of the typhoons and CAAN's for central pressure is the measure of the intensity of the typhoons. The figure shows that the proposed model, as well as the second competing model (no seasonality), performs well in the sense that these agree with the statistics obtained by historical records at both latitudes. On the other hand, the simulations with the first competing model (spatial homogeneity) fail to generally reproduce the statistics obtained from the historical record.

In Figure 7, the statistics are shown for the month September only. It is seen that the simulated results from the proposed model fit the historical statistics for all three state variables at both latitudes. On the other hand, the first competing model fails to reproduce the statistics obtained from the historical record especially at 35°N, which may be accounted by the accumulation of errors in the simulations starting from lower latitudes. The second competing model also fails notably at 35°N, where the seasonality is more dominant.

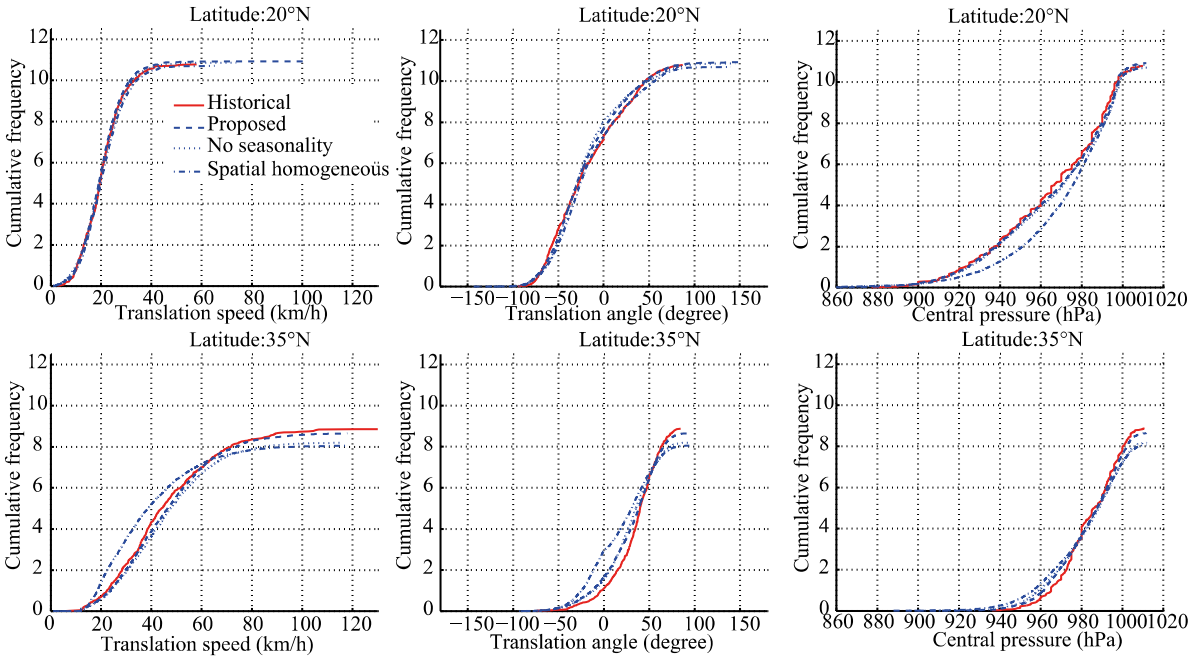

Figure 6. CAAN's calculated with the historical records and the Monte Carlo simulations as a function of the translation speed, translation angle and central pressure at latitudes 20°N and 35°N. By Monte Carlo techniques, 10000 times one- year typhoon events are simulated.

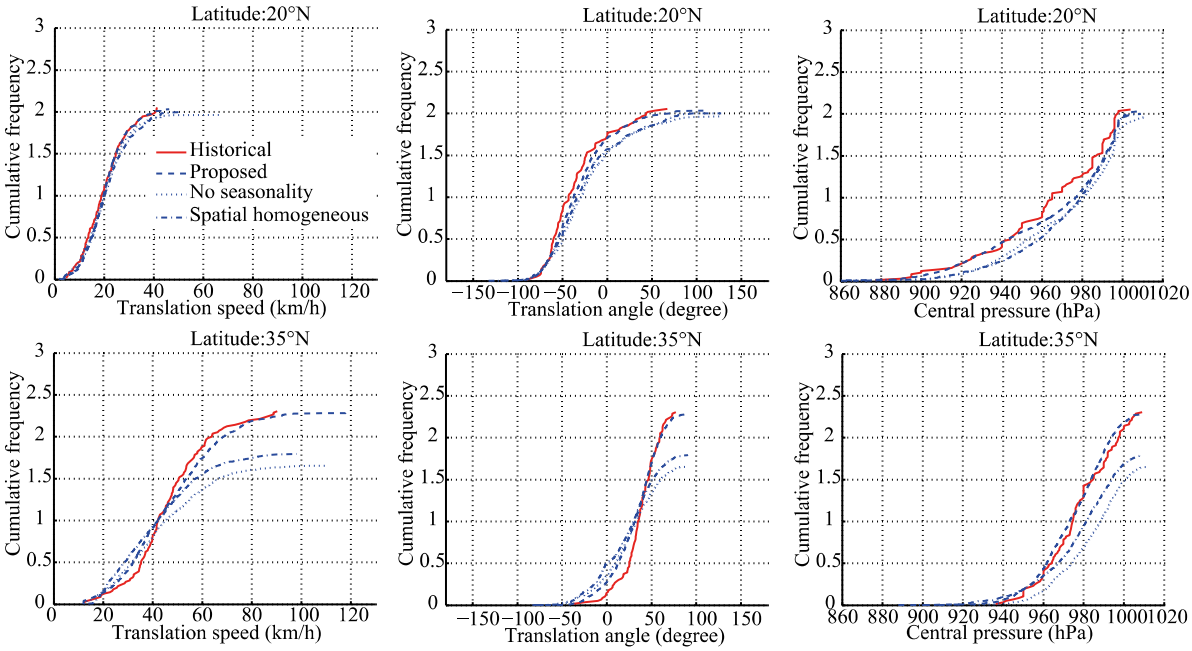

Figure 7. Cumulative average numbers of typhoons in September calculated with the historical records and the Monte Carlo simulations as a function of the translation speed, translation angle and central pressure at latitudes 20°N and 35°N. By Monte Carlo techniques, 10000 times one- year typhoon events are simulated.

4 DISCUSSIONS

The simulation results imply that the spatial inhomogeneity has to be appropriately taken into account in the modeling of the typhoon transition, reflecting the observation that the statistical characteristics show spatial inhomogeneity. The simulated results illustrated in Figure 6 and Figure 7 also show the importance of modeling of seasonality in the case that the typhoon transition of a specific season is of interest. However, the seasonality has not attracted sufficient attention in the statistical modeling of typhoon transition, except for the two of the models mentioned in Section 1; i.e. Emanuel et al.[6] and Graf et al.[10]. The consideration of the seasonality may become relevant for better understating and modeling of the typhoon transition under future climate change. Therefore, it is suggested to develop the transition models for different spatial grids and seasons separately where applicable; yet the optimal size of the grids is to be further investigated.

Although not illustrated in the present paper, it is found that the choice of the functional forms among the plausible models does not play significant roles in the statistical characteristics of the typhoon transition. Since the functional forms with less number of explanatory variables require less amounts of historical records to estimate the coefficients at same levels of confidence, it is suggested to employ simpler functional forms in the case where the numbers of the historical records are limited. On the other hand, if the forecasting of emerging typhoons is of interest, models with more numbers of explanatory variables have the advantage since they facilitate the use of more information.

5 CONCLUSIONS

The modeling of the typhoon transition is investigated by the extensive statistical analysis. First, the estimated ACF's and PACF's for the state variables of typhoon indicate that the second orders of the autoregressive models are sufficient. Second, by the cAIC, it is found that for many of the grids and months simpler functional forms for the modeling of the typhoon transition are in favor. Third, the choice of the functional forms is generally not relevant in the transition modeling; however, modeling of the residual terms has significant impact on the fluctuation of the simulated typhoon tracks. Fourth, the consideration of the spatial inhomogeneity is important in general and the consideration of the seasonality is also important in case the transition of the typhoon in a specific season is of interest. Based on these statistical analyses, the modeling of typhoon transition is proposed.

Abstract

Determination of design wind speed or wind hazard analysis for structure in general requires statistically modeled typhoon information consisting of models genesis, intensity, track and wind field. However, the current typhoon intensity and track models used to simulate the typhoons around Korean peninsula statistically have difficulties in simulating randomness and dynamics of typhoons in the study region. In this paper, more realistic typhoon intensity model and track model for the typhoons around Korean peninsula are proposed. First, defining the central pressure depth (CPD), the deficit between the central and periphery pressures as the representative of a typhoon intensity, the intensity model includes SST (Sea Surface Temperature), relative change of SST, OOR (Oceanic Occupation Ratio), relative change of OOR, latitude and traveling time. An empirical typhoon intensity model is developed by multi-variate regression. The correlation coefficients of CPDs from the present model and the RSMC best tracks for the strong and weak typhoons show 0.93 and 0.76 respectively, which shows a good agreement with the historic intensity. Secondly, a tracking model to describe dynamical typhoon tracks for the typhoons around Korean peninsula was developed. The displacements of typhoon center is determined by the mean displacement and the anomaly from the autoregression (1) model, which are estimated from the historical typhoon displacements collected on the circle with the radius of pre-assigned length scale. Classifying typhoon into the Southern Boundary (SB), the Eastern Boundary (EB) and the Western Boundary (WB) typhoons according to which boundary a typhoon enters into the domain, the spatial density correlation coefficients of the present results and the historical tracks for SB, EB, WB show 0.87, 0.6, and 0.5 respectively. The intensity and the tracking models proposed in this paper are able to reasonably simulate realistic synthetic typhoon in the point of statistical view.

key words : typhoon intensity, oceanic occupation ratio, central pressure depth, sea surface temperature, typhoon track

1. Introduction

Recent disaster records in Korea have shown that natural disasters induced by typhoon are on the rise, and the estimation of typhoon wind speed both for risk assessment and structural design becomes more important. Generally, A Monte Carlo simulation is widely used to estimate the design wind speeds in typhoon-prone regions. The simulation includes statistical models for climatological characteristics of typhoon and physical models consisting mainly of a wind field model, a tracking model and a typhoon intensity model (Russell, 1971; Batts et al., 1980; Vickery et al., 2000). The typhoon intensity is defined by either maximum sustained wind speed or central pressure of a typhoon. Atkinson (1977) showed that the maximum sustained winds speed and the central pressure are highly

correlated. The reliability of the simulation is determined by how well an evolution of the central pressure is represented. Batts et al. (1980) proposed a model of the central pressure which varies on the land and stays constant on the water. Vickery et al. (2000) developed an empirical hurricane intensity model including the effects of the sea surface temperatures (SSTs) by adopting a concept of the relative intensity proposed by Darling (1991). In this paper, similar approach is taken to develop the typhoon intensity model around Korean peninsula. The developed intensity model was for the region covering the area of 30°N ~ 40°N and 120°E ~ 130°E and modeled as a function of SST, relative SST, OOR (Ocean Occupation Ratio), relative OOR, latitude and travelling time.

In the past studies of the tracking model, the typhoon tracking is postulated as moving at constant direction and speed once the typhoon reaches the region of interest. Recent statistical tracking model to describe a dynamic characteristic of typhoon has been developed and a research on simulation modeling the overall track of the typhoon is also in the progress. Vickery et al.(2000) use an autoregressive model for increments in track speed and direction, with a random error term acting as the innovation. Hall, T.M. and Stephen Jewson(2007) simply draw from the set of complete historical tracks, translating the tracks by small random displacements. In this study, an empirical tracking model was developed to simulate dynamic tracking of typhoons around Korean peninsula for the area of 28°N ~ 40°N and 120°E ~ 132°E.

2. Typhoon Intensity Model

SST used in this study is acquired from the data of NOAA Optimum Interpolation 1/4 Degree Daily Sea Surface Temperature Analysis of 1982 ~ 2009, provided by National Climate Data Center (NCDC). And climatological typhoon data are obtained from Regional Specialized Meteorological Center (RSMC) best tracks of 1982 ~ 2009. Total number of 129 typhoons was found to have passed through the study domain of 28°N ~ 40°N and 120°E ~ 132°E in 1982 ~ 2009. In the study, the typhoon intensity is represented CPD or CPD/CPD0 where the central pressure depth (CPD) and CPD0 are defined as deficits between central pressures (P_c) and periphery pressures (P_n) and CPD when a typhoon enters the designated domain, respectively. The maximum of CPD0 of sample typhoons is 88hPa during typhoon YANCY (1993) and MAEMI (2003) follow with CPD0 of 81hPa where P_n is assumed as the standard atmospheric pressure of 1,013hPa.

We also classify typhoon into the Southern Boundary (SB), the Eastern Boundary (EB), the Western Boundary (WB) and, the Northern Boundary (NB) typhoons according to which boundary a typhoon enters into the domain. SB occupies 78%, EB 12%, WB 10% and the NB does not appear. The entire WBs consist weak typhoons which enter the domain after passing the main land of China. EBs consist of 6 weak and 7 strong ones while SBs are 45 weak and 56 strong ones.

In this paper, we have an important non-dimensional dependent variable, CPD/CPD0, to analyze an effect of CPD0 based on the parameters of SST, relative SST, OOR, relative OOR, latitude and travelling time. Initial values of OOR and SST (i.e. OOR0 and SST0, respectively) are given at when a typhoon is entering into research areas. In the intensity model, to exam its dependency on the CPD0, we analyze the correlation of CPD/CPD0 with the independent variables as shown in Figure 3. The CPD0s of the typhoons of interest ranges from 0mb to 109mb, which are divided into two groups; typhoons with CPD0 greater than a certain criteria and ones smaller than the criteria (henceforth, the first group is strong typhoon and the other one is weak typhoon). Figure 2 shows a result of correlation analysis between CPD/CPD0 and other six parameters for strong and weak typhoons, respectively.

The correlation coefficient between CPD/CPD0 and 6 parameters on the all of typhoons is 0.6 which is relatively low, which shows that a single model for various CDP0s seems inappropriate. As shown in Figure 1, the correlation of the strong typhoons is relatively low where the criterion of CPD0 is less than 30mb while the correlation of weak typhoons is nearly constant.

As the results, this study set the value of 30mb as a criterion to classify the sample typhoons into weak and strong typhoons. The numbers of the strong and the weak are 63 and 66, respectively.

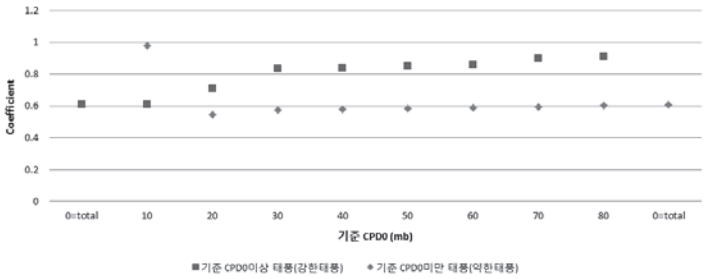

Figure 1. Correlation of model and observation for various CPD0 ranges

Typhoons gain their thermodynamic energy mainly from sea surface and experience the filling when they move over the land. In this paper, OOR (Ocean Occupation Ratio) is defined as the ration of the sea surface area which the typhoon covers to the total area which it covers. In this section we analyze the effect of OOR on the intensity.

We, first determine a representative SST&OOR, which is used to analyze the correlation with the typhoon intensity. The representative grid size for SST and OOR is, first, determined so that SST & OOR on that grid has the maximum correlation with typhoon intensity. We examine SSTs & OORs on G01×01, G03×03 and so on to G59×59, which mean average SSTs & OORs on the grids of Gnn×nn, where nn indicates the number of cells both the zonal and meridian direction in the study domain. Each grid has 1/4 degree distance both in latitude and longitude as given in NCDC data sets. Employing CPD and CPD/CPD0 as parameters, CPD/CPD0 correlates with SSTs higher than CPD for the strong typhoons (see Figure4,5). CPD/CPD0 has the highest correlation coefficient of 0.5041 with SST on the grid of G15×15 while CPD has the coefficient of 0.4863 on the grid of G13×13 for the strong typhoons. Similarly, CPD/CPD0 has a higher correlation with SST/SST0 than CPD does, where SST0 is SST when a typhoon enters into the domain. CPD/CPD0 has the highest correlation coefficient of 0.7335 with SST/SST0 on the grid of G51×G51 while CPD has the coefficient of 0.4528 on the grid of G55×55. For the weak typhoons, values of SST, SST/SST0, OOR, and OOR/OOR0 are analyzed in the same away as the strong typhoons.

We analyze a correlation between the typhoon intensity and the latitude of the center and the travelling time over the domain. For the strong typhoon the intensity has a close correlation with the latitude and travelling time. CPD/CPD0 has a correlation coefficient of -0.8406 with the travelling time while CPD has the coefficient of -0.6455 for the strong typhoon. The latitude also is correlated closely with the intensity because most typhoons move from low to high latitudes as the corresponding travelling times increase. CPD/CPD0 has a correlation coefficient of -0.7701 while CPD has the coefficient of -0.5724 for the strong typhoon.

For the weak typhoon the travelling time has the correlation coefficients of -0.4871 for CPD/CPD0 and 0.0064 for CPD, which seems to be uncorrelated with it. The latitude has correlation coefficients of -0.1365 for CPD and -0.3931 for CPD/CPD0.

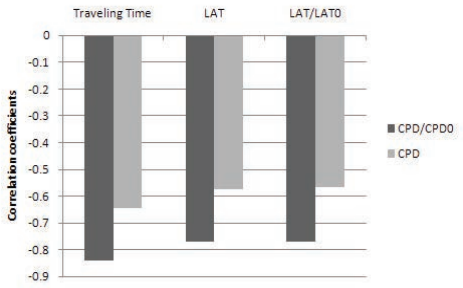

Figure 2. Correlation of typhoon intensity and latitude, traveling time about strong typhoon

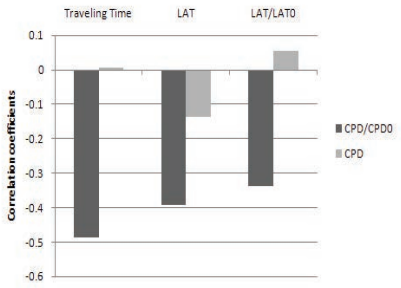

Figure 3. Correlation of typhoon intensity and latitude, traveling time about weak typhoon

In the study we consider CPD and CPD/CPD0 as the typhoon intensity and analyze correlations with SST, SST/SST0, OOR, OOR/OOR0, the latitude of the center (LAT), and, the travelling time (TT). Table 1 lists correlation and contribution coefficients of the 6 parameters. The contribution coefficient is defined as the correlation of a parameter relative to that of TT so that TT has the coefficient of 1. For the strong typhoons, SST shows lower contribution than others while for the weak typhoons, contributions of SST and SST/SST0 are dominant.

Table 1. Correlation and contribution coefficients of parameters affecting CPD/CPD0

Parameters	Strong typhoons			Weak typhoons		
	Correlation	Contribution	Grid	Correlation	Contribution	Grid
TT	-0.84	1.00		-0.49	1.00	
LAT	-0.77	0.92		-0.39	0.81	
OOR	0.73	0.86	G35×35	0.20	0.42	G55×55
OOR/OOR0	0.70	0.83	G39×39	0.09	0.18	G59×59
SST	0.50	0.60	G15×15	0.28	0.57	G15×15
SST/SST0	0.73	0.87	G51×51	0.33	0.68	G11×11

Final form of the proposed empirical typhoon intensity model is as the following

$$\frac{CPD}{CPD0} = \alpha TT + \beta LAT + \gamma OOR + \delta \frac{OOR}{OOR0} + \varepsilon SST + \xi \frac{SST}{SST0} + \eta \quad (1)$$

where the coefficients, α, β, γ, δ, ε, ζ, and η, estimated by a multi-variate regression for strong and weak typhoons.

In this study, the population of typhoon data consists of 81 strong and 50 weak typhoons. To validate this method, we build model using 40 and 25 samples from the strong and weak typhoons, respectively, which is applied to estimate CPDs for the other typhoons excluded from the samples. Figure 4 shows the application for a weak typhoon PABUK(0706) in 2007 and the mean error of CPD is 10.17%.

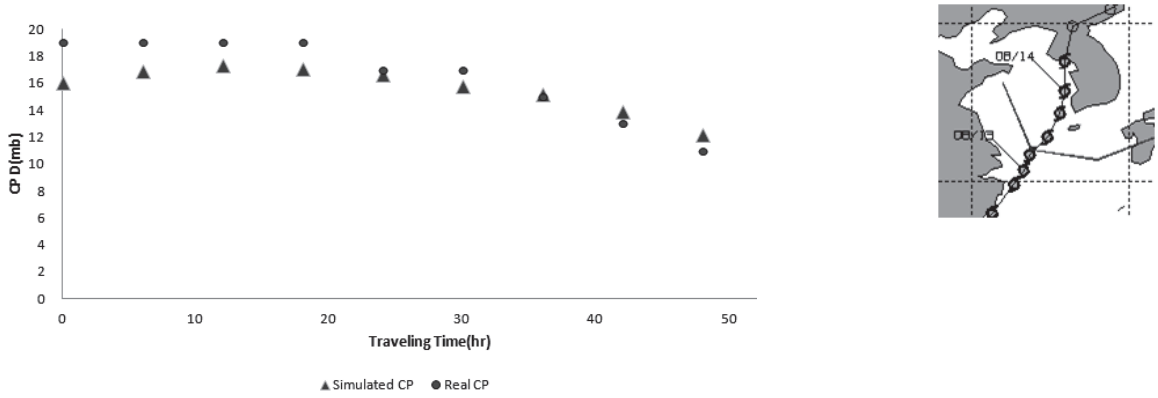

Figure 4. A comparison empirical intensity model(present) and RSMC best track for PABUK(0706)

3. Typhoon Tracking model

According to Hall & Jewson(2007), the *x* (zonal) and *y* (meridional) components of the mean 6-h displacement vector are computed by averaging historical displacements as follows.

$$\bar{x}(r) = \left(\sum_{i=1}^{N_L} x_i exp(-d_i^2/L^2)\right)/\left(\sum_{i=1}^{N_L} exp(-d_i^2/L^2)\right) \quad (2)$$

The d_i is the great-circle distance between the location **r** of the current point and the location $\mathbf{r}_i$ of the *i*-th historical center where the length scale *L* is optimized using an out of sample jackknife procedure. Following Eq. (2), $\bar{x}_{rms}$ is obtained using weighted averages of deviations of center displacements about the optimal mean displacement.

$$\bar{x}_{rms} = \sqrt{\left(\left(\sum_{i=1}^{N_L} x_i^2 exp(-d_i^2/L^2)\right)/\left(\sum_{i=1}^{N_L} exp(-d_i^2/L^2)\right)\right)} \quad (3)$$

Eqs. (2) and (3) can also be applied to y direction. Figure 5 shows the RMS on the forecast error while the length scale is increasing by 20 km from *L*=100 km. As the length scale is growing, the RMS of the forecast error is decreasing where 100 km <= *L* <= 520 km. At the length scale of *L* = 520 km, there is minimum RMS resulting in computational times that are prohibitively expensive. There is a scenario with length scale of *L* = 300 km that has 0.4 km larger RMS on the forecast error than case with minimum RMS. In this case, however the samples are a third of the case, *L*=520 km, resulting in less expensive cost on the simulation times. In this research, the length scale, *L*, is set to 350 km.

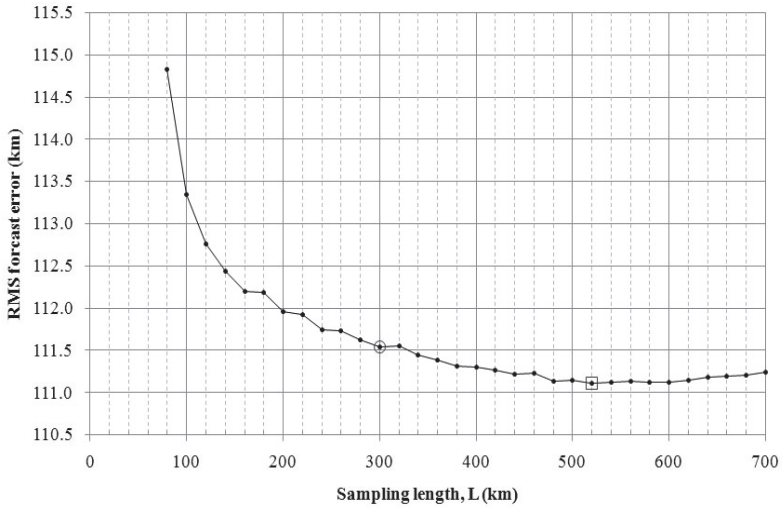

Figure 5. Mean-track average forecast error versus averaging length-scale

According to Hall and Jewson (2007), an anomaly between the previous and current points on the typhoon track determines next displacement. An anomaly at initial location of typhoon is computed from the mean displacement randomly obtained in the normal distribution and RMS given by

$$u = \bar{u} + \epsilon_u u_{rms}, \qquad v = \epsilon_v v_{rms} \quad (4)$$

where *u, v* are normalized Cartesian directions of *x, y* in latitude and longitude, respectively, u is normalized $\bar{x}$. ϵ is a random number on the Gaussian distribution that has 0 mean and 1 variance. In this model, the next travel point of typhoon center is defined so that it moves toward the average travel direction $\bar{u}$, and then moves that point toward horizontal *u* and vertical *v*, and then connect the starting point with the new point. Figure 6 shows the anomalies of record data in scatter plot. These anomalies $\bar{u}, \bar{v}$ represent correlation between their values at the previous step. $\overline{u_n}$ and $\overline{v_n}$ are computed from $(u - \bar{u})/u_{rms}$ and v/v_{rms} by employing the RMS, respectively. These panels show the high correlation at that lag-1.

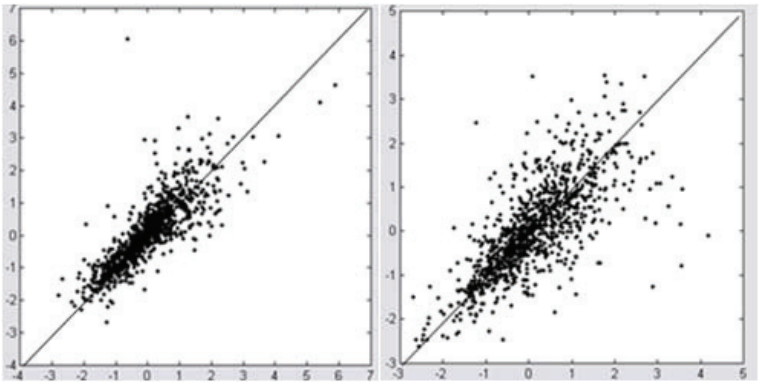

Figure 6. Correlation between present (n) and previous (n+1) at u, v direction

After comparing regression coefficients via auto regressive process (henceforth AR) of $\bar{u}, \bar{v}$ from lag-1 to lag-8, AR with 6 hours step is used. In the directions of *u* and *v*, coefficients on lag-1 are 0.836 and 0.693, respectively, which are relatively larger than other coefficients less than 0.1.

From second point, the anomaly is obtained based on the previous data and the regression coefficient $\emptyset$ given by

$$\overline{u_{n+1}} = \emptyset_u \overline{u_n} + s_u \varepsilon_{u'} \quad \overline{v_{n+1}} = \emptyset_v \overline{v_n} + s_v \varepsilon_v \quad (s = 1 - \emptyset^2) \tag{5}$$

The Eq. (5) represents anomalies from the second point. Based on Eq. (5), the path of the typhoon is estimated by employing Eq. (6) while Eq. (4) initialize the typhoon location.

$$u = \bar{u} + \bar{u} u_{rms}, \qquad v = \bar{v} v_{rms} \tag{6}$$

In this section, we represent verification of the empirical tracking model. To this end, a spatial frequencies of typhoon paths obtained from the empirical model are compared with those of RSMC data. The study area of 30°N ~40°N in latitude and 120°E ~130°E in longitude is divided in 10-by-10 matrix. The comparisons are made respectively for typhoons in different entering directions and each matrix is normalized by the maximum value. Figure 7 shows the entry to south direction into our domain and the spatial correlation between synthetic tracks and historical tracks shows a coefficient of 0.87. Other entry directions show less correlations of 0.62 for WB and 0.5 for EB.

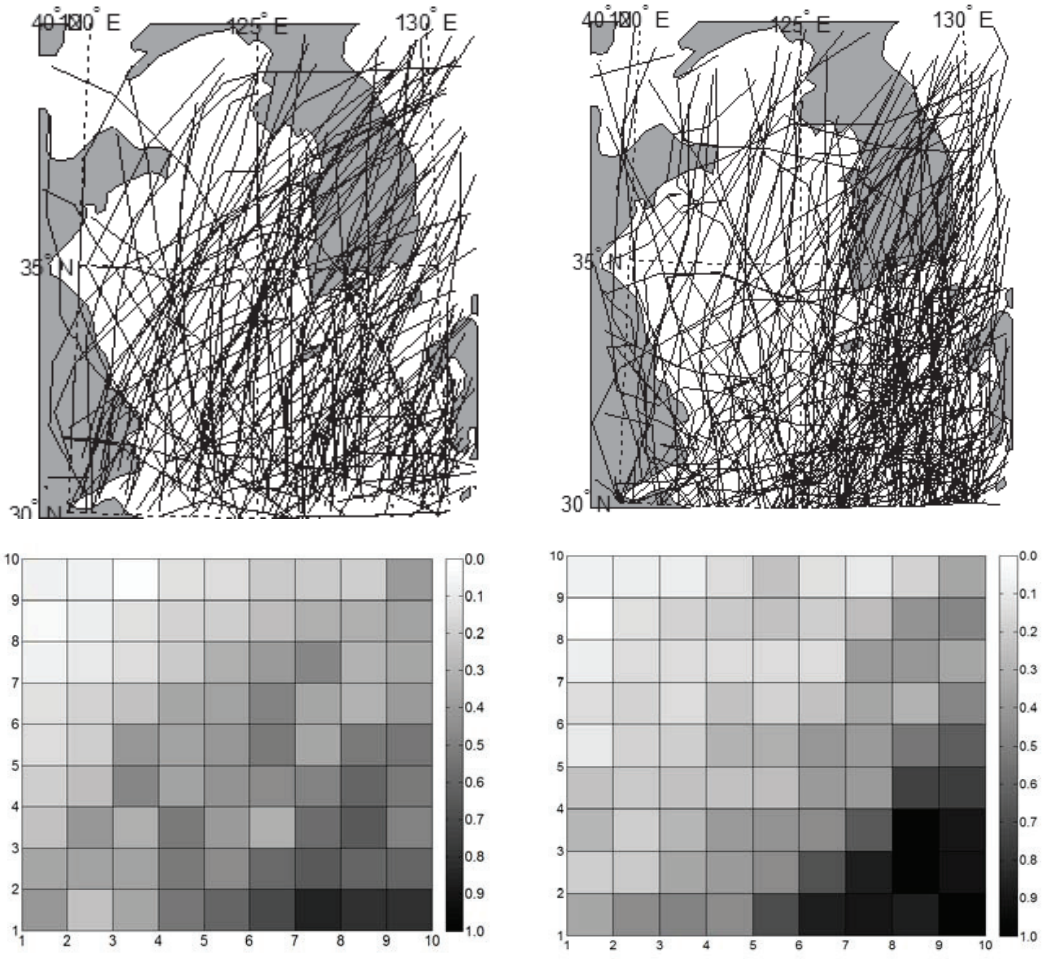

Figure 7. Tracks and spatial frequencies of typhoons from RSMC and present method for SB entry

4. Conclusions

In the study we develop empirical typhoon intensity and tracking models for the regions around Korean peninsula. The typhoon intensity, represented by CPD/CPD0 is modeled as a function of the travelling time, the latitude of the center, SST, SST/SST0, OOR, OOR/OOR0 using a multi-variate regression for the strong and weak typhoons, which were categorized by a criteria of CPD0 at 30mb. In strong typhoons, SST showed small correlation with CPD/CPD0 but other parameters have high correlation. But in weak typhoons, OOR and OOR0 has small correlation and SST, SST/SST0 has high correlation.

The simulated CPDs using the model show a good agreement with the recorded CPDs on the RSMC best tracks, and improvement over existing methods based on the constant CPD and filling rate models.

In this paper, an empirical tracking model to describe dynamical typhoon tracks for the typhoons around Korean peninsula was also presented. The displacements of typhoon center is determined by the mean displacement and the anomaly from the autoregression (1) model, which are estimated from the historical typhoon displacements collected on the circle with the radius of pre-assigned length

scale. Classifying typhoon into the Southern Boundary (SB), the Eastern Boundary (EB) and the Western Boundary (WB) typhoons according to which boundary a typhoon enters into the domain, the spatial density correlation coefficients of the present results and the historical tracks for SB, EB, WB show 0.87, 0.62, and 0.5, respectively. The empirical intensity and the tracking models proposed in this paper are able to simulate realistic synthetic typhoon in the point of statistical view in applications to estimate wind speeds for the structural design and the wind risk assessment.

ABSTRACT: Studies on equivalent static wind load (ESWL) distributions are reviewed, and essential matters and necessary conditions of the ESWL are discussed. Then, the efficiency and advantages of multiple-target ESWLs are demonstrated. As an example of a multiple-target ESWL, the universal ESWL (U-ESWL) proposed by Katsumura, Tamura et al. (2004, 2007) is explained in detail. Reproduced largest load effects by GLF-ESWL, LRC-ESWL and U-ESWL are compared with the real largest load effects obtained by time-domain response analysis for some different types of roof systems including an actual airport terminal roof structure. The results demonstrate the feasibility and usefulness of the U-ESWL.

KEYWORDS: Universal Equivalent Static Wind Load, Gust Loading Factor (GLF), Load-Response Correlation (LRC) method, Wind Resistant Design, Long-span Roof, Load Effect

1 INTRODUCTION

Structural design of a building is generally based on largest "load effects", such as internal forces (bending moments, shear forces, axial forces) and stresses in structural members, and in some cases on the largest story deformation or displacement of a particular part of the building. In structural design of buildings, wind load is not applied separately. We have to consider the combined effects of wind load and many other loads such as dead load, snow load, live load and so on. Therefore, it is convenient and necessary to determine a so-called Equivalent Static Wind Load (ESWL) for combinations with other loads. The ESWL is the static load providing the largest "load effects" due to dynamic wind excitations.

Many studies have been made on ESWL. The ESWL reproducing the largest response of a structure was first introduced by Davenport [1] as that produced by the Gust Loading Factor (GLF) method. Accurate evaluation of the maximum load effect is very important in the structural design of a building, and many studies on the ESWL followed Davenport [1], e.g. Simiu [2], Solari [3], Holmes [4], Kasperski [5], Davenport [6], Piccardo & Solari [7], [8], Zhou & Kareem [9], Chen & Kareem [10], [11], Tamura et al. [12], Repetto & Solari [13], and Kwon & Kareem [14].

The GLF method proposed by Davenport [1] was a milestone in the history of wind resistant design of buildings and structures. It has been widely adopted in many modern wind load codes and standards, including some major codes. The ESWL distribution given by the GLF method is proportional to the mean wind pressure/force distribution. The mean wind pressure/force distribution is a temporarily averaged distribution and such a distribution never happens in any instance. Therefore, the ESWL given by the GLF is an unrealistic distribution.

The Load-Response Correlation (LRC) method proposed by Kasperski [5] should be raised as another milestone. The LRC approach is based on a very sophisticated idea with an insight into the physical mechanism of the wind force and response relation. LRC can reproduce the most probable wind load distribution causing a particular maximum (minimum) wind load effect, as Tamura et al. [12] reported by comparing the LRC-ESWLs and ensemble averaged actual pres-

sure distributions causing largest load effects obtained by a conditional sampling (CS) technique. Thus, LRC gives a realistic ESWL distribution.

By the way, when we combine the wind load with dead load or snow load in order to estimate the maximum resultant load effects in a roof beam as an example, not only the up-lift wind effect but also the down-lift wind effect should be considered in determining the critical situation for the targeted beam. Therefore, we should consider both of the largest positive side wind load effect (maximum wind load effect) and the largest negative side wind load effect (minimum wind load effect), and two ESWLs reproducing both the maximum and minimum load effects should be determined (Tamura et al. [12], Kasperski [15], Katsumura, Tamura et al. [16]). In this paper, the term "largest load effect" is used for either the maximum or minimum load effect when it is not necessary to clearly indicate one or the other, or when it is intended to mean both of them.

2 EQUIVALENT STATIC WIND LOAD (ESWL) REPRODUCING LARGEST LOAD EFFECTS

There are various wind load distributions that can reproduce the largest load effect targeted in structural design, if the target is only one load effect. For example, if the target load effect is the maximum tip displacement (Load Effect 1 in Fig.1), any ESWL distribution can be set to reproduce the same tip displacement as shown in Fig.1, i.e. the GLF method, the LRC method, the CS technique, and even a concentrated force at any particular point. They can all reproduce the same maximum tip displacement if the value of each ESWL is appropriately set. In this context, any wind load distribution will work for the ESWL, if there is only one target load effect.

2.1 *Wind-induced response of long-span roof structures*

Time domain dynamic response analyses using fluctuating pressure data obtained by a simultaneous multi-channel pressure measuring system (SMPMS) have been conducted in the practical design of buildings and structures such as long-span roof structures, structures with non-linear dynamic characteristics, and buildings adopting non-linear damping devices since the 1980's in Japan (Tamura, [17]). For tall buildings with complicated sectional shapes changing along the vertical axis, as for many recent tall buildings, eccentricity causes complicated coupled motions of translational and torsional vibration components, and three-dimensional time-domain dynamic response analysis using those resultant fluctuating wind force components or by directly applying pressures obtained by the SMPMS is required to appropriately estimate the combined effects of the various wind force components and the resultant three-dimensional motions. For other buildings, a simpler but sufficiently accurate method is required for wind resistant design. ESWLs reproducing largest load effects have been examined for this purpose.

The wind-induced response behavior of long-span roof structures is very complicated, showing significant contributions of multiple vibration modes of up to 100 or more. The largest load effects such as bending moments, shear forces, and axial forces in a huge number of members, e.g. 10,000 or more, should be considered and their largest values should never happen simultaneously. It is also necessary to consider the effects of wind directions. Different members reach their largest load effects for different wind directions. The structural designer should design all structural members based on the largest load effects found in each member under such complicated conditions. Thus, it is obviously difficult to design such structures using traditional building codes or standards based on the GLF or LRC method, which basically reproduce one particular load effect for a specifically targeted member.

As mentioned before, if there is only one target load effect , say Load Effect 1 in Fig.1, any one of the ESWL distributions shown in Fig.1 would do to reproduce the target load effect. However, if there are two target load effects, say Load Effect 1 and Load Effect 2 in Fig.1, all of the ESWLs except for the U-ESWL would be needed to determine another ESWL distribution to reproduce Load Effect 2 as shown in Fig.1. Thus, if there are *N* target load effects, we need to determine *N* different ESWL distributions to reproduce them. The only exception is the U-ESWL, which can reproduce any number of multiple largest load effects for all the targeted members.

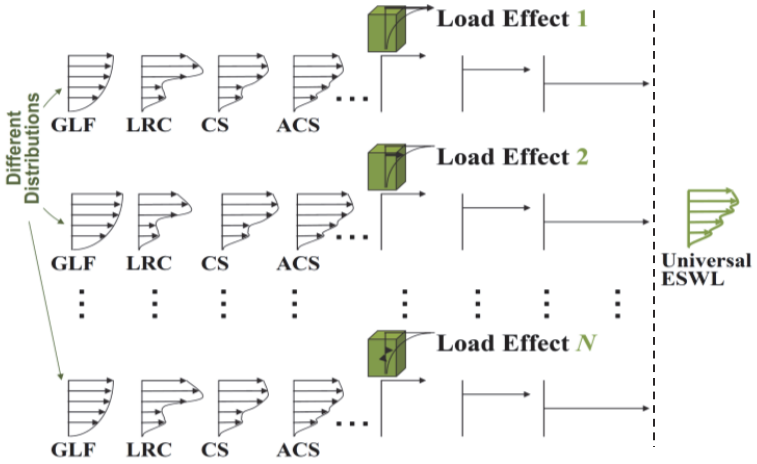

Figure 1. Various ESWL distributions reproducing target load effects

2.2 *Largest load effects and single-target ESWL distributions and multiple-target ESWL distributions*

As an example of single-target ESWLs like those produced by the GLF and LRC methods, let's assume the target largest load effect, $\hat{r}$, is an internal force at a particular point of a beam excited by dynamic wind load. The target load effect is expressed as a scalar value.

$$\hat{r} = \sum_i I_{ri}\hat{F}_i = \{I_r\}^T\{\hat{F}\} \qquad (1)$$

Here, the ESWL distribution $\{\hat{F}\}$ reproducing the largest load effect $\hat{r}$ is given in a vector expression, and $\{I_r\}^T$ is an influence function vector. Once the ESWL $\{\hat{F}\}$ is obtained, the single target largest load effect $\hat{r}$ can be given as the product of the influence function vector $\{I_r\}^T$ and the ESWL vector $\{\hat{F}\}$. Thus, a static analysis can reproduce the load effect equivalent to the largest dynamic load effect.

As an example of the multiple-target U-ESWLs, let's assume target largest load effects at various points of the same beam. The largest load effects should be expressed in a vector form as:

$$\{\hat{R}\} = [I_R]\{\hat{F}\} \qquad (2)$$

Here, $\{\hat{R}\}$ is the largest load effect vector, in which elements are the target load effects at various points, and $[I_R]$ is the influence function matrix. The target largest load effects are given as the product of the influence function matrix $[I_R]$ and the ESWL vector $\{\hat{F}\}$. A scalar value of the target load effect $\hat{r}$ on the left hand side of Eq.(1) is replaced by a target load effect vector $\{\hat{R}\}$ in Eq.(2), and the influence function vector $\{I_r\}^T$ in Eq.(1) is replaced by the influence function matrix $[I_R]$ in Eq.(2). These are differences between mathematical expressions of a single-target ESWL and a multiple-target ESWL.

2.3 *U-ESWL reproducing multiple load effects*

As a multiple-target ESWL distribution, Katsumura, Tamura et al. [16], [18], [19] proposed a U-ESWL method to reproduce all targeted largest load effects $\{\hat{R}\}$ based on Eq.(2).

For the U-ESWL, the targeted largest load effects can theoretically be any load effects, and the number of targeted load effects is not necessarily the same as the number of structural members. An U-ESWL distribution $\{\hat{F}\}$ estimated for the target largest load effects $\{\hat{R}\}$ is assumed to be expressed by a linear combination of a set of basic wind load distributions (BWLD) $\{f_i\}$ as:

$$\{\hat{F}\} = c_1\{f_1\} + c_2\{f_2\} + \cdots\cdot c_M\{f_M\} = [F_0]\{C\} \qquad (3)$$

Here, $[F_0]$ is the BWLD matrix consisting of the BWLD vectors $\{f_i\}$, and $\{C\}$ is the combination factor vector. It is also very important that any wind load distributions, even a set of concentrated forces, are theoretically available for the BWLDs, $\{f_i\}$. It is of course better to use the most efficient distributions for the BWLDs. In Katsumura, Tamura et al. [16], [18], [19], the POD eigenvectors of the wind pressure field acting on the building/structure model obtained by SMPMS are used, but it should be emphasized again that the POD eigenvectors are not necessarily required for the BWLDs in Eq.(3).

Combining Eqs.(2) and (3), the target largest load effect vector $\{\hat{R}\}$ is given as:

$$\{\hat{R}\} = [I_R]\{\hat{F}\} = [I_R][F_0]\{C\} = [R_0]\{C\} \qquad (4)$$

Once the BWLD matrix $[F_0]$ is given, as the influence function matrix $[I_R]$ can be obtained accordingly for the structural system, the product matrix $[R_0] = [I_R][F_0]$ can be a known matrix. Then, the problem is only to solve the combination factor vector $\{C\}$ based on the target largest load effect vector $\{\hat{R}\}$. The target largest load effects $\{\hat{R}\}$ can be obtained by any response analysis, but the time-domain response analysis applying the SMPMS pressure field to an FEM model may be generally made.

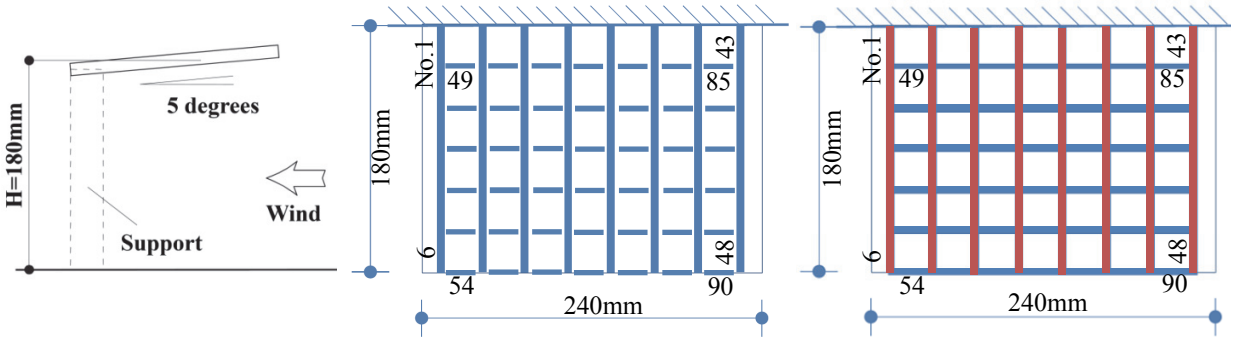
If the number of target largest load effects, N_t, is equal to the number of BWLD terms, M, in Eq.(3), i.e., $N_t = M$, Eq.(4) can be solved uniquely. If the number of target largest load effects N_t is less than M, i.e., $N_t < M$, the number of BWLD terms, M, can be appropriately reduced to N_t; thus Eq.(4) can also be solved uniquely.

However, in many cases, the number of target largest load effects, N_t, is more than the number of BWLD terms M, i.e., $N_t > M$, because of the huge number of structural members. Of course, you can increase the number of BWLD terms, M, by increasing the number of loading points for the FEM model or by any other way to equalize N_t and M. In Katsumura, Tamura, et al. [16], [18], [19], the Singular Value Decomposition (SVD) technique has been used to find the most appropriate solutions approximating the simultaneous equations given by Eq.(4). It is a matter of course that any mathematical technique can be used to obtain appropriate solutions.

2.4 *Simple cantilever roof model*

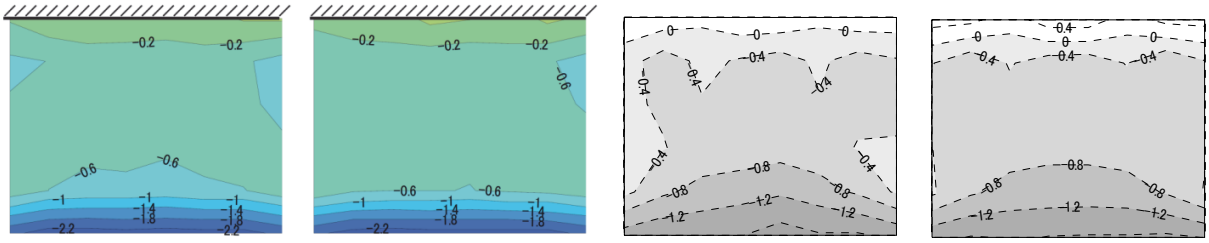
The simple cantilever roof model shown in Fig.3 was discussed in Katsumura, Tamura et al. [16], [19]. Here, the number of structural members N_m is 90, and the number of loading points is set at 48. The loading points are set on the nodes of the grid members, and the number of BWLD terms M is also set at 48. All structural members are targeted, and one largest load effect is considered for each member. Then, the number of target largest load effects is set at $N_t = N_m = 90$. In this case, $N_t > M$. As unique solutions cannot be obtained for Eq.(4), the SVD technique is applied. A wind tunnel experiment was performed to obtain fluctuating pressures acting on the upper and lower roof surfaces at the same 48 positions on the cantilever model. The net wind forces acting at these positions were applied in the FEM model for time domain dynamic response analysis.

Then, a set of largest bending moments and largest shear forces in all 90 members were extracted. Targeting these largest load effects, U-ESWL distributions were obtained. In this case, the POD eigenvectors $\{\phi_i\}$ were adopted for the BWLD vectors $\{f_i\}$. Figures 4(a) and 4(b) show the up-lift side U-ESWLs for the largest bending moments and the largest shear forces.



(a) Elevation (b) One-way type frame model (c) Two-way type frame model

Figure 3. Simple cantilever model



(a) U-ESWL (Shear Fs.) (b) U-ESWL (Bending Ms.) (c) GLF (Shear F., GLF=2.04) (d) LRC (Shear F., g_Q=4.3)

Figure 4. Up-lift side ESWLs for largest load effects on all 90 members ((a) and (b)) and for a single (maximum) largest shear force ((c) and (d)) for a one-way type model shown in Fig.3(b)

Two U-ESWLs for the largest shear forces and the largest bending moments are similar. This suggests that either Fig.4(a) or 4(b) is enough for both load effects in this case. Figures 4(c) and 4(d) show ESWLs obtained by the GLF and LRC methods, respectively, for the largest shear forces. The GLF-ESWL distribution shown in Fig.4(c) is proportional to the mean wind force distribution, which is an unrealistic distribution never happening at any instance as are the U-ESWLs shown in Figs.4(a) and 4(b). However, the LRC-ESWL shown in Fig.4(d) is a realistic distribution, which most probably generates the quasi-static component of the largest shear force of a target member.

Figure 5 compares the largest shear forces in members obtained by the time domain response analysis and those reproduced by the ESWLs (Katsumura, Tamura et al., [16]). The abscissa indicates 48 main members numbered 1 to 48. The maximum shear force in Member No.1 obtained by time-domain dynamic response analysis showed the largest value of all members, and it was selected as the target largest load effect in the calculations of ESWLs for both the GLF and LRC methods. Therefore, the largest shear forces in Member No.1 reproduced by GLF-ESWL and LRC-ESWL are exactly the same as the actual largest shear force obtained by the time-domain dynamic response analysis as indicated in the figure. However, the reproduced largest shear forces in the other members are underestimated by both GLF-ESWL and LRC-ESWL as shown in Figs.5(a) and 5(b), respectively. It is interesting that GLF-ESWL, propor-

tional to the 'unrealistic' mean wind force distribution, gives better estimation than LRC-ESWL, based on the 'realistic' instantaneous wind force distribution. This is understandable because the internal forces in the other members do not necessarily reach their maximum values at the same time that the maximum internal force in the targeted Member No.1 appears.

3 REQUIREMENTS FOR ESWL

As seen in Fig.5, the 'realistic' LRC-ESWL distribution is not necessarily better than an 'unrealistic' GLF-ESWL or U-ESWL distribution in terms of reproduction of maximum load effects for "non-targeted" members. The LRC approach can catch the typical load distribution condition causing the largest load effect in a target member (or at a target position). However, this is too typical (or too good) for the target load effect. For example, a typical LRC-ESWL distribution causing the largest bending moment at the end of a roof beam and that causing the largest bending moment at the center of a roof beam are quite different (Tamura et al., [12]). The LRC-ESWL for the beam end bending moment is obviously inappropriate for reproducing the largest beam center bending moment. Superimposition of the two ESWL distributions for these two different targets is of course also inappropriate. For such a multiple-target estimation, an U-ESWL-like approach is required. Anyway, it is strongly suggested that the LRC-ESWL is good only for the target load effect, but not for other load effects. Of course, a realistic LRC-like approach is useful for some particular purposes and has other advantages.

In order to clarify the essential matters in ESWLs, let's go back to the GLF by Davenport [1]. He assumed the following conditions for estimating the ESWL for a structure:

(1) Mean displacement caused by mean wind load is almost proportional to the 1st vibration mode.
(2) The contribution of the 1st vibration mode is predominant in the dynamic response and the contributions of other higher modes are negligible.

Under the above conditions, the distribution of the maximum displacement along the vertical axis of a tall building can be proportional to that of the mean displacement caused by the mean wind load. Therefore, even if the targeted load effect of the GLF is only the maximum tip displacement, the ESWL can also reproduce the maximum displacement at any other story. The temporary and spatially fluctuating pressure field acting on a building never shows the temporary averaged (mean) pressure distribution at any instance. Thus, the mean wind force distribution is a completely 'unrealistic' distribution, and in this regard, there is no difference from a single unrealistic concentrated load.

Thus, the original ESWL proposed by Davenport [1] was intended to reproduce not only the target largest load effect, i.e. the largest tip displacement, but also the other largest load effects simultaneously, i.e. the largest displacements of all other stories. By the way, the reason why Zhou & Kareem [9] adopted the largest base-bending moment rather than the largest tip displacement was to reproduce the largest 'internal forces', which are more important than the largest displacement in the design of tall buildings.

In general, the 1st-mode contribution is predominant for the resonant component of the wind-induced building response, but the dynamic response consists not only of the resonant component but also of the background component. The latter is not necessarily proportional to the 1st vibration mode, and the 2nd condition is not acceptable in some cases. Especially in the case of long-span roof structures, the higher mode contributions are very significant for the maximum internal forces in the structural members, and they never appear simultaneously. Thus, in general, the largest internal forces appear at different instances, and the LRC-ESWL by Kasperski [5] does not guarantee the largest internal forces in other non-targeted members.

Anyway, it is obvious that the main purpose of the ESWL is to reproduce the targeted largest load effect, and it is also essential to reproduce other non-targeted largest load effects. These two are very important requirements for ESWLs in practical applications, and it is also true that a 'realistic' wind force distribution essentially does not satisfy the latter requirement except in some special cases and only 'unrealistic' wind force distributions are possible.

Then, if these two requirements are the most important, it is very natural to directly seek an 'unrealistic' wind force distribution reproducing the largest internal forces simultaneously in all structural members. In answer to this question, Katsumura and Tamura et al. [16], [18], [19] proposed the U-ESWL to reproduce the largest load effects in all structural members.

4 REQUIRED POSITIVE-SIDE AND NEGATIVE-SIDE U-ESWL DISTRIBUTIONS

The U-ESWL distributions are derived by an inverse analysis based on the actual largest load effects in all or some important targeted members obtained by dynamic time domain response analyses applying fluctuating pressure fields. Figure 5(c) compares the actual largest shear forces reproduced by the U-ESWL shown in Fig.4(a) and the actual largest shear forces obtained by the dynamic time domain response analysis in 48 targeted members. By applying the simple U-ESWL distribution shown in Fig.4(a), all largest load effects were almost perfectly reproduced. This is quite different from the results shown in Figs.5(a) and 5(b) for GLF-ESWL and LRC-ESWL. The efficiency of the U-ESWL might be understood from Fig.5(c).

It should be noted that "two" U-ESWL distributions reproducing positive-side and negative-side largest load effects are necessary in building design, considering the combined load effects

with other loads such as dead load, snow load and so on. If we include the mean component of the pressure field, both the obtained maximum and the minimum "wind-induced" load effects in all members can be all positive, all negative, or a mixture of positive and negative. However, if the mean components of pressures are subtracted and only fluctuating components are applied, the maximum load effects can be all positive and the minimum load effects can be all negative.

For simplicity but not losing generality, we only apply the fluctuating components of pressures in the time domain analyses. The effects of the mean components can be taken into account separately or superimposed finally. Figures 7(a) - 7(c) show positive-side and negative-side U-ESWLs and the largest load effects reproduced by these two U-ESWL distributions for the two-way type cantilever frame model shown in Fig.3(c). Here, the red solid lines shown in Fig.7(c) indicate the maximum and the minimum shear forces in all 90 members obtained by time-domain response analysis. If the target load effects are the maximum and minimum shear forces in these 90 (= N_t) members, we should consider N_t positive shear forces Q_j^+ (j = 1, 2, ... N_t) and N_t negative shear forces Q_j^- (j = 1, 2, ... N_t) as the target load effects. In this case, two sets of largest shear forces should be considered for two U-ESWLs, but elements of the two sets are arbitrarily selected. It is not necessary that one set should consist of all positive shear forces and the other should consist of all negative shear forces. Any combination of the largest positive and negative shear forces is theoretically fine, if Q_j^+ and Q_j^- appear in either of the two sets as follows:

Set A: $Q_1^+, Q_2^-, Q_3^+, Q_4^+, Q_5^-, \quad \ldots \quad , Q_{Nt-1}^+, Q_{Nt}^-$
Set B: $Q_1^-, Q_2^+, Q_3^-, Q_4^-, Q_5^+, \quad \ldots \quad , Q_{Nt-1}^-, Q_{Nt}^+$

However, for general use of U-ESWL distributions and its desired robustness with various structural systems, a moderate wind load distribution like those shown in Figs.4(a) or 4(b) is better. If the combination of the signs of the largest load effects in a set was not adequate, even an obtained U-ESWL can reproduce all targeted largest load effects appropriately; the obtained ESWL distribution is too specific for the given structural system and cannot show robustness for different structural systems.

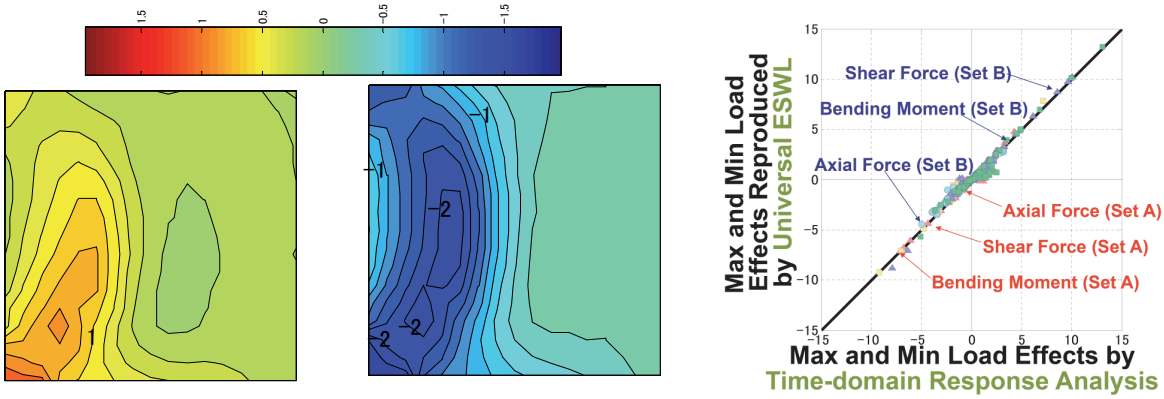
In order to overcome this difficulty, Katsumura, Tamura et al. [16] proposed to use some POD eigenvectors of fluctuating load effects in all members to decide the combination of signs of load effects for the two sets, Set A and Set B. It should be noted that the POD eigenvectors are different from those of the fluctuating pressure field used for the BWLD in Eq.(3). The POD technique is applied for a time series of internal forces in all members obtained by the time-domain response analysis.

4.1 *Two-way type cantilever roof model*

Katsumura, Tamura et al. [16] discussed the contributions of the 1st and 2nd POD modes to the fluctuating shear forces in the 90 members of the two-way frame shown in Fig.3(c). The 1st mode contribution was very significant for the along-span members, while the 2nd mode contribution was very significant for the along-ridge members. Based on these, the signs of the largest shear forces in the along-span members are set the same as the 1st POD eigenvector of the fluctuating shear forces in all members, and those of the largest shear forces in along-ridge members are set the same as the 2nd POD eigenvector. In this way, the two U-ESWL distributions are obtained as shown in Figs.7(a) and 7(b). By applying these two U-ESWL distributions, positive-side and negative-side largest wind load effects can be obtained for all members as shown in Fig.7(c).

4.2 *Flat roof models*

Following the procedure explained before, two sets of U-ESWL distributions are obtained for a truss-beam flat-roof model, as shown in Figs.10(a) and 10(b).



(a) U-ESWL for Set A (b) . U-ESWL for Set B (c) Reproduced largest shear forces

Figure 10. U-ESWL distributions for a flat-roof model and comparison of largest load effects obtained by time-domain response analysis and U-ESWLs

Figure 10(c) compares the largest axial forces, bending moments and shear forces in all members of the truss-beam model obtained by the time domain response analysis and those reproduced by the U-ESWLs. In this case, various different kinds of internal forces are simultaneously targeted, and all of them are appropriately reproduced by only two U-ESWL distributions, as shown in Figs.10(a) and 10(b). Here, the efficiency and the feasibility of the U-ESWL are clearly demonstrated.

5 CONCLUDING REMARKS

The essential matters required for ESWLs are discussed and some advantages of the multiple-target ESWL, especially U-ESWL, are demonstrated for long-span roof structures. There is no significant difference between the procedures for obtaining ESWL by the various approaches. GLF-ESWL, LRC-ESWL, U-ESWL and so on all require the following procedures:

- Getting largest load effects to be targeted, probably by time-domain response analysis
- Conducting inverse analysis to get ESWL based on given target load effect(s)
- Accumulation of ESWL distributions to create database for codification

The GLF method has been widely adopted in many wind load codes and standards, and the aerodynamic database for the GLF methods. The advantage of the simplicity of GLF is also obvious, and can be reasonably applied for tall buildings. It is also well known that many novel ideas on ESWL have been proposed and recent improvement of the GLF method is significant. The Gust Front Factor has been proposed by Kwon & Kareem [14] to envelope the GLF method and to reflect the effects of an unsteady flow field.

However, it is also true that a traditional single-target approach such as GLF or LRC has a limitation for roof structures, and the multiple-target approach such as U-ESWL is required and has the possibility of further development in its application. More studies on U-ESWL are desirable.

ABSTRACT: This paper describes a method for determining the universal wind load distribution that reproduces the largest load effect on structural members. The method is then applied to a low-rise building and a high-rise building. Quasi-static load effects are investigated for the low-rise building. The largest load effects estimated by the time history response analyses are compared with those reproduced by the GLF method, the LRC method and the universal ESWL. The goal is to provide a database of the universal equivalent static wind load distribution and to develop a wind resistant design method.

KEYWORDS: Largest load effect, Equivalent static wind load, GLF method, LRC method

1 INTRODUCTION

Increasingly complicated building shapes and structural systems have increased the importance of structural design. The safety of all of structural members needs to be confirmed in the structural design stage. Conventional methods of estimating equivalent static wind loads (ESWL) are based on a certain load effect. However, in practice, it is necessary to consider several ESWLs assuming many loading patterns. The authors have proposed a Universal ESWL that simultaneously reproduces the largest load effects on all structural members, and confirmed its effectiveness and rationality by applying it to several structures[1,2]. The technical procedure of this Universal ESWL has been discussed and established. The Universal ESWL makes it possible to reproduce all largest load effects in a unique distribution. Positive and negative load effects are reproduced by a set of the Universal ESWLs. The advantages of this unique method may not yet be sufficiently recognized by many researchers and structural designers. In this study, conventional methods for estimating an ESWL and the method for estimating the Universal ESWL are applied to several structures and the usefulness of the Universal ESWL is verified.

2 EQUIVALENT STATIC WIND LOAD FOR LOW-RISE BUILDING

In standards and laws of many countries the gust loading factor (GLF) method is adapted for estimating an ESWL for low rise buildings. However, the effects of loads acting on members of a low rise building imposed by wind forces on roofs and walls are very complicated. The GLF method is basically aimed at a certain load effect, so it cannot be guaranteed that the resulting ESWL reproduces all of the largest effects. This section investigates ESWLs for a low rise building with a gable roof.

Fluctuating wind pressure data of a low-rise building and its experimental information were down-loaded from the database of the Global COE Wind Engineering Information Center at To-

kyo Polytechnic University[3]. The experimental model was 160mm wide, 240mm deep and 160mm high, and its roof pitch was 9.4 degrees. Its mean wind pressure coefficients and fluctuating wind pressure coefficients are shown in Fig.1 and Fig.2. The maximum mean wind pressure coefficient was 0.8 on the front wall and the corresponding fluctuating wind pressure coefficient was 0.4. The minimum mean wind pressure coefficient was –1.2 on the roof's windward edge and the corresponding fluctuating wind pressure coefficient was 0.4. The mean wind pressure coefficients and the fluctuating wind pressure coefficients on the leeward side of the roof and the leeward wall were small.

Low rise buildings have rigid frames and a background component of load effects would be dominant in members. A simple structural model of a low-rise building was used in this study, as shown in Fig.3. It was constructed of steel frames in the span direction and each all frames were connected by beams and braces in the cross-span direction. The background components of load effects were calculated from the structural model from a time history of fluctuating wind pressure data. Design wind speed was assumed as 30m/s at the building height. The largest load effects on members were estimated from the time history analysis (hereafter referred to as actual largest load effect). The maximum largest axial force occurred at the upper part of the windward column of the 1st floor and the maximum largest shear force and bending moment occurred at the beam's end of the middle frame as shown in Fig.3. ESWLs based on these target largest load effects were calculated by the GLF method and the LRC method. The Universal ESWL that simultaneously reproduces actual largest axial forces, shear forces and bending moments in major members was also calculated.

The ESWL estimated by the GLF method focused on a largest axial force is shown in Fig.4. It is normalized by velocity pressure at the eaves height and the mean component of the wind force coefficient is excluded from it. Although positive and negative largest load effects were estimated, an ESWL that reproduces the same sign of the mean component of load effect is shown in this figure. The gust loading factor of the largest axial force was 3.5. The mean shear force and the mean bending moment in the frame in which the target largest load effects occurred in a member transverse to the wind direction was almost zero, so the GLF method cannot be adopted for both the largest shear force and the largest bending moment.

The ESWL estimated by the LRC method is shown in Fig.5. Although two ESWLs can be estimated from the LRC method, an ESWL that produces negative values on the roof is shown in this figure. The peak factor of the largest axial force, shear force and bending moment were 6.7, 7.1 and 4.3 respectively. The ESWLs are asymmetric to the wind direction and show quite different distributions from the axial force, shear force and bending moment.

The Universal ESWL that simultaneously reproduces largest axial force, shear force and bending moment in main structural members is shown in Fig.6. In the previous study, it was confirmed using a POD eigen vector of fluctuating wind pressure that the Universal ESWL would show a natural and realistic distribution. In this Universal ESWL for low rise buildings, the 1st to 10th POD eigen modes were superimposed. Two Universal ESWLs were estimated for combination of positive and negative largest load effects. Target largest load effects on members were selected by using the same sign as the POD 1st eigen mode of load effect[1]. The Universal ESWL shows asymmetric distribution and is different from the ESWLs estimated by either the GLF method or the LRC method.

Figures 7-9 compare actual largest load effects and those reproduced by all ESWLs. The abscissa shows actual largest load effects for all members and the ordinate shows that reproduced by all ESWLs. The largest load effects are normalized by the maximum actual largest load effects. Comparatively high correlation can be seen in the comparison of largest axial forces estimated by the GLF method and the LRC method and the largest bending moments estimated by the LRC method. However, the correlations of largest shear forces decrease in the LRC method.

Comparison of largest axial force, shear force and bending moment reproduced by the Universal ESWL are shown in Fig.9. The largest load effects reproduced by the Universal ESWL shows comparatively high correlation with the actual largest load effects by the unique distribution.

3 CONCLUSION

In the conventional GLF method and the LRC method, the ESWLs are estimated from a certain target load effect. From a physical point of view, mean or fluctuating wind pressure distributions have been used for the ESWLs that are expected to reproduce the largest load effects in all structural members. The more complicated the structure becomes, for example a low-rise building, the more the target largest load effects increase. A reasonable ESWL would be a complicated distribution apart from the mean or the fluctuating wind pressure distribution. The Universal ESWL automatically provides a reasonable distribution for any building structure and any combination of load effects. It may have been possible to realize a more reasonable ESWL distribution after accumulation of many structural types and designs. We have been developing the database of the Universal ESWL.

Wind-induced vibrations and equivalent static wind loading for cable-stayed bridges

Yong-Xin YANG, Yao-Jun GE

State Key Laboratory for Disaster Reduction in Civil Engineering
Department of Bridge Engineering at Tongji University, Shanghai 200092, China

ABSTRACT: Although cable-stayed bridges generally have higher rigidity and natural frequencies, flutter instability still can pose threats to some aerodynamic bluff girder sections, such as box girder section with cantilevered slab and two-isolated-girder section. Experimental researches on the flutter instability of these girder sections were carried out to find effective ways to improve their flutter performance. While the adoption of twin box girder can be an effective solution to improve the flutter stability of cable-stayed bridges, more attention should be paid to its vortex-induced vibration performance. Based on a long-span cable-stayed bridge, the vortex-induced vibration performance of twin box girder section was evaluated and aerodynamic control measure was proposed to mitigate the vibration response. Since it is more convenient for a bridge engineer to evaluate buffeting responses of a bridge structure by some kind of equivalent static wind loading than comprehensive buffeting analysis, the method to calculate equivalent wind load of cable-stayed bridges caused by buffeting response, which is recommended by the China Code for wind-resistant design of highway bridges, was demonstrated.

KEYWORDS: vortex-induced vibration; flutter; vortex-induced vibration; vibration control measure; wind tunnel test; equivalent static wind load

1 INTRODUCTION

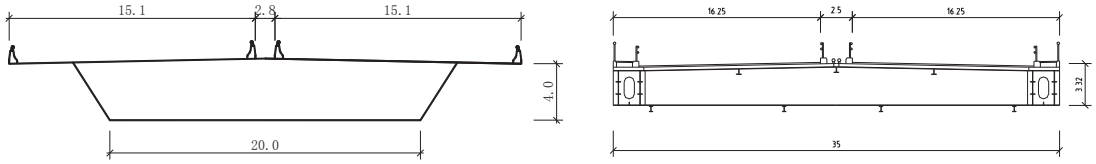
With the rapid increase of span length, bridge structures are becoming more flexible and more vulnerable to wind-induced vibrations. Compared with suspension bridges with similar main span, cable-stayed bridges usually have higher rigidity and natural frequencies, which implies better aerodynamic stability. However, if the shape of a main girder hasn't been optimized enough to obtain good aerodynamic performance, there still will exist flutter instability problems even when the main span of a cable-stayed bridge isn't very large. For those girder sections which has been optimized to have better flutter performance, another possible self-excited vibration, vortex-induced vibration, may affect the operating performance of a bridge if happens. Furthermore, buffeting always exists when a bridge is exposed to turbulent flow, which is very common in the Atmospheric Boundary Layer. Different from the way flutter and vortex-induced vibration are dealt with, it is more convenient for a bridge engineer to evaluate the buffeting responses of a bridge structure by some kind of equivalent static wind loading, than comprehensive three-dimensional frequency domain or time domain buffeting analysis. In this paper, problems related to flutter and vortex-induced vibration of cable-stayed bridges and their countermeasures are introduced based on some engineering projects in China, and the method to calculate equivalent wind load caused mainly by buffeting response, which is recommended by the China Code for wind-resistant design of highway bridges (cable-stayed bridges and suspension bridges), will be demonstrated.

2 FLUTTER INSTABILITY

Generally speaking, cable-stayed bridges have better flutter performance than suspension bridges for higher rigidity resulted from their unique structural system. Even for a super long-span cable-stayed bridge which have a main span over 1 kilometer, flutter instability never posed a real threat after a spatial cable system and a reasonable girder section were adopted. However, the span length isn't the only key factor which determines the flutter performance of a long-span bridge, as the infamous original Tacoma Narrows Bridge, which suffered from flutter-induced collapse, was not the longest bridge at that time. The dynamic performance of the structural system composed of girder, stay-cables and pylon also matters, as well as the aerodynamic configuration of the girder section. For cable-stayed bridges with middle-range main spans, aerodynamically blunter composite main girders are more preferred by designers in most cases to traditional flat single box steel girders for economical reasons.

2.1 STRUCTURAL INFORMATION

The two girder sections (Figure 1) investigated in this research have been widely used as the main girder section of cable-stayed bridges, especially when the bridge span is not very large. Section A, box girder section with cantilevered slab, and Section B, two isolated rectangular box girder, are main girders of the Main Bridge and the Kezhushan Bridge respectively, which are two major crossings of East Sea Bridge over two main navigational channels between the Yangshan International Deep Water Harbor and Shanghai city.



a) Section A b) Section B

Figure 1 Two girder sections of cable-stayed bridges

Although the main spans of these two bridge are not very large, the torsional fundamental frequency are lower than 0.6 Hz and the ratios between the torsional and bending fundamental frequencies are no more than 1.65, due to their general structural layout (single cable plane or parallel cable plane) and composite girder sections.

2.2 FLUTTER PERFORMANCE

Sectional model tests and aeroelastic mode tests were carried out to examine the flutter performance of these two cable-stayed bridges in TJ-1 and TJ-3 Boundary Layer Wind Tunnel in the State Key Laboratory for Disaster Reduction in Civil Engineering (SKLDRCE) of Tongji University as shown in Figure 2.

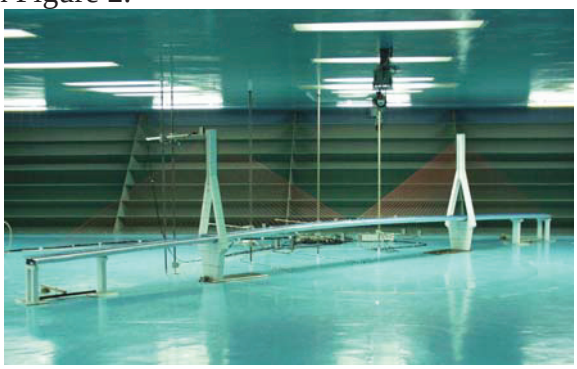


Figure 2 Sectional model and aeroelastic model wind tunnel test for flutter performance

The measured flutter critical speeds for both girder sections of these two cable-stayed bridges are listed in table 1. For Section A, the structure is very aerodynamically stable even after wind speed exceeds 100 m/s when the wind angle of attack is zero or negative. However, when the wind angle of attack turns positive, the flutter onset speed decreases dramatically and is below the flutter checking wind speed. This is the characteristics of the aerodynamic performance for this type of girder section. The flutter performance of Section B is worse than Section A since this is a blunter girder section. The results of aeroelastic model tests generally have good agreement with sectional model tests.

Table 1 Flutter critical speed of the original section（m/s）

Girder	Test	–3°	0°	+3°	[U_{cr}]
Section A	Sectional model	>176	145.0	81.4	84.6
	Aeroelastic model		>100	82.6	
Section B	Sectional model	96.2	74.8	69.0	79.9
	Aeroelastic model		72.5		

Based on the testing results, the flutter critical speeds for both original structures cannot meet the requirement of flutter checking speeds of 84.6 m/s for the main navigational channel bridge and 79.9 m/s for Kezhushan Bridge, so effective preventive measures had to be considered to stabilize the original bridges.

2.3 FLUTTER CONTROL

In order to improve the aerodynamic stability of the main navigational bridge, central barrier was installed on the bridge deck (Section A) as shown in Figure 3. Three different heights of central barrier were chosen to investigate the controlling effect of this aerodynamic measure, which are 0.8m, 1.0m and 1.2m respectively, or 20%, 25% and 30% of the girder depth respectively.

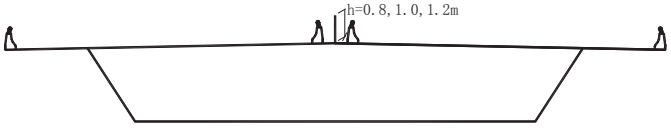

Figure 3 Girder section A with central barrier

The measured flutter critical speeds are listed in table 2. As the results shown, the flutter controlling effect of central barrier is excellent. For three types of central barrier the flutter onset speeds are all exceed the wind speed requirement, and the section with 1.2 m high central barrier has the best aerodynamic performance which increases the flutter onset speed by approximately 11%.

Table 2 Flutter critical speed of Section A with central barriers（m/s）

Angle of attack	–3°	0°	+3°
Original section	>176	145.0	81.4
0.8m central barrier	>176	151.8	85.8

1.0m central barrier	>176	151.8	85.8
1.2m central barrier	>176	154.0	90.2

As mentioned previously, when at positive angle of attack the aerodynamic stability of the original girder section A is rather low and different from those at negative and zero angle of attack. It can be inferred that adjusting aerodynamic configuration of the windward inclined web and the bottom slab will affect the aerodynamic stability of the girder section dramatically. So several measures concerning various positions of the inspection rails were investigated in wind tunnel tests. These testing sections are shown in Figure 4.

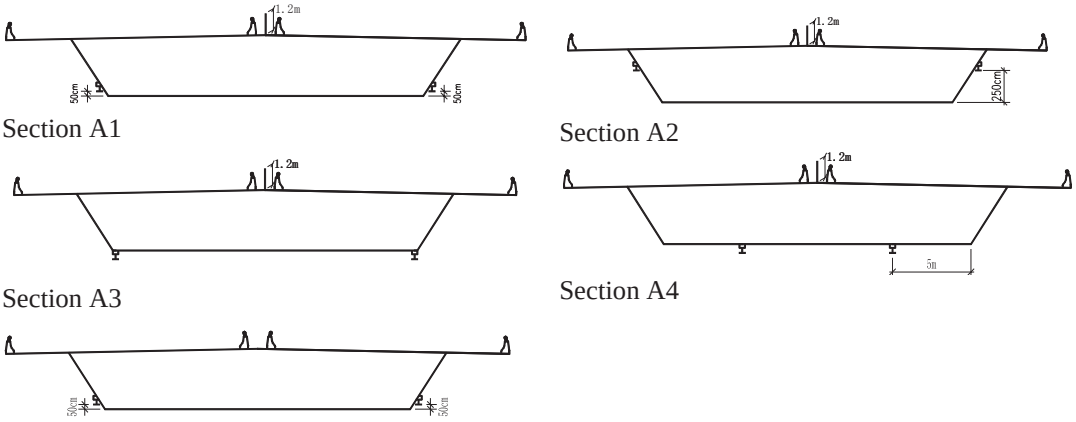

Figure 4 Girder section A with different locations of inspection rails

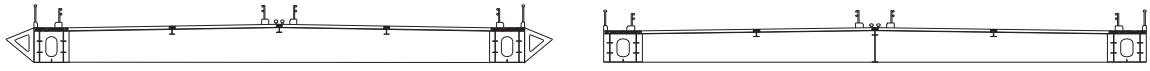
Section A1 has inspection rails on the bottom of the inclined web, while section A2 has inspection rails on the upper side of the inclined web. In section A3 and section A4 the inspection rails are on the bottom slab. These four sections all have 1.2m high central barrier on the bridge deck. In section A5 the position of inspection rails is the same as in section a, but has no central barrier on the bridge deck. The wind tunnel testing results for these sections with inspection rails are listed in table 3.

Table 3 Flutter critical speed of sections A with different locations of inspection rails (m/s)

Angle of attack	–3°	0°	+3°
Original section	>176	145.0	81.4
Section A1	>176	162.8	94.6
Section A2	>176	151.8	88.0
Section A3	>176	121.0	79.2
Section A4	>176	154.0	90.2
Section A5	>176	154.0	90.2

From the testing results we can see that the aerodynamic stabilities of sections with central barrier and inspection rails being appropriately positioned have been improved remarkably except section A3. Section A1 which has 1.2m central barrier and inspection rails at the bottom of the inclined web has the best aerodynamic performance considering flutter instability. For section A5 which has inspection rails at the same position as section a and no central barrier, the aerodynamic stability also has been improved by 11% and exceeds the flutter verification speed. As section A5 also has economic advantage, this flutter control measure is finally recommended to bridge designer.

The girder section B of the Kezhunshan bridge is a more bluff body compared to the original girder section A of the main navigational bridge. So the first flutter control measure taken into account is the installation of fairings. The girder section with fairings is shown in Figure 5 a).



a) Fairing b) Central stabilizer

Figure 5 Girder section B with fairings

The flutter performance of girder section B with fairings was tested in aeroelastic model wind tunnel test, and the results are listed in table 4. For each angle of attack the flutter onset speed is over the flutter verification speed 79.9 m/s, which means it is a very effective measure to improve the aerodynamic stability for such a two-isolated-girder section.

Table 4 Flutter critical speed of section B with fairings and central barrier（m/s）

Angle of attack	–3°	0°	+3°
Original section B		72.5	
Section with fairings	95.0	>100	95.0
Section with central barrier	87.5	82.5	>100

For the interest of research on the effectiveness of flutter control measures, an alternative control measure which has a central barrier installed under the bridge deck and with the same height as the girder section is investigated in this research. The girder section B with central barrier is shown in Figure 5 b). Aeroelastic model tests were carried out to verify the effectiveness of the installation of central barrier. The corresponding testing results are also shown in table 4. Although the flutter controlling effectiveness of the central barrier on this type of girder section is not as remarkable as that of the application of fairings, this measure does improve the aerodynamic stability of the original section to meet the design requirement.

3 VORTEX-INDUCED VIBRATION

Even for aerodynamic stable girder sections which have been optimized to obtain better flutter performance, another kind of self-excited vibration, vortex-induced vibration, may happen at lower wind speed range. Section C is a typical twin box girder with a central vent (Figure 6), which is the main girder of Shanghai Yangtze Bridge, a three-span cable-stayed bridge with a main span of 730m.

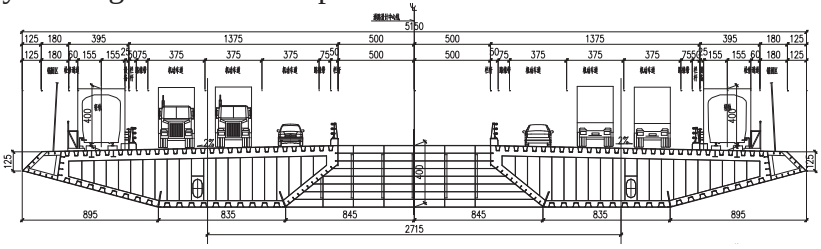


Figure 6 Girder section C

Although twin box girder has been proven to be very effective to enhance the flutter performance of super-long span bridges, more attention should be paid to the vortex-induced vibration performance of this innovative girder section, since the existence of central vent will make the vortex shedding process and its interaction with the movement of the bridge girder more complicated.

3.1 VIV PERFORMANCE

For detailed investigation on VIV responses, a combination of geometrical, mass, stiffness and Reynolds number considerations resulted in the selection of a 1:25 scale for the sectional model. These large-scale sectional models have the total length of about 3.6 m and the width of about 2.06m. The wind tunnel tests were conducted in smooth flow at Tongji University's TJ-3 Boundary Layer Wind Tunnel with the working section of the 15m width, the 2m height and the 14m length. Two rigid and streamlined temporary end walls were designed and built in the working section to accommodate the large sectional model (Figure 7), and the suspension system including eight springs and supporting frames was built in these two end walls together with four laser displacement transducers for the measurement of the response of the sectional model to vortex-shedding excitation.

Figure 7 Large-scale sectional model and supporting system

Both heaving and torsional VIV responses were observed in the testing, and the Strouhal Number and Reynolds Number at the VIV condition are 0.1230 and 90, 768 respectively. Table 1 list the maximum VIV amplitudes and some important parameters in VIV conditions.

Table 5 Maximum VIV amplitudes and important parameters

VIV in heaving (h/D)			VIV in torsion		
Amplitude	S_t	R_e	Amplitude	S_t	R_e
0.054	0.1620	29, 264	0.134	0.1230	90, 768

3.2 VIV CONTROL

Guide vane is a possible VIV control solution, which can smooth air flow around the corner of girder section. After comparisons of the VIV mitigating effects between different locations of guide vanes, the optimum location for Section C was found to be under the bottom slab near central vent, which is shown in Figure 8. The responses of the model with and without guide vanes at -3˚ wind angle of attack are shown in Figure 9. It can be seen that the torsional VIV of the original twin box girder can be mitigated effectively by the installation of guide vanes. No significant heaving VIV of the girder with guide vanes was observed except for the case at -3˚ wind angle of attack. In this case the peak amplitude of heaving VIV was reduced from 21.7 cm to 13.6 cm for the prototype bridge structure with 0.3% structural damping ratio. Guide vane seems to have better mitigating effect on torsional VIV than heaving VIV for twin box girder sections. Comparisons of maximum VIV amplitudes among +3˚, 0˚, and -3˚ wind angles of attack for girder section C and another two long-span bridges having twin-box girders with and without guide vanes at the condition of 0.3% structural damping ratio are listed in Table 6. The results also imply that the VIV control effect of guide vane is rather sensitive to the outboard and inboard shape of a twin box girder section.

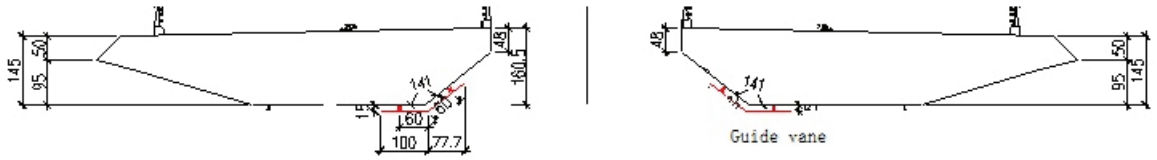

Figure 8 Section C with guide vanes

4 EQUIVALENT WIND LOAD

Buffeting always exists when a bridge is exposed to turbulent flow, which is very common in the Atmospheric Boundary Layer. For a bridge engineer, it is more convenient to evaluate the buffeting responses of a bridge by some kind of equivalent static wind load. Based on the China Code, the total wind load on a bridge structure can be calculated by the following formula:

$$L_{Total} = L_{SG} + L_R$$

Where L_{Total} is the total wind load, L_{SG} is called static gust wind load, which is actually the summation of the static wind load and the equivalent static wind load related to background buffeting responses, and L_R is the equivalent static wind load related to resonant buffeting responses, which can be calculated through Inertia Wind Loading Method.

4.1 STATIC GUST WIND LOAD

According to the China Code for the wind-resistant design of highway bridges, the method to calculate the static gust wind load is the same as static wind load. The only difference is to replace design wind speed with static gust wind speed in static gust wind load evaluation. The conversion factor from design wind speed to static gust wind speed is called static gust wind coefficient, which varies with terrain types at bridge site and horizontal wind-load-bearing length. For the Main Bridge of East Sea Bridge, this coefficient is 1.22 at the service state.

In order to get the static gust wind load, the aerodynamic force coefficients of the girder section were measured through sectional model wind tunnel tests and listed in Table 7. Coefficients of the main pylon were suggested by the code.

Table 7 Aerodynamic force coefficients

Components	Drag force (C_x)		Lift force (C_y)		Pitch moment (C_M)	
	Service	Construction	Service	Construction	Service	Construction
Girder	0.931	0.661	-0.043	0.006	0.054	0.076
Pylon	1.5	2.0	1.5	2.0	0	0

Then the static gust wind load for the main girder at the service stage can be calculated as follows.

$$\bar{W}_y^d(x) = \bar{W}_{y0}^d \alpha_{y0}^d(x) = \frac{1}{2}\rho U_c^2 B C_y = -2.814\ kN/m \tag{1a}$$

$$\bar{W}_z^d(x) = \bar{W}_{z0}^d \alpha_{z0}^d(x) = \frac{1}{2}\rho U_c^2 H C_z = 7.385\ kN/m \tag{1b}$$

$$\bar{W}_\theta^d(x) = W_{\theta 0}^d \alpha_{\theta 0}^d(x) = \frac{1}{2}\rho U_c^2 B^2 C_M = 116.614\ kN\cdot m/m \tag{1c}$$

Where, $\bar{W}_{y0}^d$、$\bar{W}_{z0}^d$、$\bar{W}_{\theta 0}^d$ are maximum values of the vertical, horizontal and torsional components of the static gust wind load for the main girder, α_{y0}^d、α_{z0}^d、$\alpha_{\theta 0}^d$ are distribution function for the three components of the static gust wind load for the main girder, and $\alpha_{y0}^d \equiv \alpha_{z0}^d \equiv \alpha_{\theta 0}^d \equiv 1$.

The static gust wind load for the main pylon at the service stage can be calculated in the similar way.

$$\bar{W}_z^p(z) = \bar{W}_{z0}^p \alpha_{z0}^p(z) = \frac{1}{2}\rho U_t^2 B_D C_D \left(\frac{z}{z_t}\right)^{2\alpha} \frac{B_D(z)}{B_D} = 29.45\left(\frac{z}{z_t}\right)^{0.2} \frac{B_D(z)}{B_D}(kN/m) \tag{2a}$$

$$\bar{W}_x^p(z) = \bar{W}_{x0}^p \alpha_{x0}^p(z) = \frac{1}{2}\rho U_t^2 B_L C_L \left(\frac{z}{z_t}\right)^{2\alpha} \frac{B_L(z)}{B_L} = 25.77\left(\frac{z}{z_t}\right)^{0.2} \frac{B_L(z)}{B_L}(kN/m) \tag{2b}$$

Where, $\bar{W}_{z0}^p$ and $\bar{W}_{x0}^p$ are in-plane and out-of-plane static gust wind load for the main pylon at the top of the pylon, while α_{z0}^p and α_{x0}^p are distribution function for the static gust wind load for the main pylon

$$\alpha_{z0}^p(z) = \left(\frac{z}{z_t}\right)^{0.2} \frac{B_D(z)}{B_D},\quad \alpha_{x0}^p(z) = \left(\frac{z}{z_t}\right)^{0.2} \frac{B_L(z)}{B_L} \tag{3}$$

C_D and C_L are in-plane and out-of-plane aerodynamic force coefficients of the main pylon.

The results of the static gust wind load for the main girder and main pylon of the Main Bridge of the East Sea Bridge is shown in Figure 10.

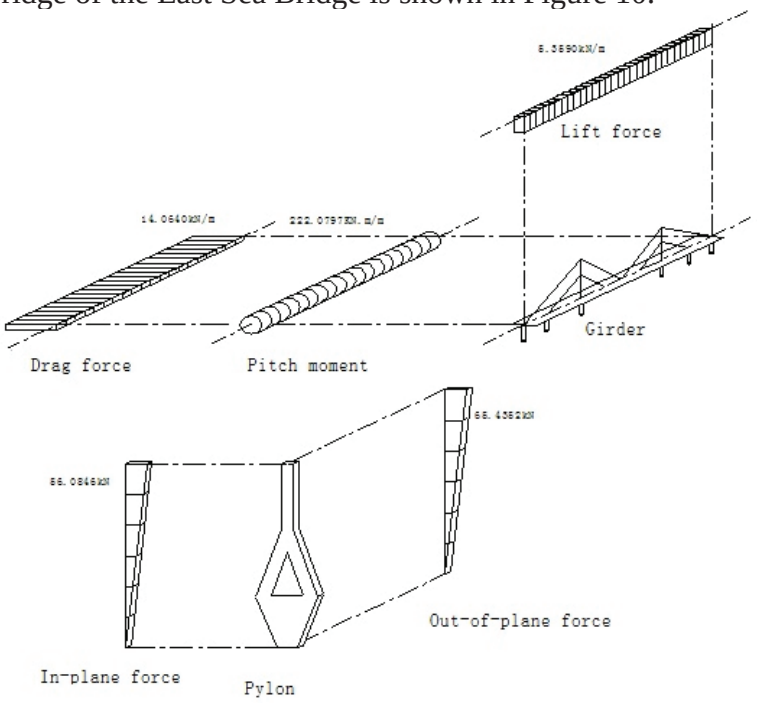

Figure 10 Static gust wind load

4.2 EQUIVALENT STATIC WIND LOAD

The equivalent static wind load related to resonant buffeting responses can be calculated through Inertia Wind Loading Method. So the equivalent wind load can be evaluated by the following formulas.

$$W_y(s)=\bar{W}_y(s)+\tilde{W}_y(s)\approx\bar{W}_{y0}\alpha_{y0}(s)+\tilde{W}_{y1}\alpha_{y1}(s)+\tilde{W}_{y2}\alpha_{y2}(s) \quad (4a)$$

$$W_z(s)=\bar{W}_z(s)+\tilde{W}_z(s)\approx\bar{W}_{z0}\alpha_{z0}(s)+\tilde{W}_{z1}\alpha_{z1}(s)+\tilde{W}_{z2}\alpha_{z2}(s) \quad (4b)$$

$$W_\theta(s)=\bar{W}_\theta(s)+\tilde{W}_\theta(s)\approx\bar{W}_{\theta0}\alpha_{\theta0}(s)+\tilde{W}_{\theta1}\alpha_{\theta1}(s)+\tilde{W}_{\theta2}\alpha_{\theta2}(s) \quad (4c)$$

Where, $\bar{W}_y$、$\bar{W}_z$、$\bar{W}_\theta$ are static gust wind load which can be calculated through equation (1) and (2), $\tilde{W}_y$、$\tilde{W}_z$、$\tilde{W}_\theta$ are vertical, horizontal and torsional components of buffeting inertial forces, $\tilde{W}_{y1}$、$\tilde{W}_{z1}$、$\tilde{W}_{\theta1}$ are peak values of three components of buffeting inertial forces for the first natural vibration mode, $\tilde{W}_{y2}$、$\tilde{W}_{z2}$、$\tilde{W}_{\theta2}$ are peak values of three components of buffeting inertial forces for the second natural vibration mode, $\alpha_{y1}(s)$、$\alpha_{z1}(s)$、$\alpha_{\theta1}(s)$ are distribution functions for the three components of buffeting inertial forces for the first natural vibration mode, $\alpha_{y2}(s)$、$\alpha_{z2}(s)$、$\alpha_{\theta2}(s)$ are distribution functions for the three components of buffeting inertial forces for the second natural vibration mode.

Based on the buffeting responses measured in aeroelastic model wind tunnel tests, the buffeting inertial forces at any measuring points on the main girder or the main pylon can be calculated through the following formula.

$$\tilde{W}_{ri}\alpha_{ri}(s_k)=(2\pi f_i)^2 g_{\sigma i}\sigma_{ri}(s_k)m_r(s_k) \qquad (r=y,z,\theta;\ i=1,2) \quad (5)$$

Where, f_i is the frequency of the ith mode, $g_{\sigma i}$ is the peak factor of the buffeting response of the ith mode, $\sigma_{ri}(s_k)$ is the root-mean-square (RMS) value of the buffeting response at measuring point s_k for the ith mode, $m_r(s_k)$—is the mass or mass moment of inertia at measuring point s_k.

For locations other than those measuring points, the buffeting inertial forces can be evaluated by

$$\tilde{W}_{ri}\alpha_{ri}(s_l)=(2\pi f_i)^2 g_{\sigma i}\sigma_{rim}m_r(s_l)\varphi_{ri}(s_l) \qquad (r=y,z,\theta;\ i=1,2) \quad (6)$$

Where, σ_{rim} is the RMS value of the buffeting response at the location corresponding to the maximum value of the modal function for the ith mode, $m_r(s_l)$ is the mass or mass moment of inertia at any location s_l on the main girder or the main pylon, $\varphi_{ri}(s_l)$—is the value of the normalized ith modal function at the location s_l.

The results of the equivalent static wind load for the main girder and main pylon of the Main Bridge of the East Sea Bridge at the design wind speed is shown in Figure 11.

5 CONCLUSIONS

Experimental researches on the flutter instability of two aerodynamically bluff girder sections, box girder section with cantilevered slab and two-isolated-girder section, which have been widely adopted in the constructions of cable-stayed bridges, were carried out to find effective ways to improve their flutter performance. For single box girder section, the aerodynamic stability under positive wind angle of attack is critical, and adding central barrier on the deck and position adjustment of inspection rails to the bottom of the inclined web are effective aerodynamic measures to improve flutter performance. For two-

isolated-girder section, installing central barrier under the bridge deck and adding fairing can both increase flutter onset speed significantly.
Based on the results of large scaled model wind tunnel tests for a long-span cable-stayed bridge, twin box girders are prone to have vortex-induced vibrations with large amplitude. Installing guide vanes at the bottom of the girder section near central vent can mitigate vortex-induced vibrations, especially in torsional motion.
According to the China Code for wind-resistant design of highway bridges, the equivalent wind load for a cable-stayed bridge is expressed by the summation of static gust wind load and equivalent static wind load. The static gust wind load can be calculated in the similar way as static wind load, and the equivalent static wind load related to resonant buffeting responses can be evaluated by Inertia Wind Loading Method.

Coupling effects of resonant components of aerodynamic loads acted on hyperbolic spacial structures

S.T. Ke, L. Zhao, Y.J. Ge

SLDRCE, Tongji University, Shanghai, China, zhaolin@tongji.edu.cn

ABSTRACT: An alternative method to account for resonant response coupling effects is proposed in this paper, in consideration that the traditional Inertial Wind Loads (IWL) method and Gust Load Factor (GLF) method are not good at the accurate analysis on resonant loading components of resonant response coupling effects between Equivalent Static Wind Loads (ESWL) and natural mode of large-span roofs and large hyperbolic cooling towers; Firstly, the generalized resonant modal displacement covariance matrix is derived from structural equation of motion; then based on IWL method, covariance matrix of elastic restoring force containing the resonant components is obtained; finally, the resonant response and equivalent static wind loads are calculated with Loads Response Correlation (LRC) method. The proposed procedure avoids the integration process of calculating elastic restoring force and fully considers the modal coupling effects, which can be used to estimate and analyze the Equivalent Static Wind Loads (ESWL) for any complex spacial structures. The calculation of ESWL of super large cooling tower demonstrates and verifies the effectiveness of the present approach.

KEYWORDS: Equivalent static wind loads; resonant components; modal coupling; covariance matrix

1 INTRODUCTION

The three-dimensional structure such as large-span roofs [1] and large hyperbolic cooling towers is usually characterized by light weight, high flexibility, low damping, low natural frequency and small interval, as a typical wind sensitive structures, wind load control should be fully considered in such structural design [2], and therefore it is greatly significant to determine the ESWL in such the structures.

The response of the structure under the effects of fluctuating wind is divided into background response and resonant response based on random vibration theory, the combination of two kinds of responses can be sued to reflect the wind load mechanism; then many scholars adopted the three-component method successfully to calculate ESWL, and made continuous improvement and development on such the method [3]. however, the method hasn't effectively dealt with the selection of resonance model and coupling effect between various components [4].

Many scholars at home and abroad have studied this issue, such as: Zhou and Gu firstly adopted the three-component method to analyze Shanghai Jinmao Tower in 1998, and compared the results with that under the GLF method, and found that the results by the three-component method was more accurate [5]; Holmes proposed to adopt the LRC method in conjunction with the IWL method to calculate ESWL of large span roofs in 2002, and also developed an expression form integrating mean wind loads, background wind loads, and inertia wind load representing multiple resonant components, but this method must be based on a smooth separation between various vibration modes [6]. Chen and Kareem by learning from the seismic analysis method, express the effect of modal resonance response coupling component as a form of the independent modal contribution rate multiplied by the correlation coefficient, think that when the

correlation coefficient is relatively greater, the modal coupling is stronger, thus CQC modal response is recommended, otherwise, SRSS combination is recommended [7]; Chen and Shen by targeting POD and Ritz , made researches on the selection of main resonance mode of long-span roofs , however, they failed to make a effective solution to the coupling effect problem between different modes [8]; Xie and Ni adopted the modal wind vibration force of full CQC combination structures based on LRC, which doesn't distinguish between resonance and background components, the ESWL calculated by such a method contains any modal background, resonance and coupling components, its accuracy is compliance with the requirements, the physical significance of the calculating result by the method is not very clear because it fails to distinguish between background and resonance components[9].

In view of the above research results, in the paper, the generalized resonant modal displacement covariance matrix is derived from the structural equation of motion, then based on the IWL theory, the covariance matrix of the elastic restoring force, which only contains the resonance component is derived , on the basis of the above, it s available to calculate resonant response and ESWL by the LRC via quasi-static force method. This method proposed in the paper avoids the integral process for solving the elastic restoring force, fully considers the coupling between various resonant components, with a clear physical significance and theoretically, it applies to resonant component calculation of ESWL of any complex structure, and finally , the method is applied to wind-induced response and ESWL calculation of a typical three-dimensional structure: super large cooling towers in Ninghai Power Plant [10], the results verify its effectiveness.

2 IMPROVED CALCULATING METHOD

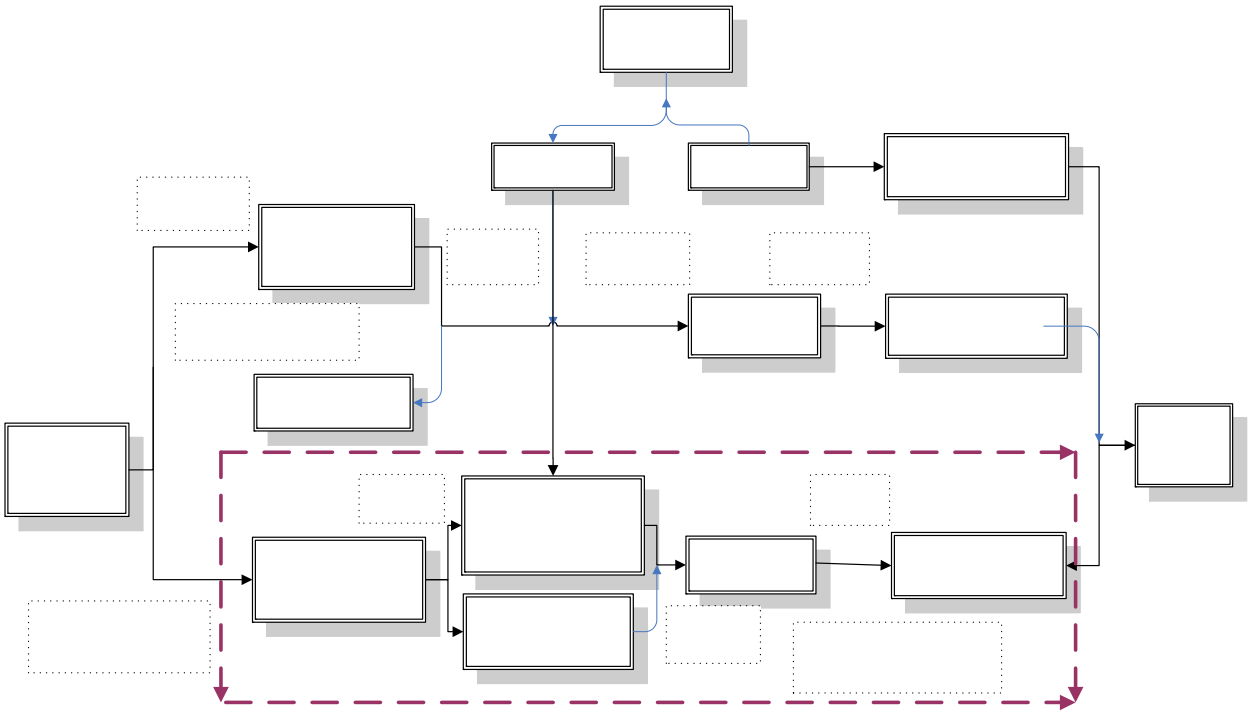

Figure 1. Theoretical framework of calculation of structural equivalent static wind load by the method proposed in the paper.

Figure 1 shows the theoretical framework of the equivalent static wind load, it is shown from the figure that the theoretical basis of the average component and background component is more clear and comprehensible, it is available to calculate it by quasi-static method, the critical step is how to extract influencing coefficient matrix, which can be obtained by the secondary development of static force via finite element software [11]. The calculation of the resonant component is mainly based on modal selection and considerations of the coupling effect between them , which is also the main problem to be solved in the paper, the calculation method of the resonance components is theoretically deduced via the following three steps.

2.1 *Generalized Resonant Modal Response Covariance Matrix*

Firstly, the parameters involved in the derivation process of the present theory are as follows: n is the number of degrees of structural freedom, m is the modal number used in the calculation, p is the number of points of excitation vector, s is the load order after POD reconstruction, ω is the circular frequency of the structure, M, C and K are respectively the quality, damping and stiffness matrix of order n, R is an n × p matrix consisting of 0 and 1, i.e., power indicator matrix, Λ = diag (ω^2_1 … ω^2_m), q is the generalized structural displacement vector, Φ is the characteristic matrix of the structure, A and D are respectively the coordinate function vector and the intrinsic modal matrix of the s and less orders before POD decomposition, I is the structural influence coefficient matrix.

Under the random excitation, the response of the structure is described by the following equation:

$$[M]\{\ddot{y}\}+[C]\{\dot{y}\}+[K]\{y\}=[R]\{p(t)\} \tag{1}$$

The response can be furthered derived via complete mode of vibration:

$$\{y(t)\}=\Phi\{q(t)\}=\sum_{i=1}^{n}\phi_i q_i(t)=\sum_{i=1}^{m}\phi_i q_i(t)+\sum_{i=m+1}^{n}\phi_i q_i(t)=\{y\}_d+\{y\}_s \tag{2}$$

In which, $\{y\ (t)\}_d$ modal contribution response of m and less orders where the resonance effect needs to be considered; $\{y\ (t)\}_s$ means only the residual modal contribution response of quasi-static effect needs to be considered.

Under $\{P\ (t)\}$ loads, its static force response is $[K]^{-1}\{P\ (t)\}$, and also can be expressed by the following equation complete vibration mode, which doesn't consider the power amplification of each vibration mode

$$[K]^{-1}\{p(t)\}=\sum_{i=1}^{n}[F]_i\{p(t)\}=\sum_{i=1}^{m}[F]_i\{p(t)\}+\sum_{i=m+1}^{n}[F]_i\{p(t)\} \tag{3}$$

In which, $[F]$ is the flexibility matrix of the i-th order vibration mode, $\{y\ (t)\}_s$ can be expressed as:

$$\{y\}_s=\sum_{i=m+1}^{n}[F]_i\{p(t)\}=[K]^{-1}\{p(t)\}-\sum_{i=1}^{m}[F]_i\{p(t)\} \tag{4}$$

Based on the equation (2), $\{y\ (t)\}$ is described with the following equation:

$$\{y(t)\} = \{y\}_d + \{y\}_s = \sum_{i=1}^{m} \phi_i q_i(t) + [K]^{-1}\{p(t)\} - \sum_{i=1}^{m} [F]_i \{p(t)\}$$

$$= \sum_{i=1}^{m} (\phi_i q_i(t) - [F]_i \{p(t)\}) + [K]^{-1}\{p(t)\}$$

(5)

Thus it's available to define resonance response with the following equation:

$$\{y(t)\}_r = \sum_{i=1}^{m} (\phi_i q_i(t) - [F]_i \{p(t)\}) \tag{6}$$

Then it is available to derive the i-th order generalized modal response that only contains the resonance component as following:

$$q_{r,i}(t) = q_i(t) - \frac{\phi_i^T \{p(t)\}}{\phi_i^T [K] \phi_i} = q_i(t) - \frac{F_i(t)}{K_i} \tag{7}$$

The cross-power spectrum of the first i-th and j-th generalized resonant modal response is:

$$S_{q_{r,i},q_{r,j}}(\omega) = \int_{-\infty}^{\infty} R_{q_{r,i},q_{r,j}}(\tau) e^{-i2\pi\omega\tau} d\tau = \int_{-\infty}^{\infty} E[q_{r,i}(t), q_{r,j}(t+\tau)] e^{-i2\pi\omega\tau} d\tau$$

$$= (H_i^*(\omega) H_j(\omega) - \frac{1}{K_i} H_j(\omega) - \frac{1}{K_j} H_i(\omega) + \frac{1}{K_i K_j}) S_{F_i,F_j}(\omega)$$

$$= (H_i^*(\omega) - \frac{1}{K_i})(H_j(\omega) - \frac{1}{K_j}) S_{F_i,F_j}(\omega) = \dot{H}_i^*(\omega) \dot{H}_j(\omega) S_{F_i,F_j}(\omega)$$

(8)

It is found from the equation (8) that the calculation of generalized resonance modal response is mainly based on how to determine the transfer function of the generalized resonance frequency response , denoted by.

Based on the above equations, the covariance matrix of generalized resonance modal response can be expressed as:

$$[C_{qq}] = \int_{-\infty}^{\infty} \dot{H}^* S_{FF} \dot{H} \, d\omega = \int_{-\infty}^{\infty} \dot{H}^* \Phi^T R D S_{AA} D^T R^T \Phi \dot{H} \, d\omega \tag{9}$$

In which, S_{AA} is the cross-power spectrum matrix of time coordinate function $A(t)$of the s and less order before POD decomposition, and is used for a reduced-order processing.

2.2 *Covariance Matrix of Elastic Restoring Force (only Containing the Resonance Component)*

By application of modal expansion theory, the elastic restoring force (only containing the resonance component) can be expressed as:

$$\{P_{eqq}\}_r = [K]\{y(t)_r\} = [K][\Phi]\{q(t)\}_r = [M][\Phi][\Lambda]\{q(t)\}_r \tag{10}$$

In combination of equation (9) and (10), the cross-covariance matrix of $\{P_{eqq}\}_r$ can be calculated as:

$$\left[C_{pp}\right]=\overline{\{P_{eqq}\}_r\{P_{eqq}\}_r}=[M][\Phi][\Lambda]\overline{\{q(t)\}_r\{q(t)\}_r}[\Lambda]^T[\Phi]^T[M]^T$$
$$=[M][\Phi][\Lambda]\left[C_{qq}\right][\Lambda]^T[\Phi]^T[M]^T$$

(11)

2.3 *LRC- Based Resonant Response and Equivalent Static Wind Load*

It is shown from the above derivation, $\{P_{eqq}\}_r$ is the elastic restoring force vector only containing the resonance component, and its precision depends on the dynamic characteristics of modal order and system adopted in the calculation of $\{q(t)\}_r$. how to solve the resonant response and equivalent static wind load is converted to how to calculate quasi-static response under $\{P_{eqq}\}_r$ effects , by the LRC principle, it is shown as:

$$\left\{r(t)\right\}_r=[I]\left\{P_{eqq}\right\}_r \tag{12}$$

When I is the flexibility matrix, $r(t)$ is the resonance response, the response covariance matrix is as following

$$\left[C_{rr}\right]=\overline{\left\{r(t)\right\}_r\left\{r(t)\right\}_r}=[I]\left[C_{pp}\right][I]^T=[I][M][\Phi][\Lambda]\left[C_{qq}\right][\Lambda]^T[\Phi]^T[M]^T[I]^T$$
$$=[I][M][\Phi][\Lambda]\int_{-\infty}^{\infty}\dot{H}^*\Phi^T RDS_{AA}D^T R^T\Phi\dot{H}\,d\omega[\Lambda]^T[\Phi]^T[M]^T[I]^T \tag{13}$$

The resonance response of the structure is

$$\boldsymbol{\sigma}_{R,r}=\sqrt{diag\left([C_{rr}]\right)}$$

(14)

In the equation, *diag(.)* is the column vector composed of diagonal elements of matrix.

The resonance ESWL responding to R_i is:

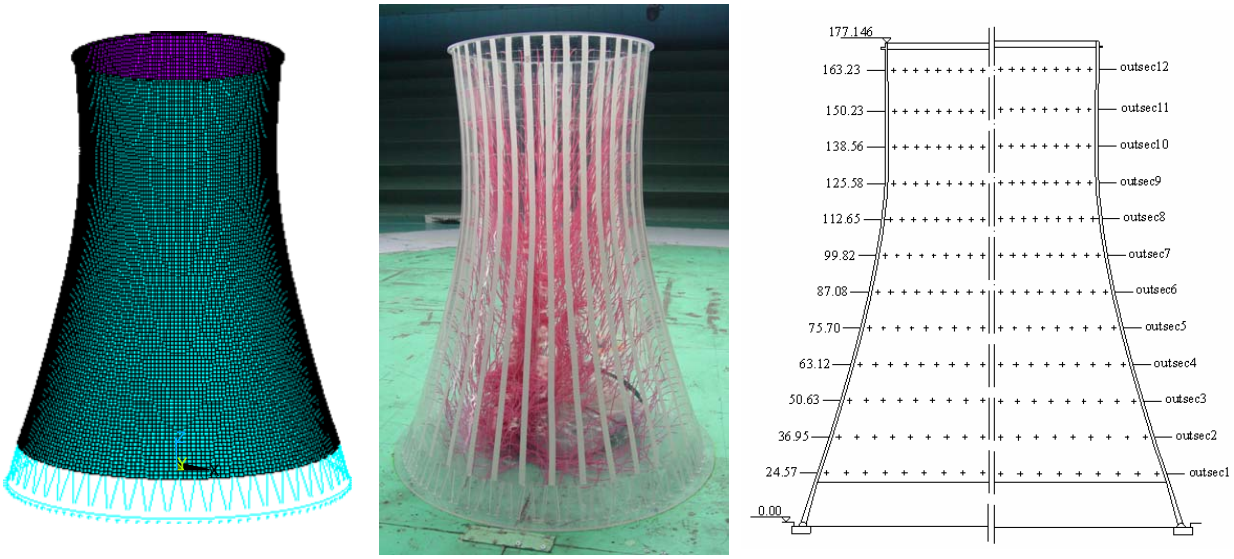
$$\boldsymbol{P}_{eBi}=\left[C_{pp}\right]\boldsymbol{I}_i^T\Big/\sigma_{Ri,r} \tag{15}$$

3 ENGINEERING APPLICATION CASES

In accordance with method proposed in the paper, the corresponding computer program DACM is built by MATLAB language, Ninghai Power Plant super large hyperbolic cooling towers, which are the highest completed towers in Asia [10], are taken as an example, the unsteady surface pressure time-histories obtained via non-rigid wind tunnel experiment are taken as incentives, POD can be adopted for reduced-order processing in the calculation of the generalized resonance modal displacement matrix.

The tower height is 177.15m, the top outer radius is 41.13m, the throat mid-surface radius is 39.11m, the air inlet mid-surface radius is 67.35m, and the diameter of 48 Y-type pillars is 1.30m. the structural modeling adopts the finite element method of the discrete structure, to discrete cooling tower wall to shell elements; the 48 pairs of Y-type pillars connecting top rigid ring and ring base are simulated by space beam elements, the Y-type pillars are fixed on bottom (see Figure 2a). all the modal information was extracted by modal analysis, the structural influencing coefficient matrix was obtained via the secondary static development. The wind tunnel test was made in the TJ-3 wind tunnel of Tongji University, the scale ratio of rigid pressure measurement

model is 1/200 (see Figure 2b), total (12 × 36 = 432) measurement points were laid out on the outside surface of tested cooling tower along the meridian and circumference (see Figure 2c) and the sampling frequency is 312.5Hz, the sampling time is 19.2s.



a) Finite element model b) wind tunnel model c) measurement model layout (unit: m)

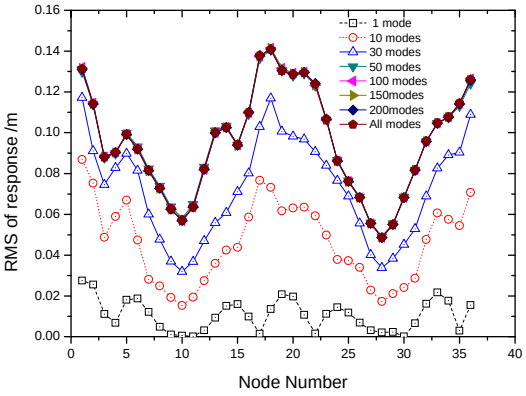
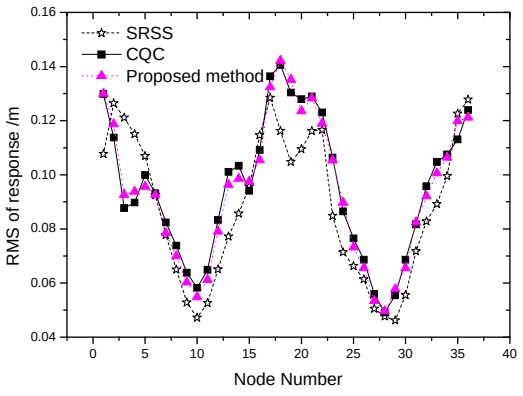
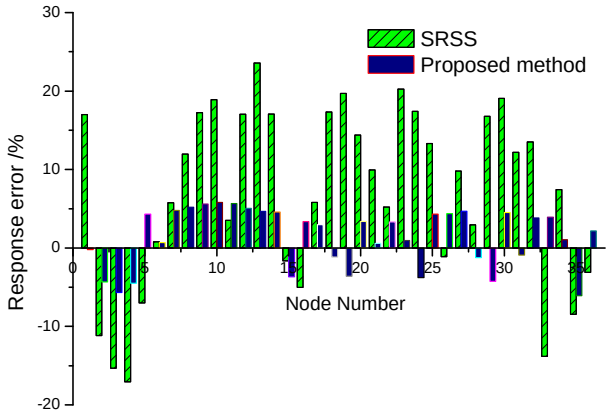
3.1 *Discussion on Cut-Off Modal and Coupling Effect*



a) CQC calculation results based on different cut-off modal number



b) Comparison chart of calculation results based on SRSS, the method proposed in the paper and full-modal CQC



c) Comparison chart of calculation error of SRSS and the method proposed in the paper

Figure 3. Comparison chart of structural displacement response based on different calculation methods.

The wind-induced response can be calculated by adopting different orders of CQC method, and SRSS and the proposed method, and evaluated in accordance with the standard of gull-modal CQC calculated results. Figure 3a shows the CQC calculated results of different orders of tower throat circumferential section (see Figure 2c Section 10), and it is found: the first order of calculated results by GLF and IWL is far lower than actual response value, and there is no predictable pattern in the changes a pattern; as the order increases, the structural response value becomes larger, when it increases to the 50th order, the response value is stabilized and basically consistent with the result from the full modal calculations. Figure 3b and 3c shows the calculation results by the SRSS method ignoring modal coupling effects and the method proposed in this paper, as well as calculation error by the CQC method ,the ignored coupling effect makes a great influence on such a structure, the average error is about 15%, by this method, the average error is only 2%, thus the proposed method is better at considering the coupling effects between the different modes.

3.2 *Power Spectrum of Typical Node Response*

The structural wind-induced response is calculated by different orders of CQC method, the SRSS method and the method proposed in the paper, and the related calculated results are evaluated based on full- modal CQC standards. Figure 3a shows the CQC calculated results of tower throat circumferential section at different orders (see Figure 2c section 10) .

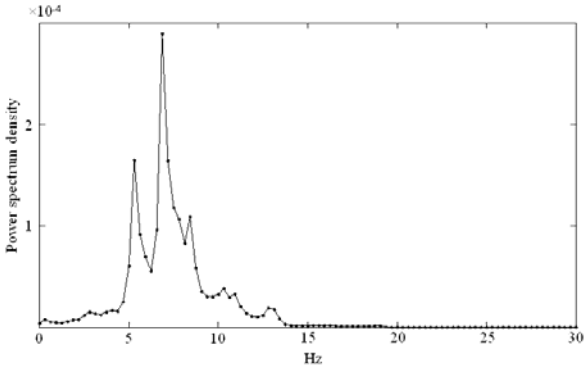


Figure 4. Functional chart of displacement power spectral density.

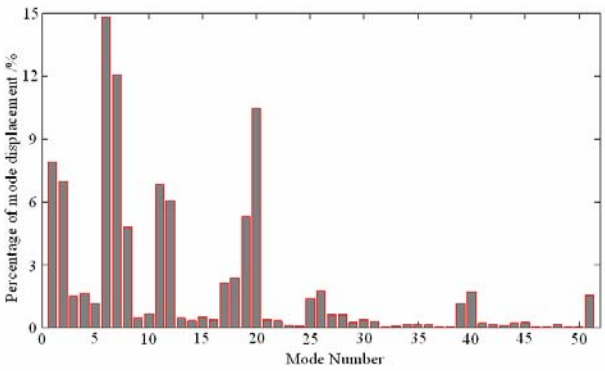

Figure 5. Proportion chart of generalized modal response value at different orders.

Figure 4 shows functional chart of displacement power spectral density of a typical node on the windward face, and it is found that the structural response is mainly resonance response the maximum resonance response is at 7Hz (corresponding to the actual frequency of 1.1Hz, corresponding with the sixth frequency). It is shown from Figure 5, the proportion chart of generalized modal response value at different orders, that the proportion of generalized modal displacement at the sixth-order accounts for the largest proportion, which is fully different with the rule for high-rise buildings and towers: the proportion of generalized modal displacement at the first-order accounts for the largest proportion; and also makes the GLF and IWL methods are no longer applicable to the wind-induced response and equivalent static wind load analysis for such this type of structures.

3.3 *Equivalent Static Wind Load*

Figure 6 compares the accurate calculated results of maximum displacement response at the tower throat circumferential section node and the corresponding displacement calculated by the static force equation under equivalent static wind loads calculated by this method applied; the results shows both two sets of displacement response are entirely consistent, and thus to further prove the effectiveness and correctness of the method proposed in the paper.

By the method proposed in the paper, it's available to calculate the ESWL corresponding to displacement response on the top of the tower, then compare the results calculated with the GBJ (IWL method) in national specification for building structure loads [12](see Figure 7), it is shown that to ignore higher order of modal contribution and coupling effect makes the calculated ESWL far less than the actual value; and on some rigid region of tower shell, the average respond is smaller or even close to zero, under this case, it is inappropriate to adopt the wind-induced vibration coefficient in the IWL method to describe the design load of the structure.

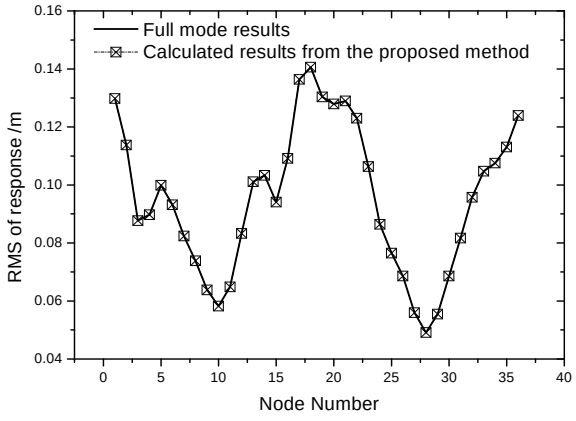

Figure 6. RMS of displacement response on throat circumferential section.

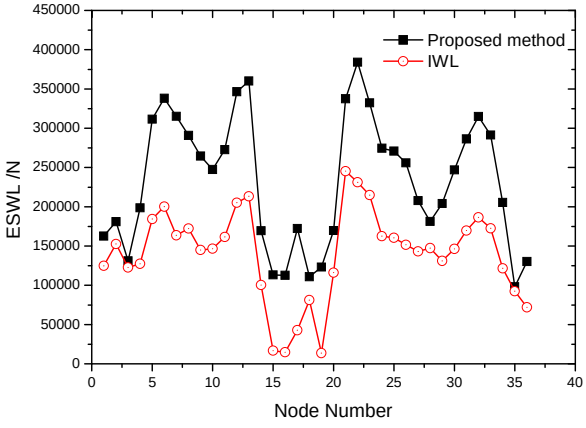

Figure 7. Profile of ESWL on throat circumferential section.

4 CONCLUSIONS

The paper focuses on the calculation of the coupling components between the resonant modes in the research on ESWL under apparent coupling effects. It derives the generalized resonant modal displacement covariance matrix and covariance matrix of elastic restoring force from structural

equation of motion, based on the multi-point simultaneous pressure test in wind tunnel, in combination with the decomposition and reduced-order of surface wind pressure by POD approach, thus integrating and expanding the LRC method again; it proposes an alternative method to account for resonant response coup ling effects; and calculates wind-induced response and ESWL based on the data of Asia's largest cooling tower, and compares calculated results between the full-modal CQC and IWL methods, thus verifies the effectiveness of the method.

It is noted that the case for calculation in the paper is equalized based on the maximum displacement, it only ensures thee accuracy of the calculation of the maximum displacement, may generate errors in calculation of the maximum internal forces. Therefore, the future research should focus on how to improve the accuracy and rationality of such consistent ESWL.

Study on the empirical mathematical model of nonlinear motion-induced aerodynamic force of bridge girder

Liao Haili [a], Suo Qifeng [a], Wang Qi [a]

[a] *Research Centre for Wind Engineering, Southwest Jiaotong University, Chengdu, China*

ABSTRACT: Based on Scanlan's linear model of motion-induced aerodynamic force (MIAF) on bridge deck section, a nonlinear MIAF model with independent variables of amplitude and reduced frequency is proposed by using Taylor expanding method. The model is composed of different harmonic components. For one freedom motion, there are only frequency multiplications in the expression, and for coupled motion, both also frequency multiplications and superposed frequency components are presented in the model. A special wind tunnel tests results verified the existence of high harmonic components in the MIAF of bridge girder under large amplitude of vertical or torsional motion, and the error between reconstructed curve and original curve of nonlinear MIAF history data indicated that the model can describe the nonlinear MIAF accurately. Combining with the free vibration equation of dynamic system, the nonlinear differential equation can describe the aerodynamic stability of girder under different amplitudes and reduced frequencies.

KEYWORDS: Streamline Box Girder; Nonlinear MIAF; Mathematic Model; Wind Tunnel Test

1 INTRODUCTION

The empirical model of motion-induced aerodynamic force (MIAF) on bridge girder proposed by Scanlan[1-4] has been used in flutter and buffeting analysis of long span bridges over 40 years. The model is based on the hypothesis of small displacement, the MIAF is only function of reduced frequency, and is independent of the amplitude of bridge girder. In recent years, because of the motive to understand aerodynamic behavior of long-span bridges under large displacement such as Tacoma's girder, the aerodynamic force of bridge girder under large amplitude oscillation has been concerned.

MIAF of bridge girder is nonlinear essentially. It has been found and verified in wind tunnel tests by many researchers. Noda[5] validated the effects of large amplitudes on aerodynamic derivatives of the flat plates with different thickness. Chen [6] found the high harmonic components in the spectrum of MIAF of π-section girder, and gave a preliminary quantification of nonlinear components. Falco[7] reported the clear nonlinear components in the MIAF of test section of early Messina Bridge. Based on the study of unsteady aerodynamic force of the Messina Bridge sectional model, the aerodynamic hysteresis phenomenon of bridge girder section was first observed by Diana [8-10], and indicated that the neglect of nonlinear component of aerodynamic force could lead to unsafely results in the analysis of aerodynamic stability. Liao[11] observed the aerodynamic hysteresis and the clear nonlinear components of MIAF of streamlined box girder, and found the distinct 8-shape hysteresis loops under the larger pitching amplitude up to 16 degree, which means that the aerodynamic forces can provide both the positive and negative works within one vibration period.

The study on the mathematic model of nonlinear MIAF of bridge girder could trace back to 1950s, after the collapse of Tacoma Bridge. Steinmann[12], proposed a polynomial expression to describe the nonlinear MIAF of H-shape girder of Tacoma Bridge based on the wind tunnel test result, with independent variable of torsional angle and angular velocity. Xu[13] gave a unsteady expression of nonlinear aerodynamic force of flexible and long-span structure by defining the instantaneous incident angle. Based on the instantaneous incident angle and its velocity, Diana [10,14,15] gave an empirical polynomial expression to describe the nonlinear aerodynamic force of bridge girder. Chen[16] based on the soft flutter phenomenon of long-span bridge, used Von Del Pol oscillator to describe the nonlinear MIAF of bridge girder. Wu[17] based on the nonlinear response of bridge, put forward an nonlinear aerodynamic force model using Volterra Series. In these nonlinear aerodynamic force models of bridge girder, Steinmann's expression is too simple to describe the aerodynamic exactly. Xu's model is too complex to be applicable in analysis, and didn't give the identification method of nonlinear variable. Diana's rheological model could describe the nonlinear aerodynamic force from test data exactly, but can't interpret the large amplitude oscillation in the post flutter of Tacoma Bridge. Chen's model ignored the unsteady of nonlinear MIAF, and also implied that there is only the third harmonic in the MIAF.

In this paper, a nonlinear MIAF expressions with independent variables of amplitude and reduced frequency were deduced by using Taylor expanding method. The empirical mathematic model of nonlinear MIAF is composed with different harmonic components. For one freedom motion, there are only frequency multiplications in the model, and for coupled motion, both also frequency multiplications and superposed frequency components are presented in the model. A special wind tunnel tests were conducted, with a 1:50 scale section model of the streamline box girder and more than 150 test cases, and MIAF of the model under different amplitudes and reduced frequencies conditions were obtained. The test results verified the existence of high harmonic components in the MIAF of bridge girder under large amplitude of vertical or torsional motion, and the high harmonic components were more remarkable spatially in a large incidence angle condition. The error between fitting curve and original curve of nonlinear MIAF history data indicated that this empirical mathematical model can describe the nonlinear MIAF accurately. Combining with the free vibration equation of dynamic system, the nonlinear differential equation can describe the aerodynamic stability of girder under different amplitudes and reduced frequencies.

2 EMPIRICAL MATHEMATIC MODEL OF NONLINEAR MIAF

2.1 *Taylor expanding expression*

Aerodynamic force on bridge section in smooth flow is the function of motion state variables, which is defined as a sum of the mean static force, and MIAF. The aerodynamic force, i.e., lift and pitching moment (upward and nose up) components per unit length are expressed as follows:

Lift: $$L = \frac{1}{2}\rho U^2 B C_L(\dot{h}, h, \dot{\alpha}, \alpha) \tag{1a}$$

Pitching Moment: $$M = \frac{1}{2}\rho U^2 B^2 C_M(\dot{h}, h, \dot{\alpha}, \alpha) \tag{1b}$$

Where ρ= air density; U= mean wind velocity; B= the bridge deck width; C_L and C_M = lift and pitching moment coefficients of one moment, respectively, which are the function of motion state variables as displacement h,α, and velocity $\dot{h},\dot{\alpha}$ in vertical and torsional freedom.

If the nonlinear aerodynamic force exists n+1 order derivative, the n order Taylor Series could be obtained at equilibrium position by expanding. Because the aerodynamic coefficients are dominant variables in the expressions, its Taylor expanding expression can represent the main characteristics aerodynamic force. Taking an example of lift coefficient, its Taylor expanding is as follow:

$$\begin{aligned} C_L &= C_L(\dot{h}_0,h_0,\dot{\alpha}_0,\alpha_0)+(\frac{\partial}{\partial\dot{h}}\dot{h}+\frac{\partial}{\partial\dot{\alpha}}\dot{\alpha}+\frac{\partial}{\partial h}h+\frac{\partial}{\partial\alpha}\alpha)C_L(\dot{h}_0,h_0,\dot{\alpha}_0,\alpha_0) \\ &+\frac{1}{2!}(\frac{\partial}{\partial\dot{h}}\dot{h}+\frac{\partial}{\partial\dot{\alpha}}\dot{\alpha}+\frac{\partial}{\partial h}h+\frac{\partial}{\partial\alpha}\alpha)^2 C_L(\dot{h}_0,h_0,\dot{\alpha}_0,\alpha_0) \\ &+\cdots+\frac{1}{n!}(\frac{\partial}{\partial\dot{h}}\dot{h}+\frac{\partial}{\partial\dot{\alpha}}\dot{\alpha}+\frac{\partial}{\partial h}h+\frac{\partial}{\partial\alpha}\alpha)^n C_L(\dot{h}_0,h_0,\dot{\alpha}_0,\alpha_0)+R_n \end{aligned} \tag{2}$$

Where the 1st term $C_L(\dot{h}_0,h_0,\dot{\alpha}_0,\alpha_0)$ = mean static, the 2nd term = the linear term of MIAF, and the 3rd term and above ones, are the nonlinear terms of MIAF, R_n= residual term.

For single freedom motion of the girder, for example vertical motion, lift coefficient could be written as the following if keeping the first three terms only,

$$\begin{aligned} C_L &= \frac{\partial C_L}{\partial\dot{h}}\dot{h}+\frac{\partial C_L}{\partial h}h+\frac{1}{2}\frac{\partial^2 C_L}{\partial\dot{h}^2}\dot{h}^2+\frac{\partial^2 C_L}{\partial\dot{h}\partial h}\dot{h}h+\frac{1}{2}\frac{\partial^2 C_L}{\partial h^2}h^2+\frac{1}{6}\frac{\partial^3 C_L}{\partial\dot{h}^3}\dot{h}^3+\frac{1}{2}\frac{\partial^3 C_L}{\partial\dot{h}^2\partial h}\dot{h}^2h+\frac{1}{2}\frac{\partial^3 C_L}{\partial\dot{h}\partial h^2}\dot{h}h^2+\frac{1}{6}\frac{\partial^3 C_L}{\partial h^3}h^3 \\ &= C^1_{\dot{h}}\dot{h}+C^1_h h+C^2_{\dot{h}^2}\dot{h}^2+C^2_{\dot{h}h}\dot{h}h+C^2_{h^2}h^2+C^3_{\dot{h}^3}\dot{h}^3+C^3_{\dot{h}h^2}\dot{h}^2h+C^3_{h^2\dot{h}}\dot{h}h^2+C^3_{h^3}h^3 \end{aligned} \tag{3}$$

Where C^n_m = nonlinear coefficients, and n=1~3, m= $h^k\dot{h}^l$, and k=0~3, l=0~3. C^n_m is the function of amplitude and reduced frequency K.

For the vertical and pitching coupled motion, the lift coefficient, if keeping the first two terms only, can be written as:

$$\begin{aligned} C_L &= \frac{\partial C_L}{\partial\dot{h}}\dot{h}+\frac{\partial C_L}{\partial h}h+\frac{\partial C_L}{\partial\dot{\alpha}}\dot{\alpha}+\frac{\partial C_L}{\partial\alpha}\alpha \\ &+\frac{1}{2}\frac{\partial^2 C_L}{\partial\dot{h}^2}\dot{h}^2+\frac{1}{2}\frac{\partial^2 C_L}{\partial h^2}h^2+\frac{1}{2}\frac{\partial^2 C_L}{\partial\dot{\alpha}^2}\dot{\alpha}^2+\frac{1}{2}\frac{\partial^2 C_L}{\partial\alpha^2}\alpha^2 \\ &+\frac{\partial^2 C_L}{\partial\dot{h}\partial h}\dot{h}h+\frac{\partial^2 C_L}{\partial\dot{\alpha}\partial\alpha}\dot{\alpha}\alpha+\frac{\partial^2 C_L}{\partial\alpha\partial\dot{h}}\alpha\dot{h}+\frac{\partial^2 C_L}{\partial\dot{\alpha}\partial h}\dot{\alpha}h+\frac{\partial^2 C_L}{\partial\alpha\partial h}\alpha h+\frac{\partial^2 C_L}{\partial\dot{\alpha}\partial\dot{h}}\dot{\alpha}\dot{h} \\ &= C^1_{\dot{h}}\dot{h}+C^1_h h+C^1_{\dot{\alpha}}\dot{\alpha}+C^1_\alpha\alpha+C^2_{\dot{h}^2}\dot{h}^2+C^2_{h^2}h^2+C^2_{\dot{\alpha}^2}\dot{\alpha}^2+C^2_{\alpha^2}\alpha^2 \\ &\quad+C^2_{\dot{h}h}\dot{h}h+C^2_{\dot{\alpha}\alpha}\dot{\alpha}\alpha+C^2_{\alpha\dot{h}}\alpha\dot{h}+C^2_{\dot{\alpha}h}\dot{\alpha}h+C^2_{\alpha h}\alpha h+C^2_{\dot{\alpha}\dot{h}}\dot{\alpha}\dot{h} \end{aligned} \tag{4}$$

Where C^n_m = nonlinear coefficients, and comparing with the Eq.3, the C^n_m adds more terms, here m= $h^k\dot{h}^l$ and $\alpha^k\dot{\alpha}^l$, and the coupled terms $h^k\dot{\alpha}^l$ and $\alpha^k\dot{h}^l$ imply the frequency superposition of aerodynamic force in different motions. One in particular is that the nonlinear coefficients are obtained only in the steady harmonic vibration, not in the arbitrary motion.

2.2 *Plural expression*

For harmonic oscillation with frequency ω at a given wind speed (taking an example of vertical motion)

$$h = h_0 e^{i\omega t},\quad \dot{h} = i\omega h,\quad i = \sqrt{-1} \tag{5a}$$

The 2nd order variables in Eq.3 are:

$$h^2 = h_0^2 e^{i2\omega t},\quad \dot{h}h = i\omega h_0^2 e^{i2\omega t},\quad \dot{h}^2 = -\omega^2 h_0^2 e^{i2\omega t} \tag{5b}$$

The 3rd order variables in Eq.3 are:

$$h^3 = h_0^3 e^{i3\omega t},\quad \dot{h}h^2 = i\omega h_0^3 e^{i3\omega t},\quad \dot{h}^2 h = -\omega^2 h_0^3 e^{i3\omega t},\quad \dot{h}^3 = -i\omega h_0^3 e^{i3\omega t} \tag{5c}$$

The above motion variables can be replaced with $\alpha = \alpha_0 e^{i\omega t}$ for torsional motion.

Replacing the motion variables in Eq.3 by the Eq.5a-5c, the first term in the new equation is as follows:

$$C_L^1 = \frac{\partial C_L}{\partial \dot{h}} i\omega h + \frac{\partial C_L}{\partial h} h = 2K^2 (iH_1^* + H_4^*)\frac{h}{B} = (iH_1^{1\#} + H_4^{1\#}) h_{r0} e^{i\omega t} \tag{6a}$$

Where $H_1^{1\#} = 2K^2 H_1^*$, $H_4^{1\#} = 2K^2 H_4^*$ are defined as the 1st order harmonic component aerodynamic derivatives of lift coefficient; $h_{r0} = h_0 / B$, is the reduced amplitude in vertical; H_1^* and H_4^* are aerodynamic derivatives.

Similarly, the second term is:

$$C_L^2 = (iH_1^{2\#} + H_4^{2\#})(h/B)^2 = (iH_1^{2\#} + H_4^{2\#})(h_{r0})^2 e^{i2\omega t} \tag{6b}$$

Where $H_1^{2\#} = \omega B^2 \frac{\partial^2 C_L}{\partial \dot{h} \partial h}$, $H_4^{2\#} = \frac{1}{2} B^2 (\frac{\partial^2 C_L}{\partial h^2} - \omega^2 \frac{\partial^2 C_L}{\partial \dot{h}^2})$, are defined as the 2nd order harmonic component aerodynamic derivatives of lift coefficient.

The third term is:

$$C_L^3 = (iH_1^{3\#} + H_4^{3\#})(h/B)^3 = (iH_1^{3\#} + H_4^{3\#})(h_{r0})^3 e^{i3\omega t} \tag{6c}$$

Where $H_1^{3\#} = \frac{1}{6} B^3 (3\omega \frac{\partial^3 C_L}{\partial \dot{h} \partial h^2} - \omega^3 \frac{\partial^3 C_L}{\partial \dot{h}^3})$, $H_4^{3\#} = \frac{1}{6} B^3 (\frac{\partial^3 C_L}{\partial h^3} - 3\omega^2 \frac{\partial^3 C_L}{\partial \dot{h}^2 \partial h})$, are defined as the 3rd order harmonic component aerodynamic derivatives of lift coefficient.

For a given amplitude and reduced frequency *K*, the lift coefficient in Eq.3 can be expressed as,

$$C_L^V = (iH_1^{1\#} + H_4^{1\#}) h_{r0} e^{i\omega t} + (iH_1^{2\#} + H_4^{2\#}) h_{r0}^2 e^{i2\omega t} + (iH_1^{3\#} + H_4^{3\#}) h_{r0}^3 e^{i3\omega t} \tag{7a}$$

In which superscript *V* indicates the vertical motion condition.

Similarly, the pitching moment due to vertical motion can be expressed as:

$$C_M^V = (iA_1^{1\#} + A_4^{1\#}) h_{r0} e^{i\omega t} + (iA_1^{2\#} + A_4^{2\#}) h_{r0}^2 e^{i2\omega t} + (iA_1^{3\#} + A_4^{3\#}) h_{r0}^3 e^{i3\omega t} \tag{7b}$$

Where $A_1^{j\#}$ and $A_4^{j\#}$ are the pitching moment coefficient aerodynamic derivatives corresponding to the j^{th} order harmonic component.

If the girder's motion is only in torsional, the aerodynamic lift coefficient and pitching moment coefficient can be similarly deduced as follows:

$$C_L^T = (iH_2^{1\#} + H_3^{1\#}) \alpha_0 e^{i\omega t} + (iH_2^{2\#} + H_3^{2\#}) \alpha_0^2 e^{i2\omega t} + (iH_2^{3\#} + H_3^{3\#}) \alpha_0^3 e^{i3\omega t} \tag{7c}$$

$$C_M^T = (iA_2^{1\#} + A_3^{1\#}) \alpha_0 e^{i\omega t} + (iA_2^{2\#} + A_3^{2\#}) \alpha_0^2 e^{i2\omega t} + (iA_2^{3\#} + A_3^{3\#}) \alpha_0^3 e^{i3\omega t} \tag{7d}$$

Where $H_2^{j\#}$ and $H_3^{j\#}$, $A_2^{j\#}$ and $A_3^{j\#}$, are the lift and pitching moment coefficient aerodynamic derivatives corresponding to the j^{th} order harmonic component. The superscript T indicates the pitching motion condition. The real parts indicate the nonlinear aerodynamic stiffness terms, and the imaginary parts indicate the nonlinear aerodynamic damping terms.

Comparing with the conventional linear model, the 1st order harmonic aerodynamic derivatives $H_k^{1\#}, A_k^{1\#}(k=1\sim 4)$ in Eq.7a-7d , can be written as

$$H_1^{1\#}=2K^2H_1^*,\quad H_4^{1\#}=2K^2H_4^*,\quad A_1^{1\#}=2K^2A_1^*,\quad A_4^{1\#}=2K^2A_4^* \tag{8a}$$

$$H_2^{1\#}=2K^2H_2^*,\quad H_3^{1\#}=2K^2H_3^*,\quad A_2^{1\#}=2K^2A_2^*,\quad A_3^{1\#}=2K^2A_3^* \tag{8b}$$

Where, $H_k^*, A_k^*(k=1\sim 4)$ are the usual aerodynamic derivatives defined by Scanlan.

According to the Taylor expanding, the complex expressions of lift and pitching moment under coupled motion (only keeping the 2nd order harmonic components)

$$\begin{aligned}C_L=&(iH_1^{1\#}+H_4^{1\#})h_{r0}e^{i\omega_1 t}+(iH_1^{2\#}+H_4^{2\#})h_{r0}^2e^{i2\omega_1 t}+(iH_2^{1\#}+H_3^{1\#})\alpha_0e^{i\omega_2 t}+(iH_2^{2\#}+H_3^{2\#})\alpha_0^2e^{i2\omega_2 t}\\&+(iH_{12}^{2\#}+H_{34}^{2\#})h_{r0}\alpha_0e^{i(\omega_1+\omega_2)t}\end{aligned} \tag{9a}$$

$$\begin{aligned}C_M=&(iA_1^{1\#}+A_4^{1\#})h_{r0}e^{i\omega_1 t}+(iA_1^{2\#}+A_4^{2\#})h_{r0}^2e^{i2\omega_1 t}+(iA_2^{1\#}+A_3^{1\#})\alpha_0e^{i\omega_2 t}+(iA_2^{2\#}+A_3^{2\#})\alpha_0^2e^{i2\omega_2 t}\\&+(iA_{12}^{2\#}+A_{34}^{2\#})h_{r0}\alpha_0e^{i(\omega_1+\omega_2)t}\end{aligned} \tag{9b}$$

Where, $H_{12}^{2\#}$ and $H_{34}^{2\#}$ had been defined as the velocity coupling aerodynamic derivative and the displacement coupling aerodynamic derivative, corresponding with the 2nd order harmonic component; ω_1 and ω_2 are the vertical and torsional circle frequency respectively.

Comparing to the 2nd order expression of single freedom motion, there are not only frequency multiplication of independent freedom motion, but also frequency superposition of coupled freedom motion in MIAF. Because of the difference between the amplitude and frequency of the two different motions, the MIAF becomes more complicated due to the non-multiplications.

2.3 *Harmonic expression*

Considering the application of the nonlinear MIAF expressions, the plural expressions need to be transfer to the real expression using Euler's formula. Taking lift coefficient in vertical motion as an example, Eq.6a could be written as:

$$(iH_1^{1\#}+H_4^{1\#})h_{r0}e^{i\omega t}=X_{LV}^1h_{r0}\cos(\omega t+\theta)+iX_{LV}^1h_{r0}\sin(\omega t+\theta)\,. \tag{10}$$

where: $X_{LV}^1=\left|iH_1^{1\#}+H_4^{1\#}\right|$, $\theta_{LV}^1=\tan^{-1}(\dfrac{H_1^{1\#}}{H_4^{1\#}})$

The real part and imaginary part can be chosen according to the application. In this paper the imaginary part had been chosen i.e. the sinusoidal motion is assumed, and the transfer expressions of Eq.7a-7d are as follows,

$$C_L^V=X_{LV}^1h_{r0}\sin(\omega t+\theta_{LV}^1)+X_{LV}^2h_{r0}^2\sin(2\omega t+\theta_{LV}^2)+X_{LV}^3h_{r0}^3\sin(3\omega t+\theta_{LV}^3) \tag{11a}$$

Where, $X_{LV}^j=\left|iH_1^{j\#}+H_4^{j\#}\right|$, $\theta_{LV}^j=\tan^{-1}(\dfrac{H_1^{j\#}}{H_4^{j\#}})$, j=1~3

$$C_M^V=X_{MV}^1h_{r0}\sin(\omega t+\theta_{MV}^1)+X_{MV}^2h_{r0}^2\sin(2\omega t+\theta_{MV}^2)+X_{MV}^3h_{r0}^3\sin(3\omega t+\theta_{MV}^3). \tag{11b}$$

Where, $X_{MV}^{j}=\left|iA_1^{j\#}+A_4^{j\#}\right|$, $\theta_{MV}^{j}=\tan^{-1}(\frac{A_1^{j\#}}{A_4^{j\#}})$, j=1~3

$$C_L^T=X_{LT}^1\alpha_0\sin(\omega t+\theta_{LT}^1)+X_{LT}^2\alpha_0^2\sin(2\omega t+\theta_{LT}^2)+X_{LT}^3\alpha_0^3\sin(3\omega t+\theta_{LT}^3) \quad (11c)$$

Where, $X_{LT}^{j}=\left|iH_2^{j\#}+H_3^{j\#}\right|$, $\theta_{LT}^{j}=\tan^{-1}(\frac{H_2^{j\#}}{H_3^{j\#}})$, j=1~3

$$C_M^T=X_{MT}^1\alpha_0\sin(\omega t+\theta_{MT}^1)+X_{MT}^2\alpha_0^2\sin(2\omega t+\theta_{MT}^2)+X_{MT}^3\alpha_0^3\sin(3\omega t+\theta_{MT}^3) \quad (11d)$$

Where, $X_{MT}^{j}=\left|iA_2^{j\#}+A_3^{j\#}\right|$, $\theta_{MT}^{j}=\tan^{-1}(\frac{A_2^{j\#}}{A_3^{j\#}})$, j=1~3

For the coupled motion, assume the following relation of two motions,

$h_{r0}=\lambda\alpha_0$, $\omega_1=\gamma\omega_2$

The lift can be written as:

$$\begin{aligned}C_L&=X_{LV}^1\lambda\alpha_0\sin(\gamma\omega_2 t+\theta_{LV}^1)+X_{LV}^2\lambda^2\alpha_0^2\sin(2\gamma\omega_2 t+\theta_{LV}^2)+X_{LT}^1\alpha_0\sin(\omega_2 t+\theta_{LT}^1)\\&+X_{LT}^2\alpha_0^2\sin(2\omega_2 t+\theta_{LT}^2)+X_{LVT}^2\lambda\alpha_0^2\sin[(1+\gamma)\omega_2 t+\theta_{LVT}^2]\end{aligned} \quad (12a)$$

Where, $X_{LV}^{j}=\left|iH_1^{j\#}+H_4^{j\#}\right|$, $\theta_{LV}^{j}=\tan^{-1}(\frac{H_1^{j\#}}{H_4^{j\#}})$; $X_{LT}^{j}=\left|iH_2^{j\#}+H_3^{j\#}\right|$, $\theta_{LT}^{j}=\tan^{-1}(\frac{H_2^{j\#}}{H_3^{j\#}})$, j=1~2;

$X_{LVT}^{2}=\left|iH_{12}^{2\#}+H_{34}^{2\#}\right|$, $\theta_{LVT}^{2}=\tan^{-1}(\frac{H_{12}^{2\#}}{H_{34}^{2\#}})$

And the pitching moment can be written as

$$\begin{aligned}C_M&=X_{MV}^1\lambda\alpha_0\sin(\gamma\omega_2 t+\theta_{MV}^1)+X_{MV}^2\lambda^2\alpha_0^2\sin(2\gamma\omega_2 t+\theta_{MV}^2)\\&+X_{MT}^1\alpha_0\sin(\omega_2 t+\theta_{MT}^1)+X_{MT}^2\alpha_0^2\sin(2\omega_2 t+\theta_{MT}^2)\\&+X_{MVT}^2\lambda\alpha_0^2\sin[(1+\gamma)\omega_2 t+\theta_{MVT}^2]\end{aligned} \quad (12b)$$

Where, $X_{MV}^{j}=\left|iA_1^{j\#}+A_4^{j\#}\right|$, $\theta_{MV}^{j}=\tan^{-1}(\frac{A_1^{j\#}}{A_4^{j\#}})$; $X_{MT}^{j}=\left|iA_2^{j\#}+A_3^{j\#}\right|$, $\theta_{MT}^{j}=\tan^{-1}(\frac{A_2^{j\#}}{A_3^{j\#}})$, j=1~2;

$X_{MVT}^{2}=\left|iA_{12}^{2\#}+A_{34}^{2\#}\right|$, $\theta_{MVT}^{2}=\tan^{-1}(\frac{A_{12}^{2\#}}{A_{34}^{2\#}})$

Eqs.11a-11d and Eqs. 12a-12b show clearly that, if the motion of bridge girder is the sinusoidal or cosine, the nonlinear MIAF is composed of different frequency multiplication components for single freedom motion, and is composed of different multiplication and non-multiplication components under coupled motion. The amplitude indicates the value of different harmonic components, and the initial phase indicates the lag. These equations also indicate that, if amplitude and the initial phase of different harmonic components are known, the nonlinear coefficients can be calculated.

2.4 *Discussion*

The configuration of bridge girder determines its aerodynamic property, and the proportions of harmonic components in nonlinear MIAF are different while the girder sections are different. As to the same bridge girder section, the proportions of harmonic components in nonlinear MIAF are different while the amplitudes are different, because of the distinct change of aerodynamic

configuration during oscillation. Even for the same bridge girder section and the same amplitude, the proportions of harmonic components in nonlinear MIAF are also different while the reduced frequencies are different, because of the distinct difference in flow fields under different *K*. Thus the nonlinear aerodynamic parameters in the expression are sensitive to motion and flow conditions. The selection of order in MIAF model should base on the wind tunnel tests. For example if there is only the 3rd order harmonic in the nonlinear MIAF signal derived from testing, the 3rd order components can be kept.

3 IDENTIFICATION OF NONLINEAR AERODYNAMIC COEFFICIENTS

3.1 *Expression of nonlinear aerodynamic coefficients*

Under the condition of the given amplitude and reduced frequency, Eq.3 and Eq.11a describe the same MIAF, so the nonlinear aerodynamic coefficient in Eq.3 can be expressed by using the amplitude and initial phase. Based on the nonlinear MIAF obained from the wind tunnel tests under a given condition, the nonlinear aerodynamic coefficients $C^k_{\dot{h}^m h^n}$ (k=1~3,m,n=0~3) in Eq.3 can be described as

$$C^k_{\dot{h}^m h^n} = \frac{X^k_{VL} k!}{\omega^m} \sin(\theta^k_{VL} + \frac{n\pi}{2}) \tag{13}$$

Where, k=1,2……n, is the order of nonlinear harmonic components; m and n is the nonlinear aerodynamic coefficient order which represents the derivative order of velocity and displacement. X^k_{VL} is the amplitude of the K^{th} order vertical lift harmonic component and the θ^k_{VL} is the initial phase.

3.2 *Identification method*

The nonlinear coefficients in Eq.3 can be identified by least-square method. Based on the original signal obtained from test, one can identify the amplitude X^k_{VL} and initial phase θ^k_{VL} of different harmonic components by using FFT method, but these coefficients can't reconstruct the nonlinear MIAF due to the unacceptable errors. If taking those X^k_{VL} and θ^k_{VL} as the initial values and then applying the least-square method, the exact amplitude X^k_{VL} and initial phase θ^k_{VL} of different harmonic components can be found. It is noted that if the original signal was contaminated by noise, a signal process is definitely required to minimize or eliminate the influence.

3.3 *Examples*

To demonstrate the identification method and verify its accuracy, a sinusoidal signal composed of five order harmonic components with different amplitude and initial phase are constructed.

$$\begin{aligned} X = {} & A_1 \sin(\omega t + P_1) \\ & + A_2 \sin(2\omega t + P_2) + A_3 \sin(3\omega t + P_3) \\ & + A_4 \sin(4\omega t + P_4) + A_5 \sin(5\omega t + P_5) \end{aligned} \tag{14}$$

Where ω= 11.3097 rad/s, A_j= amplitude, P_j= initial phase, j=1~5, the values are shown in Table 1. Table 2 gives the results of identified parameters in Eq.14. The results show that the identification method can minimize the error between identification value and given value, and also can reconstruct the original signal.

4 WIND TUNNEL TEST

To obtain nonlinear MIAF and assess its characteristic, tests were conducted in Φ3.2m wind tunnel of Low speed Aerodynamics Institute, China Aerodynamics Research and Development Center (CARDC).A model with streamline box girder section (0.776m wide, 1.2m long) was tested in this study, which was made of glass fiber reinforced plastics to ensure the adequate stiffness and minimal mass and mass moment of inertia. The test model was fixed on the rigid holder and drive by the actuating motor. The drawing of the model is shown in Fig.1. The inertia force , static force and MIAF were acquired through a strain balance directly, and the pure MIAF was obtained by subtracting the inertial force(acquired at the same motion state under windless condition) and static force (mean value of the aerodynamic force).

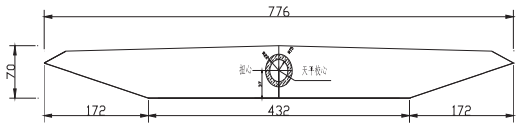

Fig 1 The cross-section of test model

Fig. 2 shows the aerodynamic coefficients in time domain and frequency domain, for the motion condition torsional n with amplitude 20°and at reduced frequency 0.35. In time domain, the pitching motion of models can be described by $\alpha = \alpha_0 \cos(2\pi ft)$, and for the pitching motion $h = h_0 \cos(2\pi ft)$. When the pitching angle is up to 20deg, the coefficient of aerodynamic moment is a distortional wave with high order harmonics, which can be seen clearly on spectrum (Fig. 2). The 2nd and the 3rd order components are so clear that have become the dominant components in high harmonics. On the other hand, with increasing of oscillation amplitude, the high-order har-

monics plays a more and more important role. The similar results had been obtained in the vertical motion tests. The error between original signal and reproduced signal is shown in Fig. 3.

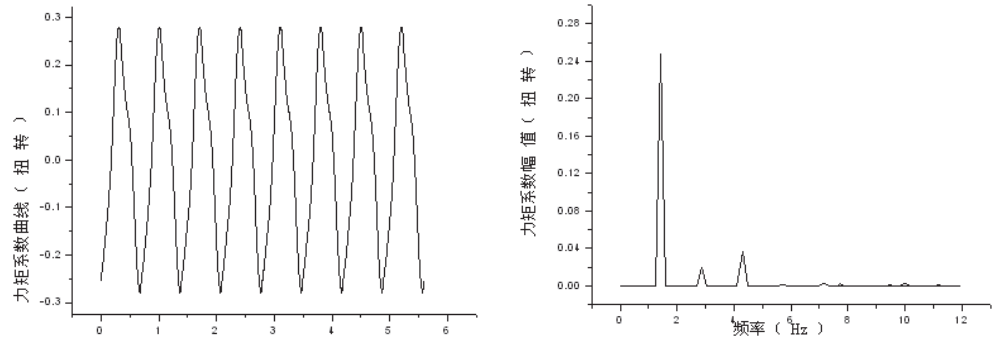

Fig 2. The aerodynamic moment coefficient history curve and spectrum under torsional motion（α_0=20°, K=0.35）

5 CONCLUSIONS

The nonlinear MIAF expressions with independent variables of amplitude and reduced frequency are deduced by using Taylor expanding method, which is composed of different harmonic components. Wind tunnel tests results verified the existence of high harmonic components in the MIAF of bridge girder, and the error between reconstructed curve and original curve indicated that the model can describe the nonlinear MIAF accurately.

ABSTRACT: By taking a cable-stayed bridge as background, the non-linear vortex-induced force on its flat fully-closed box girder was investigated via a series of wind tunnel tests of spring-suspended sectional model at a large scale of 1/25, in which the dynamic displacements of the model and the dynamic forces acting on the outer cladding of the model were simultaneously measured. A non-linear least square fitting method based on the measured history of vortex-induced force was established at first to identify the relevant parameters of various empirical models of vortex-induced force. The well known Scanlan's nonlinear empirical model for the vortex-induced force was then examined by comparing the calculated displacement response with the measured one, and was demonstrated to be not suitable for the vortex-induced force of the flat box girder. A novel empirical model was finally proposed and proved to be proper to the vortex-induced force of the flat box girder. By using this novel model, not only the measured history of vortex-induced force can be well fitted, but also the measured history of dynamic displacement of the sectional model can be well reproduced via numerical calculation.

1 INTRODUCTION

The flexible steel bridges with low damping often suffer vortex-induced vibrations (VIV) at relatively low wind speeds. However, the VIV with small amplitude is sometimes allowable, unless it could possibly cause fatigue problems to the structure or discomfort problems to its users. Therefore, a careful prediction of the VIV performance via wind tunnel test or theoretical analysis is very necessary for a bridge suspected of VIV problems. In this connection, a reliable model of vortex-induced force (VIF) should be firstly established to describe the strongly-nonlinear interaction between fluid and structure. Nevertheless, no completely successful analytical method has yet been developed, starting from basic flow principles, to represent the response behavior of an elastic bluff body under the action of vortex shedding (Scanlan, 1986). Instead, it has been relatively fruitful in building empirical models of uncoupled VIF based on wind tunnel tests, such as proposed by Vickery & Basu(1983), Staubli(1983) , Scanlan(1986) and Larsen(1995), and the fluid oscillator models by Hartlen & Currie(1970), Landl(1975), Tamura & Matsui(1979), Berger(1987) and Diana & Cheli(1995). Among these proposed VIF models, only a few, such like the nonlinear model proposed by Scanlan(1986), as well as its generalized model proposed by Larsen(1995), are applicable to bridge VIV because of the special characteristic of vortex shedding mechanism of bluff bridge decks.

Secondly, the identification of the parameters in the empirical models is to some extent decided whether a model is applicable or not. Since the difficulty on the technique of measuring

pure VIF on bluff bodies, almost all the existing parameter identification processes have based on the displacement responses of VIV, instead of the force history excited by vortex shedding. Several assumptions have been induced to deduce the approximate solution of the nonlinear differential equation of motion (Ehsan *et al*. 1990; Larsen 1995). In spite of that, it is still unknown how these assumptions will affect the analysis result.

In this study, a new technique of sectional model wind tunnel test was developed to investigate the VIF directly. The special technique could simultaneously measure the total force (consisting of vortex-induced force and the inertial force), the VIV displacement and acceleration of an oscillating deck model, in free vibration tests, via force balances along with laser displacement sensors and acceleration sensors respectively. The reliability of existing Scanlan and Larsen's models and their parameter identification methods were judged by the vortex-induced force history. Moreover, a novel promising empirical model for VIF on a closed box bridge girder is proposed and its parameters are identified using nonlinear least square method.

2 MODEL, WIND TUNNEL AND MEASUREMENT SYSTEM

2.1 *Sectional model design*

The Xiangshan Harbor Bridge, a typical long span highway bridge in China, was taken as an example to investigate the vortex-induced force on closed box bridge deck. The Xiangshan Harbor Bridge is a cable-stayed bridge with a main span of 688m over the Xiangshan Harbor in Ningbo of China. The deck of the bridge is of flat steel trapezoidal box girder, which is 32.0m wide, 3.5m high and with two sets of side fairing of about 56 degrees.

Considering that the VIV performance is always sensitive to the aerodynamic configuration of bluff bodies, the deck exterior appearance, including the side fairings, hand rails, protection rails and maintenance traces, were modeled in the light of the principle of geometric similarity seriously. The geometric scale of the sectional model was set to be 1:20 while its length is 3.600m after a careful consideration of many factors. These factors include the size of working section of the wind tunnel, the sufficiently large aspect ratio (length-over-width) requirement for the model, the lock-in wind speeds, the frequency of the mass-spring system, and the sensitivity and capacity of the force balance. After scaled, the cross section of the model is 1.600m wide (noted as *B*) and 0.175m high (noted as *D*). The configuration of the model cross section is illustrated in Fig. 1.

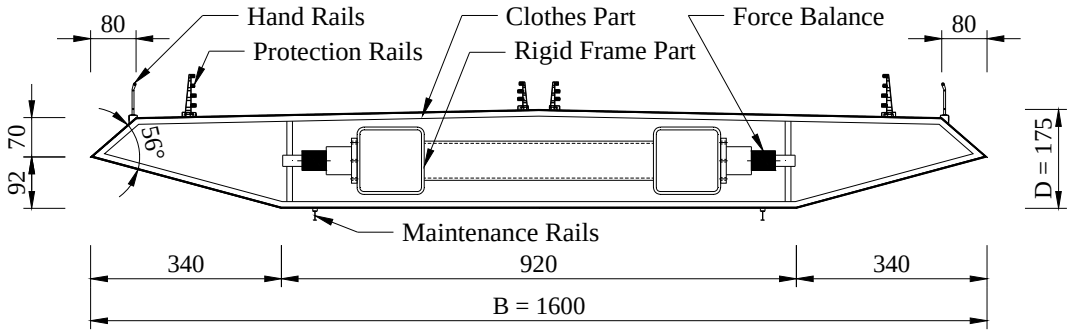

Figure 1. Cross Section of the sectional model (Unit: mm).

The force balance technique was adopted in this study for it is the most reliable way of measuring fluctuating lift in wind engineering. To get the pure vortex-induced force acting on an oscillating bridge deck, the inertial force, which could obtained from the product of acceleration

and mass, along with the aerodynamic force in still air, should be subtracted from the total force measured by the force balance. In factor, the aerodynamic force is always very small regarding to the inertial force caused by the motion of the model. The numerical error will be inevitably induced in this subtraction when the mass connected to the balances is too large. While, low mass of sectional model will result in wake of stiffness and large deformation of the elastically supported "rigid body". To avoid this confliction, an innovative improvement was made in this study. The model was designed into two parts. One of which was the "clothes part" made of wood plates and thin-walled stainless steel tube stiffeners to shape the bridge deck as light as possible, while the other was the "frame part" made of steel tubes to provide the stiffness of the model (See Fig. 1). The force balances were set interiorly between the clothes part and the rigid frame part while the frame part was elastically mounted on an eight spring system (See Fig. 2). Thus, the sampled force signal could contain less inertial components rather than the whole inertial force of the cumbersome sectional model. In other words, the demand of the precision on force balance could not be too rigorous any more. Furthermore, in order to promote the veracity of the aerodynamic force obtained, the clothes part was divided into three segments. The main segment set in middle of the model is 2.400m long, and the two side ones are 0.598m long each, with 2mm wide gaps between the main segment. With the force balances measuring only the forces come from the mid segment, the effects caused by the three dimensional flow around the ends of the model could be significantly eliminated.

2.2 *TJ-3 wind tunnel and measurement system*

Wind tunnel tests were carried out in TJ-3 boundary layer wind tunnel of the State Key Laboratory for Disaster Reduction in Civil Engineering at Tongji University, Shanghai, China. The facility is a closed-circuit wind tunnel which has a test section of 15m wide, 2m high and 14m long. The achievable mean wind speed in the tunnel ranged from 1.0 to 17.6m/s. The whole spring-mass system of the bridge deck model was fixed on two temporarily streamline walls built in the interior of TJ-3 wind tunnel (See Fig. 3). All the tests were carried out in smooth flow. The flow field between the walls was verified by hot wires at the cross section parallel to the central axes of the deck. The maximum non-uniformity of mean wind within the cross section is less than 2% and the turbulence intensity within the same cross section is less than 2.5%.

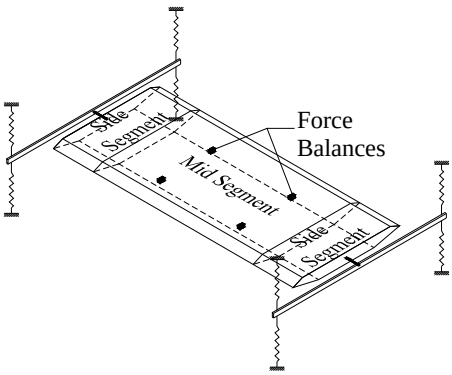

Figure 2. Set up of the sectional model

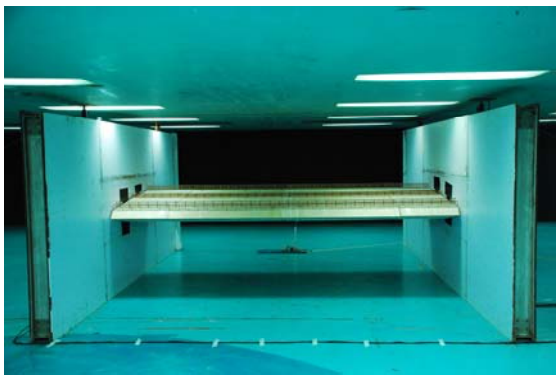

Figure 3. Sectional model in TJ-3 wind tunnel

To obtain the time-histories of oscillation curves of the model at a given position and a given wind speed, four accelerometers along with four laser displacement sensors were mounted on each end of the two support arms. Four electric bridge of the strain force balances were powered by a high-accuracy potentionstatic DC power supply and connected to an eight channels DC

voltage amplifier. A 16-channel data acquisition unit and a computer were used to digitize and record the measurement data. Calibration of the force measurement system was performed before the test to obtain the calibration factor of each force balance, reflecting the relationship between the applied forces and the normalized output voltages. In factor, there were non-neglectable phase delays between the different types of sensors, for the electrical impedances are not the same in each electric circuit. A simple mass-spring oscillator was designed to modify the sampled time histories of force, displacement and acceleration (See Fig. 4). Fig. 5 and Fig. 6 illustrated the normalized time histories before and after modification respectively.

3 WIND TUNNEL TEST RESULTS AND DISCUSSIONS

3.1 *The added mass parameter m_0 and added damping parameter c_0 in still air*

Air will certainly result in forces on oscillating deck model regardless of whether the air is flowing or not. But, in the differential equation of motion, the aerodynamic force acting on the model in still air is used to be idealized to zero. This idealization will cause problems when the system parameters are identified through free vibration responses in still air while the aerodynamic force is measured by experiment. Because the system parameters used in the equation of motion are identified in still air. That has automatically taken into account the still air force effect. But the special force measured in flowing air still contains the component represent the force effect in static air. In this study, this still air aerodynamic force effect mentioned above is considered by introducing added mass parameter m_0 and added damping parameter c_0. Therefore, the total air force in "lock-in" was the summation of inertial force caused by added mass, damping force caused by added damping, and the pure aeroelastic force regarded as the special vortex-induced force caused by the flowing air. The referred parameters m_0 and c_0 can be identified via the free decay responses and the force history by the force sensors.

The total force measured by the force balances can be regard as the forces come from equivalent mass m_e and damping c_e, as described by Equation 1:

$$f_{measured} = m_e y'' + c_e y' = (m_s + m_0) y'' + c_0 y' = f_{inertial} + f_{static} \tag{1}$$

where $f_{measured}$ = total force measured per unit length; m_s = mass of the measured mid segment per unit length; m_0 = added mass per unit length; and c_0 = added damping per unit length;

$f_{inertial}$ is inertial force caused by the mass of the mid segment per unit length, which could be express as:

$$f_{static} = m_s y'' \tag{2}$$

f_{static} is the still air force per unit length:

$$f_{static} = m_0 y'' + c_0 y' \tag{3}$$

The velocity response can be indirectly obtained from displacement signal by central difference method in time domain. Fig. 7a to Fig. 7d shows the sampled displacement, acceleration, total measured force along with the computed velocity histories of free decay vibration response in still air. With the measured total force history along with the response history of acceleration and velocity, the identification of the parameters of equivalent mass m_e and damping c_e was operated by time domain least square fitting method (See Fig. 7e). The added mass m_0 and added damping c_0 can be obtained by Equation 1, for the mass of the mid segment m_e could directly weighted by the force balances. Then the still aerodynamic force history could be reproduced by the parameters m_0 and c_0 (See Fig. 7f).

(d) Velocity history (e) Least square fitting of $f_{measured}$ (f) Still air force $f_{stastic}$

Figure 7. Force and response history of free decay vibration of sectional model in still air

3.2 *The pure vortex-induced force at "lock-in"*

With the estimated parameters m_0 and c_0 (or m_e and c_e), it is easy to obtain the pure vortex-induced force at "lock-in". Just as the operation conducted in the still air, the total force along with the VIV response histories were recorded via the sensors equipped on the model. Then the pure vortex-induced force could be achieved by subtract the inertial force of the mid segment and the still air force caused by the added mass and damping from the measured force. Taking the VIV performance at the wind speed of 9.10m/s as example, the time histories of responses and forces were illustrated in Fig. 8. To verify the reliability of the indirectly measured vortex-

induced force, a time domain analysis on the response of the sectional model was conducted by Newmark-β method, inputting the special vortex-induced force history obtained above.

(c) The tested displacement response and the computed response (d) y in frequency domain

Figure 9. The vortex-induced force and response in time and frequency domain

Fig. 9a shows the vortex-induced force time history in detail and Fig. 9b shows the amplitude spectrum of the vortex-induced force. Fig. 9c and Fig. 9d illustrate the response and force signals in frequency domain, with the ordinate to be the magnitudes of the signal. It can be observed that while the response histories. It can be observed form the figures that, while the motion responses are harmonic-like signals, the vortex-induced force history is much complicate. The vortex-induced force history has two negative peaks and two positive peaks during one period. It results in the significant double and triple frequency components, which could be the main reason for the nonlinear phenomena in VIV. As the computed response is very close to the tested, both in time and frequency domain, it could be concluded that the tested force is reliable and with high precision.

4 SCANLAN'S NONLINEAR MODEL AND PARAMETER IDENTIFICATION METHOD

4.1 *Scanlan's nonlinear model*

Empirical models describing the across-flow response of a rigid bluff body mounting on linear springs submerged in a fluid stream with uniform velocity can be written as following

$$m(y'' + 2\xi\omega_1 y' + \omega_1^2 y) = f_{VIV}(y, y', y'', U, t) \tag{4}$$

where m = mass per unit length; ω_1 = mechanical structure circular frequency; ξ = mechanical structure damping ratio; y = displacement response in across-flow direction; U = the mean follow speed.

Scanlan (1986) proposed a semi-empirical nonlinear model yield the general form mentioned above. In which, the vortex-induced forcing function was defined as

$$f_{VIV}(y, y', y'', U, t) = \frac{1}{2}\rho U^2 (2D)\left[Y_1(K)\left(1 - \varepsilon\frac{y^2}{D^2}\right)\frac{y'}{U} + Y_2(K)\frac{y}{D} + \frac{1}{2}\tilde{C}_L \sin(\omega t + \varphi)\right] \tag{5}$$

where D = characteristic length of the bluff body, in this study, it is the depth of the bridge deck; ρ = air density; the reduced frequency $K = \omega D/U$, where ω is the vortex frequency; and the phase φ.

The non-dimensional form of Equation 4 with the substitution of f_{VIV} in Equation 5 is

$$\begin{aligned} &\eta''(s) + 2\xi K_1 \eta'(s) + K_1^2 \eta(s) = \\ &m_r Y_1(K)[1 - \varepsilon\eta^2(s)]\eta'(s) + m_r Y_2(K)\eta(s) + \frac{1}{2} m_r C_{LV} \sin(Ks + \theta) \end{aligned} \tag{6}$$

where $\eta(s) = y(t)/D$; the mass ratio $m_r = \rho D^2/m$.

4.2 *Parameter identification method via GTR or DTR method*

Ehsan and Scanlan (1990) has developed a parameter identification procedure via the "Decay to Resonance (DTR)" or "Grow to Resonance (GTR)" response of the sectional model in wind tun-

nel tests. The approximate analysis solution of the Van der Pol type function described by Equation 6 was firstly deduced by introducing the slow variation and Van der Pol assumption. The last term of the direct forcing was dropped for the value of C_{LV} was thought to be very small. Then the approximate solution could be described like following

$$\eta(s)=\frac{\beta}{\sqrt{1-\left(\frac{A_0^2-\beta^2}{A_0^2}\right)e^{-(\alpha\beta^2/4)s}}}\cos\left\{Ks-\frac{1}{2K}\left[m_r Y_2(K)+\left(K^2-K_1^2\right)\right]s-\psi_0\right\} \tag{7}$$

where A_0 and ψ_0 are the initial amplitude and phase of the "Decay to Resonance (DTR)" or "Grow to Resonance (GTR)", respectively. α and β are variables containing parameters ε and Y_1

$$\alpha = m_r Y_1(K)\varepsilon \tag{8}$$

$$\beta=\frac{2}{\sqrt{\varepsilon}}\left(1-\frac{2\xi K_1}{m_r Y_1(K)}\right)^{1/2} \tag{9}$$

The variable α and β could be obtained from the resonance amplitude and the envelope of the decay or grow stage of the response. Thus, the parameters ε and Y_1 could be obtained by equation (8) and (9). Furthermore, the parameter Y_2, which was thought to be very small, could also be obtained from the difference between the mechanical frequency and the total frequency during VIV.

When the parameters were identified, not only the vortex-induced oscillating response, but also the vortex-induced fore can be numerically achieved. In this section, the GTR method was adopted to identify the parameters. The estimated parameters are shown in Table 1. Fig. 10 shows the non-dimensional vortex-induced forcing f_{nonVIV} histories achieved by wind tunnel tests and computation. Fig. 11 shows the tested and computed grow to resonance non-dimensional histories. It can be observed from the figures that, although the response of the sectional model calculated from Scanlan's nonlinear empirical model, which parameters are identified via the motion response, is quite close to the test response history, the parameter described vortex-induced force history is remarkably dissimilar to the tested force. The parameter described force has three negative peaks as well as three positive peaks in one period, while, the tested force history has only two negative peaks and two positive peaks.

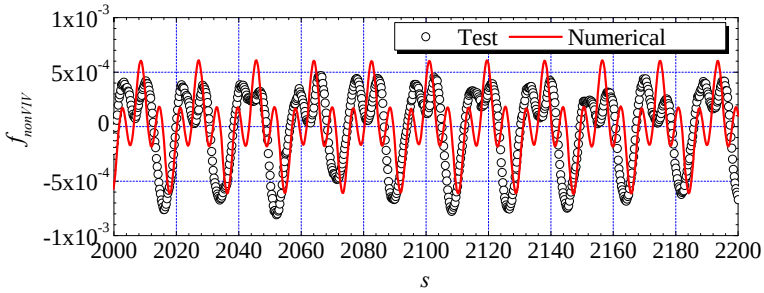

Figure 10. Non-dimensional vortex-induced force history (Scanlan's model, parameters identified via GTR method)

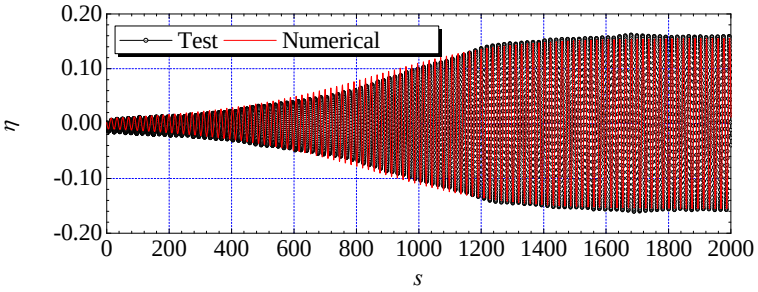

Figure 11. Non-dimensional displacement response (Scanlan's model, parameters identified via GTR method)

4.3 *Parameter identification method via LSQ method*

Just as described above, with the parameters identification method proposed by Ehsan and Scanlan, the Scanlan's nonlinear empirical model could not perfectly rebuild the tested vortex-induced force. That could result from two possible reasons, first, the parameter identification procedure is not suitable for its improper assumptions induced in the approximate solution, and second, the model itself is not able to describe the vortex-induced force.

In this section, a direct curve fitting method based on the nonlinear least square (LSQ) technique was developed to identify the parameters in Scanlan's nonlinear empirical model. The sum squared error was regarded as the objective function, and the numerical optimization function can be defined as

$$R(Y_1, Y_2, \varepsilon, C_L, K, \varphi) = \sum \left(f_{nonVIV}(s_i) - \hat{f}_{nonVIV}(s_i) \right)^2 \tag{10}$$

where $\hat{f}_{nonVIV}(s_i)$ is the estimated non-dimensional vortex-induced force described by Scanlan's model at time s_i, and f_{nonVIV} is the tested value at the same time. The objective is to find Y_1, Y_2, ε, C_L, K and φ to make the value of function $R(Y_1, Y_2, \varepsilon, C_L, K, \varphi)$ to be minimum. The Levenberg-Marquardt method was adopted to solve the nonlinear Equations 11.

$$\begin{cases} \sum_{i=1}^{n} (f_{nonVIV}(s_i) - \hat{f}_{nonVIV}(s_i))(1 - \varepsilon \frac{\eta_i^2}{D^2})\eta_i' = 0 \\ \sum_{i=1}^{n} (f_{nonVIV}(s_i) - \hat{f}_{nonVIV}(s_i))\eta_i^2 \eta_i' = 0 \\ \sum_{i=1}^{n} (f_{nonVIV}(s_i) - \hat{f}_{nonVIV}(s_i))\eta_i = 0 \\ \sum_{i=1}^{n} (f_{nonVIV}(s_i) - \hat{f}_{nonVIV}(s_i))\sin(Ks_i + \varphi) = 0 \\ \sum_{i=1}^{n} (f_{nonVIV}(s_i) - \hat{f}_{nonVIV}(s_i))s_i \cos(Ks_i + \varphi) = 0 \\ \sum_{i=1}^{n} (f_{nonVIV}(s_i) - \hat{f}_{nonVIV}(s_i))\cos(Ks_i + \varphi) = 0 \end{cases} \tag{11}$$

Scanlan's	GTR	16.397	0	—	81.199	—	—	—	—
Scanlan's	LSQ	8.406	-2.179	—	-18.671	—	0.792	0.680	-1.997
New model	LSQ	11.966	-2.194	89.408	—	103.361	-0.022	0.4477	-0.0128

The identified parameters for Scanlan's nonlinear model by LSQ method was given in Table 1. Fig. 12 and Fig. 13 shows the rebuilt force and the numerical solution of the differential equation of motion, with the vortex-induced force described by Scanlan's model and the parameters by LSQ method. The results show that, the coefficient of the nonlinear aerodynamic term, ε, was a negative value. That will certainly result in nonlinear negative aerodynamic damping in the numerical system. In other words, the negative aerodynamic damping will grow if the oscillation amplitude grows, and the system will show divergence finally, just as the response history illustrated in Fig. 13.

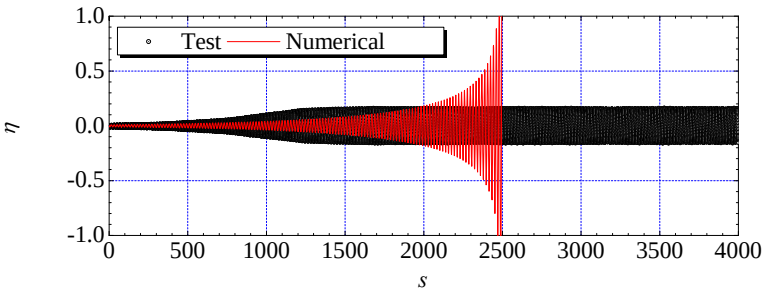

Figure 13. Non-dimensional displacement response (Scanlan's model, parameters identified via LSQ method)

5 NEW VORTEX-INDUCED FORCE MODEL

The evidences above show overwhelmingly that the Scanlan's nonlinear empirical model is not proper to predict the vortex-induced force on closed bridge deck. A new empirical model was suggested, after a really hard try of possible models with the general form of Equation 4, to properly describe the vortex-induced force on the bridge deck. The new model can be defined as

$$f_{VIV}(y,y',y'',U,t)=\frac{1}{2}\rho U^2(2D)\left[Y_1(K)\left(1-\varepsilon_N\frac{y'^2}{D^2}\right)\frac{y'}{U}+Y_2(K)\frac{y}{D}+Y_3\frac{y'y}{UD}+\frac{1}{2}\tilde{C}_L\sin(\omega t+\varphi)\right] \quad (12)$$

This new model also induced a cubical term to ensure that the oscillation is self-limiting, but the special nonlinear aerodynamic damping term was in phase with the cube of velocity, instead of with the product of square displacement and velocity used in Scanlan's model. Furthermore, a second order nonlinear term, which was in phase the product of displacement and velocity, was induced to the model as well, for the remarkable force component of double frequency observed in Fig. 9b. The LSQ method was also adopted to identify the parameters in the new model. The values of the parameters in the new model are given in Table 1. Fig. 14 and Fig. 15 show the vortex-induced force and the response calculated by the new model. The results show that, with the parameters estimated by LSQ method, the new model could not only perfectly rebuild the vortex-induced force, but also reliably predict the vortex response by numerically solving the nonlinear differential equation of motion. However, the computed response is a little larger than the tested response. It could be result from the lack of spanwise correlation on the vortex-induced force and the incoming flow, for the force tested was only the aerodynamic force acting on the mid segment of the model, while the oscillation system was driven by the force acting on the whole model.

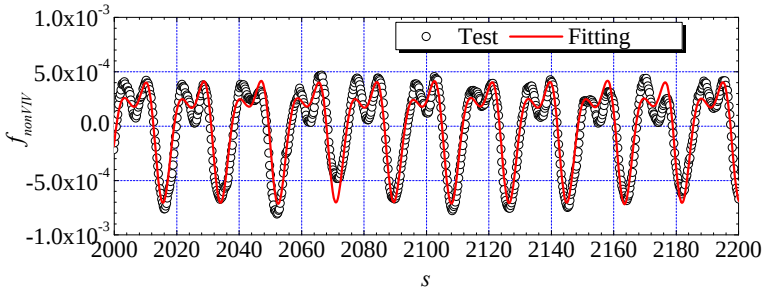

Figure 14. Non-dimensional vortex-induced force history (New model, parameters identified via LSQ method)

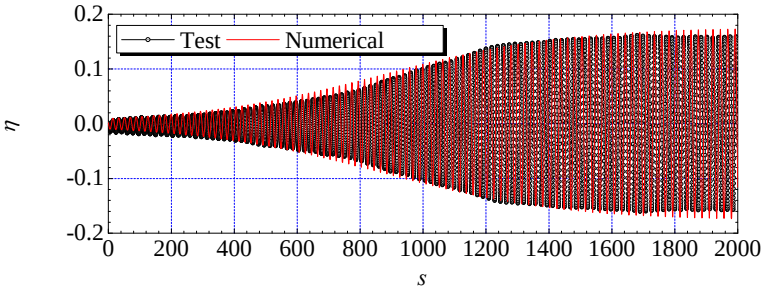

Figure 14. Non-dimensional displacement response (New model, parameters identified via LSQ method)

6 CONCLUSIONS

By taking a closed box bridge deck as an example, the vortex-induced force was tested by sectional wind tunnel tests. The test results has shown that the vortex-induced force is evidently nonlinear, for the significant double and triple frequency components observed in the amplitude spectrum of the tested force.

The reliability of the well known Scanlan's nonlinear empirical model and the parameter identification procedure suggested by Ehsan and Scanlan was discussed. A new parameter estimate procedure, which was based on least square technique to directly fitting the vortex-induced force history, was also developed. By comparing the vortex-induced force and structure response rebuilt by Scanlan's model with the measured results, it can be concluded that the Scanlan's

nonlinear empirical model could not properly describe the special vortex-induced vibration phenomenon.

A new promising nonlinear model was proposed. The model still introduced a three order term to ensure the self-limiting property as well as a second order term to adapt the double frequency component of the vortex-induced force. Aided with the parameters identified by the nonlinear least square fitting method, the new model could either perfectly fit the tested force history, or exactly reproduce the response of VIV.

ABSTRACT: Unsteady aerodynamic forces can be computed efficiently in time domain by Rational Function Approximation (RFA) method. However, parameter values of existing RFA models are not unique for given input-output characteristics. This property will cause difficulties in nonlinear aerodynamic analysis where interpolations among parameter values may be required. When parameters cannot be uniquely determined, such interpolations may be erroneous. This paper firstly discusses the general form of differential equations for unsteady aerodynamic forces. Then, a new time domain aerodynamic model, namely the Cascade model, is suggested. It can be found that the new model has unique parameters. Finally, the new model is used to fit flutter derivatives and static coefficients of a bridge deck obtained from wind tunnel tests. The unsteady transfer matrix and Quasi-Static limit matrices of the new model are fitted simultaneously. The output time history of the new model under given input is compared with results of frequency-response analysis.

1 INTRODUCTION

A reliable aerodynamic force model is core to the prediction of bridge response in wind. Bridge deck sections are generally irregular bluff bodies, which features complicated unsteady characteristics. Although being widely used, traditional frequency domain approaches[1] show significant drawbacks. Firstly, frequency-dependent coefficients, such as flutter derivatives and aerodynamic admittance functions, are difficult to be integrated into structure analysis which is often conducted in time domain. Secondly, superposition based frequency domain methods cannot reasonably consider aerodynamic nonlinearity. Researchers have re-formulated unsteady aerodynamics in time domain by using aerodynamic indicial functions or Rational Function Approximation (RFA) techniques[2][3]. These methods successfully modeled the frequency-dependent characteristics or memory effects of aerodynamics and can be readily used in structural analysis[4]. Aerodynamic nonlinearity has been widely observed[5] in wind tunnel tests. When simulating nonlinear aerodynamic forces, model parameters need to be switched among different values for different wind velocities or angle of attacks. This usually requires interpolation among parameter values. However, traditional RFA models do not have unique parameters. This means that two models with identical transfer characteristics may have totally different parameter values. Therefore, interpolations among different parameter values may be erroneous. To overcome this difficulty, a new unsteady model with unique parameters is required.

2 EXISTING METHODS

In time domain, unsteady aerodynamic forces can be computed by convolution of indicial functions[6]

$$\boldsymbol{f}(t) = \boldsymbol{A}_0\boldsymbol{x}(t) + \boldsymbol{A}_1\dot{\boldsymbol{x}}(t) + \boldsymbol{A}_2\ddot{\boldsymbol{x}}(t) + \int_{-\infty}^{t} \boldsymbol{I}_{fx}(t-\tau)\dot{\boldsymbol{x}}(\tau)\, d\tau \tag{1}$$

where $\boldsymbol{A}_0$, $\boldsymbol{A}_1$and $\boldsymbol{A}_2$ = aerodynamic stiffness, damping and mass matrices, respectively; $\boldsymbol{I}_{fx}(t)$ = indicial function matrix; $\boldsymbol{f}$ = aerodynamic forces; $\boldsymbol{x}$ = structural displacements. Computation of eq.(1) is not efficient due to existence of convolution term. Therefore, researchers have proposed some computationally more efficient alternatives, such as the Roger's RFA method[2] and the Minimum-State RFA method[3].

Using the Leibniz integration formula, the following equation for the convolution term can be obtained:

$$\left[\int_{-\infty}^{t} \boldsymbol{I}_{fx}(t-\tau)\dot{\boldsymbol{x}}(\tau)d\tau\right]' = \boldsymbol{I}_{fx}(0)\dot{\boldsymbol{x}}(t) + \int_{-\infty}^{t} \boldsymbol{I}'_{fx}(t-\tau)\dot{\boldsymbol{x}}(\tau)d\tau \tag{2}$$

By assuming that indicial functions $\boldsymbol{I}_{fx}(t)$ are power series of e, that

$$\boldsymbol{I}_{fx}(t) \approx \sum_{i=1}^{n_l} \boldsymbol{A}_{2+i} e^{-\lambda_i t} \tag{3}$$

the following differential equations can be derived.

$$\begin{cases} \boldsymbol{f} = \boldsymbol{A}_0\boldsymbol{x} + \boldsymbol{A}_1\dot{\boldsymbol{x}} + \boldsymbol{A}_2\ddot{\boldsymbol{x}} + \sum_{i=1}^{n_l} \boldsymbol{\phi}_i \\ \dot{\boldsymbol{\phi}}_i = \boldsymbol{A}_{2+i}\dot{\boldsymbol{x}} - \lambda_i\boldsymbol{\phi}_i, \qquad (i = 1, \dots n_l) \end{cases} \tag{4}$$

where

$$\boldsymbol{\phi}_i = \int_{-\infty}^{t} \boldsymbol{A}_{2+i} e^{-\lambda_i(t-\tau)}\dot{\boldsymbol{x}}(\tau)\, d\tau\,, \qquad (i = 1, \dots n_l) \tag{5}$$

are aerodynamic state variables. It is noteworthy that Eqs. (4) can be solved in time domain efficiently without convolution.

Laplace transform of eqs.(4) can be written as

$$\begin{Bmatrix} \hat{\boldsymbol{f}} \\ \boldsymbol{0} \\ \boldsymbol{0} \\ \boldsymbol{0} \end{Bmatrix} = \begin{bmatrix} \boldsymbol{A}_0 + \boldsymbol{A}_1 s + \boldsymbol{A}_2 s^2 & \boldsymbol{I} & \dots & \boldsymbol{I} \\ -\boldsymbol{A}_3 s & (\lambda_1 + s)\boldsymbol{I} & & \\ \vdots & & \ddots & \\ -\boldsymbol{A}_{2+n_l} s & & & (\lambda_{n_l} + s)\boldsymbol{I} \end{bmatrix} \begin{Bmatrix} \hat{\boldsymbol{x}} \\ \hat{\boldsymbol{\phi}}_1 \\ \vdots \\ \hat{\boldsymbol{\phi}}_{n_l} \end{Bmatrix} \tag{6}$$

where s = complex frequency; hat symbol ˆ represents Laplace transform of a variable. After eliminating states $\hat{\boldsymbol{\phi}}_i$ from eqs.(6), the well-known Roger's Rational Function Approximation of aerodynamic transfer matrix can be obtained:

$$\boldsymbol{T}(s) = (\boldsymbol{A}_0 + \boldsymbol{A}_1 s + \boldsymbol{A}_2 s^2) + \sum_{i=1}^{n_l} \frac{\boldsymbol{A}_{2+i} s}{(\lambda_i + s)} \tag{7}$$

The above expression can be used to fit parameters $\boldsymbol{A}_0$, $\boldsymbol{A}_1$, $\boldsymbol{A}_2$, $\boldsymbol{A}_{2+i}$ and λ_i with experimentally identified flutter derivatives.

Karpel suggested another RFA model, namely the Minimum-State model, as follows:

$$\begin{Bmatrix} \hat{\boldsymbol{f}} \\ \boldsymbol{0} \end{Bmatrix} = \begin{bmatrix} \boldsymbol{A}_0 + \boldsymbol{A}_1 s + \boldsymbol{A}_2 s^2 & \boldsymbol{D} \\ -\boldsymbol{E}s & \boldsymbol{R} + \boldsymbol{I}s \end{bmatrix} \begin{Bmatrix} \hat{\boldsymbol{x}} \\ \hat{\boldsymbol{\phi}} \end{Bmatrix} \tag{8}$$

where $\boldsymbol{A}_0$, $\boldsymbol{A}_1$, $\boldsymbol{A}_2$, $\boldsymbol{D}$, $\boldsymbol{E}$ are full parameter matrices; $\boldsymbol{R}$ is a diagonal parameter matrix:

$$\boldsymbol{R} = \begin{bmatrix} \lambda_1 & & \\ & \ddots & \\ & & \lambda_{n_l} \end{bmatrix} \tag{9}$$

By eliminating state variables $\hat{\boldsymbol{\phi}}$ from eqs.(8), transfer matrix of the Minimum-State

model can be obtained:

$$\boldsymbol{T}(s) = \boldsymbol{A}_0 + \boldsymbol{A}_1 s + \boldsymbol{A}_2 s^2 + \boldsymbol{D}(\boldsymbol{R} + \boldsymbol{I}s)^{-1}\boldsymbol{E}s \tag{10}$$

Expression above can be used to determine parameters by nonlinear Least Square.

In time domain, the Minimum-State model can be written as

$$\begin{cases} \boldsymbol{f} = \boldsymbol{A}_0\boldsymbol{x} + \boldsymbol{A}_1\dot{\boldsymbol{x}} + \boldsymbol{A}_2\ddot{\boldsymbol{x}} + \boldsymbol{D}\boldsymbol{\phi} \\ \dot{\boldsymbol{\phi}} = \boldsymbol{E}\dot{\boldsymbol{x}} - \boldsymbol{R}\boldsymbol{\phi} \end{cases} \tag{11}$$

Both of the Roger's model and the Minimum-State model can reproduce aerodynamic memory effect without convolution. As mentioned previously, the Roger's model is based on the assumption that aerodynamic indicial functions can be expressed as power series of e, indicating that indicial functions are monotonically decreasing. However, there is no evidence supporting this assumption for bluff bodies. Our experience shows that, in many cases, the Roger's expression (7) cannot fit bridge deck flutter derivatives very well. The Minimum-State model is superior to the Roger's model since the Minimum-State model has more adjustable parameters than the Roger's model, and therefore can achieve similar fitting precision with less state variables.

It should be noticed that the coefficient matrices of state variables $\widehat{\boldsymbol{\phi}}$ in the augmented equations of both of the two models (see eqs.(6) and (8)) are diagonal, which mean that the coupling effects among state variables cannot be considered. It can also be observed from eqs.(6) and (8) that state variables (or variable groups) of both two models are arranged in parallel. This means that positions of different state variables and corresponding matrices can be exchanged mutually without modifying the input-output behavior of the system. Models with identical transfer matrix can have multiple sets of parameters, making it difficult to compare and interpolate among different models.

3 DISCUSSION ON THE GENERAL FORM OF UNSTEADY AERODYNAMICS

3.1 General equations

The unsteady characteristics of aerodynamic forces are caused by the movement of the surrounding air, which is relatively independent of structure oscillations and cannot be fully observed from the resulting aerodynamic forces. To correctly reproduce unsteady aerodynamic forces, the air movement must be considered simultaneously. The state variables in the Roger's and the Minimum-State RFA can be viewed as some descriptions of the air movement. These variables are governed by additional differential equations and are coupled with structure displacements. It is reasonable to assume a more general aerodynamic system that consists of two sets of differential equations: one to govern the air movement described by state variables, the other to generate output forces, as shown in eqs.(12).

$$\begin{cases} \boldsymbol{f} = \boldsymbol{g}_x(\boldsymbol{x}, \dot{\boldsymbol{x}}, \ddot{\boldsymbol{x}}, \boldsymbol{\phi}, \dot{\boldsymbol{\phi}}) \\ \dot{\boldsymbol{\phi}} = \boldsymbol{g}_\phi(\boldsymbol{x}, \dot{\boldsymbol{x}}, \ddot{\boldsymbol{x}}, \boldsymbol{\phi}) \end{cases} \tag{12}$$

where $\boldsymbol{x}$ = structure displacements; $\boldsymbol{\phi}$ = aerodynamic state variables; $\boldsymbol{f}$ = output forces; $\boldsymbol{g}_\phi$ and $\boldsymbol{g}_x$ = differential expressions. Any linear or nonlinear expressions of $\boldsymbol{g}_\phi$ and $\boldsymbol{g}_x$ that match experimental or CFD observations can be used.

Our discussion will focus on the following linear version of eqs. (12).

$$\begin{cases} \boldsymbol{f} = \boldsymbol{A}_0\boldsymbol{x} + \boldsymbol{A}_1\dot{\boldsymbol{x}} + \boldsymbol{A}_2\ddot{\boldsymbol{x}} + \boldsymbol{R}_0\boldsymbol{\phi} + \boldsymbol{R}_1\dot{\boldsymbol{\phi}} \\ \dot{\boldsymbol{\phi}} = -(\boldsymbol{T}_0\boldsymbol{x} + \boldsymbol{T}_1\dot{\boldsymbol{x}} + \boldsymbol{P}\boldsymbol{\phi}) \end{cases} \tag{13}$$

where $\boldsymbol{A}_0, \boldsymbol{A}_1, \boldsymbol{A}_2, \boldsymbol{R}_0, \boldsymbol{R}_1, \boldsymbol{T}_0, \boldsymbol{T}_1$ and $\boldsymbol{P}$ are frequency-independent parameters matrices.

Laplace transform of eqs.(13) reads

$$\begin{cases} \hat{\boldsymbol{f}} = (\boldsymbol{A}_0 + \boldsymbol{A}_1 s + \boldsymbol{A}_2 s^2)\hat{\boldsymbol{x}} + (\boldsymbol{R}_0 + \boldsymbol{R}_1 s)\hat{\boldsymbol{\phi}} \\ \quad (\boldsymbol{T}_0 + \boldsymbol{T}_1 s)\hat{\boldsymbol{x}} + (\boldsymbol{P} + \boldsymbol{I}s)\hat{\boldsymbol{\phi}} = \boldsymbol{0} \end{cases} \tag{14}$$

From the second equation of (14), we have

$$\hat{\boldsymbol{\phi}} = -(\boldsymbol{P} + \boldsymbol{I}s)^{-1}(\boldsymbol{T}_0 + \boldsymbol{T}_1 s)\hat{\boldsymbol{x}} \tag{15}$$

Substituting eq.(15) into the first equation of (14), one obtains the transfer matrix of (13):

$$\boldsymbol{T}(s) = \boldsymbol{A}_0 + \boldsymbol{A}_1 s + \boldsymbol{A}_2 s^2 - (\boldsymbol{R}_0 + \boldsymbol{R}_1 s)(\boldsymbol{P} + \boldsymbol{I}s)^{-1}(\boldsymbol{T}_0 + \boldsymbol{T}_1 s) \tag{16}$$

Similar to traditional RFA methods, parameters in model (13) can be determined by comparing the transfer matrix (16) to aerodynamic derivatives obtained by wind tunnel tests.

When fitting transfer matrix to frequency-dependent stiffness and damping matrices obtained through experiments, the nominal aerodynamic stiffness matrix $\boldsymbol{K}(s)$ and damping matrix $\boldsymbol{C}(s)$ can be obtained as follows:

$$\boldsymbol{C}(s) = \mathrm{Im}\big(\boldsymbol{T}(s)\big)/\mathrm{Im}(s)\,, \qquad \boldsymbol{K}(s) = \mathrm{Re}\big(\boldsymbol{T}(s)\big) - \mathrm{Re}(s)\boldsymbol{C}(s) \tag{17}$$

where Re(*) and Im(*) = real and imaginary parts of complex quantities, respectively. $\boldsymbol{T}(s)$ can be expressed in nominal stiffness and damping matrices as

$$\boldsymbol{T}(s) = \boldsymbol{K}(s) + \boldsymbol{C}(s)s \tag{18}$$

3.2 Stability Condition

Since state variables $\boldsymbol{\phi}$ are internal Degree of Freedoms (DoFs), the stability of $\boldsymbol{\phi}$ must be studied. Free oscillations of $\boldsymbol{\phi}$ are determined by

$$\boldsymbol{P}\boldsymbol{\phi} + \dot{\boldsymbol{\phi}} = \boldsymbol{0} \tag{19}$$

The complex frequency of free oscillation can be solved from

$$|\boldsymbol{P} + \boldsymbol{I}s| = 0 \tag{20}$$

where

$$s = -\lambda_i^p, \qquad \big(i = 0,1, \ldots n_\phi - 1\big) \tag{21}$$

is the complex frequency; $\boldsymbol{\lambda}^p$ = Eigenvalues of $\boldsymbol{P}$; n_ϕ = number of state variables. To make $\boldsymbol{\phi}$ stable, the real part of s must be negative. Therefore, the following stability condition can be imposed:

$$\mathrm{Re}(\boldsymbol{\lambda}^p) > 0 \tag{22}$$

It can be inferred that the Roger's and Minimum-State models are stable as long as λ_is in (6) and (9) are positive.

3.3 Limit characteristics

When reduced wind velocity approaches infinity, the complex frequency s approaches zero. In such cases, unsteady aerodynamic forces degenerate into Quasi-Static wind forces. This indicates that the unsteady transfer matrix (16) should equal transfer matrix of Quasi-Static model when s approaches zero. This limit characteristic is especially important for super long span bridges whose reduced wind velocities can be very high.

The term $(\boldsymbol{P} + \boldsymbol{I}s)^{-1}$ can be linearized at $s = 0$ through Taylor expansion:

$$(\boldsymbol{P} + \boldsymbol{I}s)^{-1} \approx \boldsymbol{P}^{-1} + \left[\frac{\mathrm{d}(\boldsymbol{P} + \boldsymbol{I}s)^{-1}}{\mathrm{d}s}\right]_{s=0} s = \boldsymbol{P}^{-1} - \boldsymbol{P}^{-1}\boldsymbol{P}^{-1}s \tag{23}$$

where

$$\frac{\mathrm{d}(\boldsymbol{P}+\boldsymbol{I}s)^{-1}}{\mathrm{d}s} = -(\boldsymbol{P}+\boldsymbol{I}s)^{-1}\boldsymbol{I}(\boldsymbol{P}+\boldsymbol{I}s)^{-1} \tag{24}$$

Substitute $(\boldsymbol{P}+\boldsymbol{I}s)^{-1}$ in (23) into (16) and linearize $\boldsymbol{T}(s)$ at $s=0$, the approximated expression of $\boldsymbol{T}(s)$ can be obtained:

$$[\boldsymbol{T}(s)]_{s=0} \approx (\boldsymbol{A}_0 - \boldsymbol{R}_0\boldsymbol{P}^{-1}\boldsymbol{T}_0) + (\boldsymbol{A}_1 - \boldsymbol{R}_1\boldsymbol{P}^{-1}\boldsymbol{T}_0 + \boldsymbol{R}_0\boldsymbol{P}^{-1}\boldsymbol{P}^{-1}\boldsymbol{T}_0 - \boldsymbol{R}_0\boldsymbol{P}^{-1}\boldsymbol{T}_1)s \tag{25}$$

Expressions of nominal aerodynamic stiffness and damping matrices when s approaches zero can be obtained:

$$\boldsymbol{K}_{s0} = \lim_{s\to 0}\boldsymbol{T}(s) = \boldsymbol{A}_0 - \boldsymbol{R}_0\boldsymbol{P}^{-1}\boldsymbol{T}_0 \tag{26}$$

$$\boldsymbol{C}_{s0} = \lim_{s\to 0}\frac{\mathrm{d}\boldsymbol{T}(s)}{\mathrm{d}s} = \boldsymbol{A}_1 - \boldsymbol{R}_1\boldsymbol{P}^{-1}\boldsymbol{T}_0 + \boldsymbol{R}_0\boldsymbol{P}^{-1}(\boldsymbol{P}^{-1}\boldsymbol{T}_0 - \boldsymbol{T}_1) \tag{27}$$

where $\boldsymbol{K}_{s0}$ and $\boldsymbol{C}_{s0}$ = Quasi-Static limit aerodynamic stiffness and damping matrices, respectively. To ensure model correctness in both ordinary and high reduced wind velocity ranges, the transfer matrix $\boldsymbol{T}(s)$ and the limit stiffness and damping matrices $\boldsymbol{K}_{s0}$ and $\boldsymbol{C}_{s0}$ should be fitted simultaneously.

4 A NEW AERODYNAMIC MODEL: THE CASCADE MODEL

Here, we propose a new unsteady aerodynamic model which has unique parameters theoretically. The new model also considers interactions among different aerodynamic state variables by adding off-diagonal entries to matrix $\boldsymbol{P}$; thus, it can model more complicated aerodynamic behaviors of bluff bodies.

4.1 Differential equations

In the new model, the unsteady part of an aerodynamic force component is represented by a state variable:

$$\boldsymbol{f} = \boldsymbol{A}_0\boldsymbol{x} + \boldsymbol{A}_1\dot{\boldsymbol{x}} + \boldsymbol{A}_2\ddot{\boldsymbol{x}} + \boldsymbol{\phi}_0 \tag{28}$$

where $\boldsymbol{x}$ = input displacements (or wind fluctuations for buffeting forces); $\boldsymbol{f}$ = output aerodynamic forces; $\boldsymbol{\phi}_0$ = state variables representing unsteady components of $\boldsymbol{f}$; $\boldsymbol{A}_0$, $\boldsymbol{A}_1$and $\boldsymbol{A}_2$ = aerodynamic stiffness, damping and mass matrices which generate steady parts of $\boldsymbol{f}$. We assume that the evolution of $\boldsymbol{\phi}_0$ does not only depend on inputs $\boldsymbol{x}$, but also depend on another set of state variables, namely $\boldsymbol{\phi}_1$. So the governing differential equations of $\boldsymbol{\phi}_0$ can be written as

$$\dot{\boldsymbol{\phi}}_0 = -(\boldsymbol{C}_0\dot{\boldsymbol{x}} + \boldsymbol{B}_0\boldsymbol{\phi}_0 + \boldsymbol{\phi}_1) \tag{29}$$

where $\boldsymbol{C}_0, \boldsymbol{B}_0$ = parameters matrices to be determined.

Analogously, the governing differential equations of $\boldsymbol{\phi}_1$ can be written as

$$\dot{\boldsymbol{\phi}}_1 = -(\boldsymbol{C}_1\dot{\boldsymbol{x}} + \boldsymbol{B}_1\boldsymbol{\phi}_1 + \boldsymbol{\phi}_2) \tag{30}$$

…

The above procedure will eventually lead to the following differential equations:

$$\begin{cases} \boldsymbol{f} = \boldsymbol{A}_0\boldsymbol{x} + \boldsymbol{A}_1\dot{\boldsymbol{x}} + \boldsymbol{A}_2\ddot{\boldsymbol{x}} + \boldsymbol{\phi}_0 \\ \dot{\boldsymbol{\phi}}_0 = -(\boldsymbol{C}_0\dot{\boldsymbol{x}} + \boldsymbol{B}_0\boldsymbol{\phi}_0 + \boldsymbol{\phi}_1) \\ \vdots \\ \dot{\boldsymbol{\phi}}_{n-2} = -(\boldsymbol{C}_{n-2}\dot{\boldsymbol{x}} + \boldsymbol{B}_{n-2}\boldsymbol{\phi}_{n-2} + \boldsymbol{\phi}_{n-1}) \\ \dot{\boldsymbol{\phi}}_{n-1} = -(\boldsymbol{C}_{n-1}\dot{\boldsymbol{x}} + \boldsymbol{B}_{n-1}\boldsymbol{\phi}_{n-1}) \end{cases} \tag{31}$$

where n = number of rational terms; $\boldsymbol{A}_j, \boldsymbol{C}_i, \boldsymbol{B}_i (j = 0,1,2;\ i = 0,1,\dots n-1)$ are parameter matrices which can be determined by model fitting. It can be observed from eq.(31) that the

evolution of $\boldsymbol{\phi}_{n-1}$ depends on inputs $\boldsymbol{x}$, and the evolution of $\boldsymbol{\phi}_i$(i=0,2,…n-2) depends on both $\boldsymbol{x}$ and $\boldsymbol{\phi}_{i+1}$. Each set of state variables $\boldsymbol{\phi}_i$ can be understood as an unsteady correction term to the governing differential equations of *parent variables*. Here, the *parent variables* refer to the lower set of state variables, i.e. $\boldsymbol{\phi}_{i-1}$,or the outputs $\boldsymbol{f}$. Because state variable sets are arranged in series, we call new model the Cascade model.

4.2 Transfer matrix

Laplace transform of eqs.(31) can be written as

$$\begin{Bmatrix} \hat{\boldsymbol{f}} \\ \boldsymbol{0} \\ \boldsymbol{0} \\ \vdots \\ \boldsymbol{0} \\ \boldsymbol{0} \end{Bmatrix} = \begin{bmatrix} \boldsymbol{A}_0 + \boldsymbol{A}_1 s + \boldsymbol{A}_2 s^2 & \boldsymbol{I} & \boldsymbol{0} & \boldsymbol{0} & \dots & \boldsymbol{0} \\ \boldsymbol{C}_0 s & \boldsymbol{B}_0 + \boldsymbol{I}s & \boldsymbol{I} & \boldsymbol{0} & \dots & \boldsymbol{0} \\ \boldsymbol{C}_1 s & \boldsymbol{0} & \boldsymbol{B}_1 + \boldsymbol{I}s & \boldsymbol{I} & \dots & \boldsymbol{0} \\ \vdots & \vdots & \vdots & \vdots & \ddots & \vdots \\ \boldsymbol{C}_{n-2} s & \boldsymbol{0} & \boldsymbol{0} & \boldsymbol{0} & \dots & \boldsymbol{I} \\ \boldsymbol{C}_{n-1} s & \boldsymbol{0} & \boldsymbol{0} & \boldsymbol{0} & \dots & \boldsymbol{B}_{n-1} + \boldsymbol{I}s \end{bmatrix} \begin{Bmatrix} \hat{\boldsymbol{x}} \\ \hat{\boldsymbol{\phi}}_0 \\ \hat{\boldsymbol{\phi}}_1 \\ \hat{\boldsymbol{\phi}}_2 \\ \vdots \\ \hat{\boldsymbol{\phi}}_{n-1} \end{Bmatrix} \tag{32}$$

The expression of $\hat{\boldsymbol{\phi}}_{n-1}$ can be obtained from the nth equation of eqs.(32):

$$\hat{\boldsymbol{\phi}}_{n-1} = -(\boldsymbol{B}_{n-1} + \boldsymbol{I}s)^{-1} \boldsymbol{C}_{n-1} s \hat{\boldsymbol{x}} \tag{33}$$

The recursive equation of $\hat{\boldsymbol{\phi}}_i$(i=0,1,…n-2) can be obtained from the $(i+1)$th equation of eqs. (32):

$$\hat{\boldsymbol{\phi}}_i = (\boldsymbol{B}_i + \boldsymbol{I}s)^{-1} \left(-\boldsymbol{C}_i s \hat{\boldsymbol{x}} - \hat{\boldsymbol{\phi}}_{i+1} \right) \tag{34}$$

Based on eq.(33) and the recurrence relation (34), $\hat{\boldsymbol{\phi}}_k$ can be written as follows:

$$\hat{\boldsymbol{\phi}}_k = \sum_{i=k}^{n-1} \left((-1)^{k-i-1} \left[\prod_{j=i}^{k} \left(\boldsymbol{B}_j + \boldsymbol{I}s \right) \right]^{-1} \boldsymbol{C}_i s \right) \hat{\boldsymbol{x}}, \qquad (k = 0,1, \dots, n-1) \tag{35}$$

Notice that eq.(35) is computationally inefficient since each summation term contains a matrix inversion, which can be extracted outside of the summation symbol as follows:

$$\hat{\boldsymbol{\phi}}_k = \boldsymbol{\Omega}_k^{-1} \left[\sum_{i=k}^{n-2} \left((-1)^{k-i-1} \boldsymbol{\Omega}_{i+1} \boldsymbol{C}_i s \right) + (-1)^{n-k} \boldsymbol{C}_{n-1} s \right] \hat{\boldsymbol{x}}, \qquad (k = 0,1, \dots, n-1) \tag{36}$$

where

$$\boldsymbol{\Omega}_i = \prod_{j=n-1}^{i} \left(\boldsymbol{B}_j + \boldsymbol{I}s \right), \qquad (i = 0,1, \dots, n-1) \tag{37}$$

Substitute the expression of $\hat{\boldsymbol{\phi}}_0$ in (36) into the first equation of (32), one obtains the transfer matrix of the Cascade model:

$$\boldsymbol{T}(s) = \boldsymbol{A}_0 + \boldsymbol{A}_1 s + \boldsymbol{A}_2 s^2 + \boldsymbol{\Omega}_0^{-1} \left[\sum_{i=0}^{n-2} \left((-1)^{i+1} \boldsymbol{\Omega}_{i+1} \boldsymbol{C}_i s \right) + (-1)^n \boldsymbol{C}_{n-1} s \right] \tag{38}$$

It should be noted that transfer matrix $\boldsymbol{T}(s)$ can also be computed by eq.(16); however, eq.(38) is computationally more efficient.

4.3 Quasi-Static limit characteristics

According to eqs. (26) and (27), the Quasi-Static limit stiffness and damping matrices of the Cascade model can be written as

$$\boldsymbol{K}_{s0} = \lim_{s\to 0} \boldsymbol{T}(s) = \boldsymbol{A}_0, \qquad \boldsymbol{C}_{s0} = \lim_{s\to 0} \frac{\mathrm{d}\boldsymbol{T}(s)}{\mathrm{d}s} = \boldsymbol{A}_1 - \boldsymbol{R}_0\boldsymbol{P}^{-1}\boldsymbol{T}_1 \tag{39}$$

where

$$\boldsymbol{T}_1 = \begin{bmatrix} \boldsymbol{C}_0 s \\ \vdots \\ \boldsymbol{C}_{n-1} s \end{bmatrix}, \qquad \boldsymbol{P} = \begin{bmatrix} \boldsymbol{B}_0 & \boldsymbol{I} & \boldsymbol{0} & \dots & \boldsymbol{0} \\ \boldsymbol{0} & \boldsymbol{B}_1 & \boldsymbol{I} & \dots & \boldsymbol{0} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ \boldsymbol{0} & \boldsymbol{0} & \boldsymbol{0} & \dots & \boldsymbol{I} \\ \boldsymbol{0} & \boldsymbol{0} & \boldsymbol{0} & \dots & \boldsymbol{B}_{n-1} \end{bmatrix}, \qquad \boldsymbol{R}_0 = \left[\underbrace{\boldsymbol{I} \quad \boldsymbol{0} \quad \dots \quad \boldsymbol{0}}_{n}\right] \tag{40}$$

By using the blockwise inversion technique, $\boldsymbol{P}^{-1}$ can be divided into $n \times n$ blocks, each of which can be computed as follows:

$$\boldsymbol{P}^{-1}[i,j] = \begin{cases} (-1)^{j-i} \prod_{r=i}^{j} \boldsymbol{B}_{n-r}^{-1} & (i \le j) \\ \boldsymbol{0} & (i > j) \end{cases}, \qquad (i,j = 0,1,\dots,n-1) \tag{41}$$

4.4 Stability

According to stability condition (22), all real parts of Eigenvalues of $\boldsymbol{P}$ must be positive to make the Cascade model stable. For $\boldsymbol{P}$ shown in (40), this condition can be converted into more efficient ones as follows:

$$\mathrm{Re}(\boldsymbol{\lambda}^{\boldsymbol{B}_i}) > 0, \qquad (i = 0,1,\dots,n-1) \tag{42}$$

where $\boldsymbol{\lambda}^{\boldsymbol{B}_i}$ are Eigenvalues of $\boldsymbol{B}_i$.

4.5 Parameter uniqueness

With transfer matrix expression (38), the Laplace transform of outputs $\boldsymbol{f}$ can be expressed as:

$$\hat{\boldsymbol{f}} = \left\{\boldsymbol{A}_0 + \boldsymbol{A}_1 s + \boldsymbol{A}_2 s^2 + \boldsymbol{\Omega}_0^{-1}\left[\sum_{i=0}^{n-2}\left((-1)^{i+1}\boldsymbol{\Omega}_{i+1}\boldsymbol{C}_i s\right) + (-1)^n \boldsymbol{C}_{n-1} s\right]\right\}\hat{\boldsymbol{x}} \tag{43}$$

Left multiplying $\boldsymbol{\Omega}_0$ on both sides of eq.(43), one obtains

$$\boldsymbol{\Omega}_0\hat{\boldsymbol{f}} = \left\{\boldsymbol{\Omega}_0(\boldsymbol{A}_0 + \boldsymbol{A}_1 s + \boldsymbol{A}_2 s^2) + \sum_{i=0}^{n-2}\left((-1)^{i+1}\boldsymbol{\Omega}_{i+1}\boldsymbol{C}_i s\right) + (-1)^n \boldsymbol{C}_{n-1} s\right\}\hat{\boldsymbol{x}} \tag{44}$$

Notice that $\boldsymbol{\Omega}_0$ defined in eq.(37) can be expanded into a matrix polynomial which has the following form:

$$\boldsymbol{\Omega}_0 = \boldsymbol{H}_0 + \boldsymbol{H}_1 s + \cdots + \boldsymbol{H}_{n-1} s^{n-1} + \boldsymbol{I} s^n \tag{45}$$

Also notice that the coefficient matrix of $\hat{\boldsymbol{x}}$ on the right side of eq.(44) can be expanded into a $n+2$ degree polynomial. Therefore, eq. (44) can be expanded into the following form:

$$(\boldsymbol{H}_0 + \boldsymbol{H}_1 s + \cdots + \boldsymbol{H}_{n-1} s^{n-1} + \boldsymbol{I} s^n)\hat{\boldsymbol{f}} = (\boldsymbol{G}_0 + \boldsymbol{G}_1 s + \cdots + \boldsymbol{G}_{n+2} s^{n+2})\hat{\boldsymbol{x}} \tag{46}$$

where $\boldsymbol{H}_i$ and $\boldsymbol{G}_i$ = matrices resulting from polynomial expansion; $\boldsymbol{H}_i$ = $n_f \times n_f$ matrix; $\boldsymbol{G}_i$ = $n_f \times n_x$ matrix; n_f and n_x = sizes of $\boldsymbol{f}$ and $\boldsymbol{x}$, respectively.

Eq. (46) can be written in time domain as

$$\boldsymbol{f}^{(n)} = \boldsymbol{G}_0\boldsymbol{x} + \boldsymbol{G}_1\dot{\boldsymbol{x}} + \cdots + \boldsymbol{G}_{n+2}\boldsymbol{x}^{(n+2)} - \boldsymbol{H}_0\boldsymbol{f} - \boldsymbol{H}_1\dot{\boldsymbol{f}} - \cdots - \boldsymbol{H}_{n-1}\boldsymbol{f}^{(n-1)} \tag{47}$$

It should be noticed that both eq.(47) and eq.(43) contain $n_f n_f n + n_f n_x(n+3)$ entries in all matrices, indicating that the conversion from eq.(43) to eq. (47) are reversible. It is obvious that different parameters of eq. (47) or (46) will lead to different input-output (or transfer) characteristics. Thus, it can also be concluded that parameters of the Cascade model

are unique.

5 FITTING THE CASCADE MODEL

Matrices $\boldsymbol{A}_0, \boldsymbol{A}_1, \boldsymbol{A}_2, \boldsymbol{C}_0, \boldsymbol{C}_1, \ldots \boldsymbol{C}_{n-1}, \boldsymbol{B}_0, \boldsymbol{B}_1, \ldots, \boldsymbol{B}_{n-1}$ in the Cascade Model can be determined by fitting the transfer matrix (38) and Quasi-Static limit stiffness and damping matrices (39) under the stability constraint (42) by nonlinear Least-Square (LS). We used the Levenberg-Marquardt (LM) algorithm[7] to solve the nonlinear LS problem. LM algorithm requires derivative of each fitting function with respect to each parameter. To obtain these derivatives, we developed a symbolic computation program to deduce derivatives automatically based on the Automatic Differentiation (AD) technique[8]. The AD technique is based on the fact that any algebraic expressions is composed of elementary operations and can be differentiated by successively application of Chain Rule. LM algorithm only searches local-optimal parameters. To ensure a reasonable global-optimal solution, we recommend that several sets of randomly generated initial values should be used.

To examine the model fitting procedure, we fitted the Cascade model against the dimensionless Theodorsen aerodynamic model[9] , which is shown in eq.(48).

$$\begin{Bmatrix} \frac{L}{\rho U^2 B} \\ \frac{M}{\rho U^2 B^2} \end{Bmatrix} = \begin{bmatrix} \pi\left(Gk + \frac{k^2}{4}\right) & \pi\left(\frac{Gk}{4} - F\right) \\ -\frac{\pi}{4}Gk & -\frac{\pi}{4}\left(\frac{Gk}{4} - \frac{k^2}{32} - F\right) \end{bmatrix} \begin{Bmatrix} \frac{h}{B} \\ \alpha \end{Bmatrix} + \begin{bmatrix} -\pi F & -\pi\left(\frac{G}{k} + \frac{1}{4} + \frac{F}{4}\right) \\ \frac{\pi}{4}F & \frac{\pi}{4}\left(\frac{G}{k} - \frac{1}{4} + \frac{F}{4}\right) \end{bmatrix} \begin{Bmatrix} \frac{\dot{h}}{U} \\ \frac{B\dot{\alpha}}{U} \end{Bmatrix} \tag{48}$$

where $k = \omega B/U$ is the dimensionless circular frequency; B = chord length; L = lift force; M = moment force; h = vertical displacement; α = torsional angle; ρ = air density; U = wind velocity; $C(k) = F(k) + iG(k)$ is the frequency-dependent Theodorsen circulation function.

The Cascade model can fit Theodorsen equations accurately with only one rational term, which has 2 state variables. The results are shown in Figure 1. In comparison, the Roger's RFA requires 2 rational terms, which has 4 state variables.

6 BRIDGE DECK SELF-EXCITED FORCES

6.1 Model fitting

In this section, both of flutter derivatives and static coefficients of a bridge deck obtained from section model wind tunnel tests are used to fit the suggested Cascade model. Transfer

matrix of the Cascade model is fitted against following dimensionless unsteady self-excited model expressed in flutter derivatives:

$$\begin{Bmatrix} \frac{L_{se}}{\rho U^2 B} \\ \frac{M_{se}}{\rho U^2 B^2} \end{Bmatrix} = \underbrace{\begin{bmatrix} k^2 H_4^* & k^2 H_3^* \\ k^2 A_4^* & k^2 A_3^* \end{bmatrix}}_{\text{stiffness matrix}} \begin{Bmatrix} \frac{h}{B} \\ \alpha \end{Bmatrix} + \underbrace{\begin{bmatrix} kH_1^* & kH_2^* \\ kA_1^* & kA_2^* \end{bmatrix}}_{\text{damping matrix}} \begin{Bmatrix} \frac{\dot{h}}{U} \\ \frac{B\dot{\alpha}}{U} \end{Bmatrix} \tag{49}$$

where $k = \omega B/U$. flutter derivatives A_i^* and H_i^* are obtained by free vibration tests at 0° Angle of Attack (AoA). They are displayed in Figure 2. In order to increase the number of available flutter derivatives data points, experimentally obtained flutter derivatives are interpolated by Akima interpolation, the interpolation results are shown in Figure 2. Expressions of unsteady nominal stiffness and damping matrices of the Cascade model are obtained using eqs. (17) based on transfer matrix expression (38).

Quasi-Static limit stiffness and damping matrices of the Cascade model are fitted by the following Quasi-Static model which is expressed in static coefficients and their derivatives:

$$\begin{Bmatrix} \frac{L}{\rho U^2 B} \\ \frac{M}{\rho U^2 B^2} \end{Bmatrix} = \underbrace{\frac{1}{2}\begin{bmatrix} 0 & -C_L'(\theta) \\ 0 & C_M'(\theta) \end{bmatrix}}_{\text{stiffness matrix}} \begin{Bmatrix} \frac{h}{B} \\ \alpha \end{Bmatrix} + \underbrace{\frac{1}{2}\begin{bmatrix} -\frac{\mathrm{H}}{\mathrm{B}} C_D(\theta) - C_L'(\theta) & m\frac{\mathrm{H}}{\mathrm{B}} C_D(\theta) + mC_L'(\theta) \\ C_M'(\theta) & -mC_M'(\theta) \end{bmatrix}}_{\text{damping matrix}} \begin{Bmatrix} \frac{\dot{h}}{U} \\ \frac{B\dot{\alpha}}{U} \end{Bmatrix} \tag{50}$$

where C_D, C_L and C_M = drag, lift and moment coefficients, respectively; m = adjustable parameter related to torsional damping coefficients, here $\mathrm{m} = 2$ is used; H/B = height-width ratio of bridge deck, for the tested deck $H/B = 0.1197$. Static coefficients of the tested bridge deck are shown in Figure 3. Only coefficients' values and derivatives at 0° angle of incidence were used.

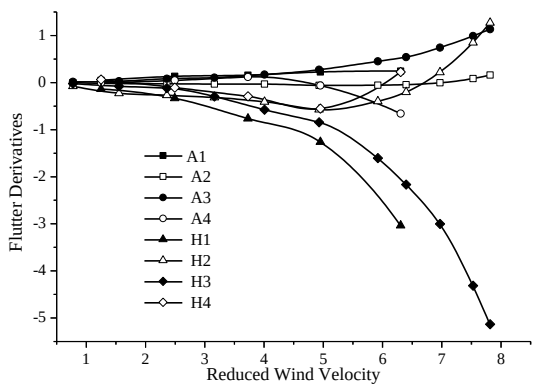

Figure 2. Bridge deck flutter derivatives

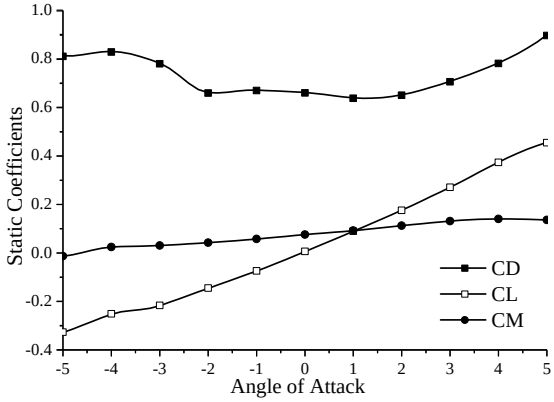

Figure 3. Bridge deck static coefficients

A Cascade model with 4 rational terms is used in fitting. For the 2 DoFs bridge deck system, there are total 8 state variables. Unsteady aerodynamic stiffness and damping matrices and Quasi-Static limit stiffness and damping matrices are fitted simultaneously under the constraint (42). Fitted and target frequency-dependent nominal stiffness and damping matrices are shown in Figure 4. Fitted and target stiffness and damping matrices when reduced wind velocity approaches infinity are shown in Table 1.

	C_{hh}	$C_{h\alpha}$	$C_{\alpha\alpha}$	$C_{\alpha h}$
Target	-0.0808154	0.161631	0.00869667	-0.0173933
Fitted	-0.0810962	0.161729	0.00661546	-0.0187633

6.2 Input-output test

A time history containing dimensionless vertical and torsional displacements is used as the input of the fitted Cascade model. The output of the fitted model is compared with the result of traditional frequency-domain analysis which uses flutter derivatives directly.

The input time history consists of a single frequency vibration segment and two zero segments on double ends, as shown in Figure 5. The dimensionless circular frequency of input is 0.3. The phase angle between torsional and vertical displacements is $\mathrm{PI}/2$. To make transitions between zero and non-zero segment smooth, a Turkey window is added to the non-zero segment of the input time history.

Dimensionless self-excited forces caused by the input oscillations are computed in time domain using the fitted Cascade model, and in frequency domain using flutter derivatives for comparison. The 4th order Runge-Kunta method is used in time domain analysis, results of which are shown in Figure 6. The frequency domain analysis is conducted using frequency-response method based on FFT and frequency-response matrix computed from flutter derivatives. Results of frequency-domain analysis are displayed in Figure 7. It can be seem that the output self-excited forces obtained by two approaches are similar.

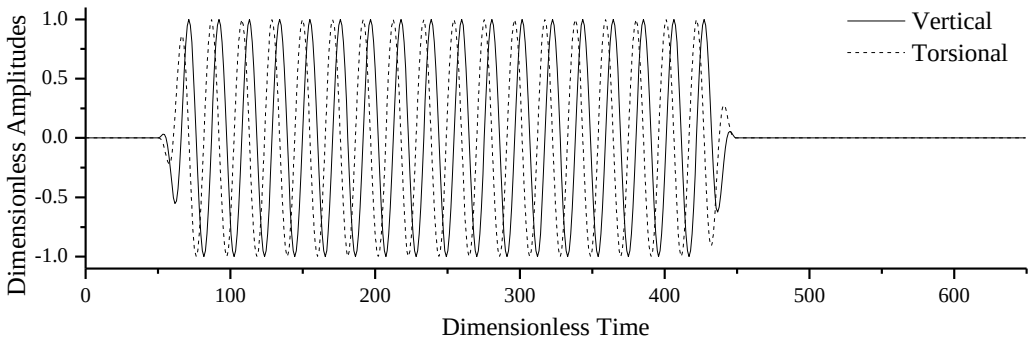

Figure 5. Input time history of vertical and torsional displacements.

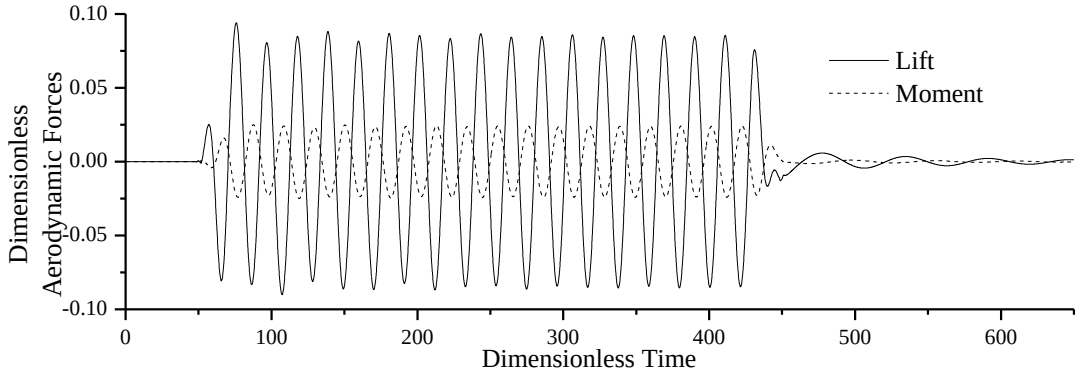

Figure 6. Self-excited forces computed by the fitted Cascade model in time domain

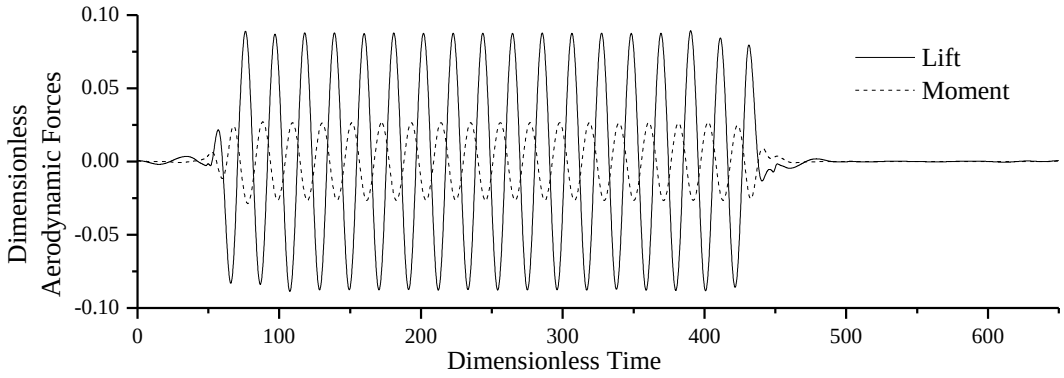

Figure 7. Self-excited forces computed by frequency-domain analysis using flutter derivatives

6.3 Conslusions

It can be seen from Figure 4 that the suggested Cascade model can well fit frequency-dependent aerodynamic stiffness and damping matrices of the tested bridge deck. At the same time, the fitted model approaches the Quasi-Static model when reduced wind velocity approaches infinity, as shown in Table 1. The input-output test showed that there are some differences between the outputs of the fitted model and outputs of frequency analysis based on flutter derivatives. This can be explained as follows: since the model fitting is conducted in a finite frequency range, transfer matrix of the fitted model outside of the frequency range cannot be constrained. The differences are caused by the unconstrained region of the transfer matrix.

ABSTRACT: A frequency domain approach, which is based on the Volterra series expansion, for non-linear bridge aerodynamics is proposed in this paper. The Volterra frequency-response functions (VFRFs) are constructed utilizing the topological assemblage scheme and identified through a full-time-domain non-linear bridge aerodynamic analysis framework. A two-dimensional numerical example of a long-span bridge is presented. The results show good comparison between the time domain simulations and the proposed frequency-domain model for non-linear bridge aerodynamics.

KEYWORDS: Non-linearity; Bridge; Buffeting; Flutter; Volterra series

1 INTRODUCTION

Wind-induced forces on bridges are traditionally represented as the sum of buffeting forces, related to the incoming wind velocity fluctuation, and the self-excited forces, generated by the bridge motion. Both these forces are modelled by linear operators (with memory) whose Frequency Response Functions (FRF) are estimated through specific wind-tunnel tests. On the other hand, when a fluid-structure interaction problem is characterized by high reduced velocity (i.e. the structure time scale is much slower than the fluid time scale) the quasi-steady assumption is invoked and the wind action is represented as a non-linear memory-less transformation of the incoming wind velocity and structural motion, which are often combined in the so-called effective angle of attack. Several experimental experiences suggest that, in some cases, both the mentioned approaches may be inadequate due to the simultaneous presence of both significant nonlinearities and memory effects.

With a specific reference to the case of long-span bridges, some attempts to fill this gap have been made adopting a band-superposition approach in which the quasi-steady model is used to represent the low-frequency part of the forces, while the high-frequency part (both buffeting and self-excited) is modelled through the usual linear models with memory, whose parameters are updated according to the instantaneous low-frequency effective angle of attack [1]. Following this formulation, the high-frequency response is provided by a differential equation whose parameters depend on both time and frequency.

To solve this problem with more efficient computational procedures, Chen & Kareem [2] transformed the problem into a full-time-domain formulation by means of a rational-function approximation and solved the equations of motion in the time domain through an integrate state-space approach. This solution, though mathematically rigorous, consists essentially of a calculation procedure and not a model, thus does not assist in the qualitative assessment of the problem.

In order to circumvent the limitations of the two above approaches, the concept of harmonic-band superposition is revised proposing a full-frequency-domain approach based on the Volterra series expansion of the dynamical systems representing both buffeting and self-excited forces. To this purpose, the governing equations (e.g. [2]) are re-casted into a block-diagram format (Fig. 2) invoking, whenever necessary, polynomial approximations. The synthesis of the result-

ing Volterra system (up to the 3rd order) is carried out adopting the topological assemblage scheme proposed in [3] for scalar systems and generalized in [4] to the case of multi-variate systems.

Section 2 provides some background on Volterra series, with particular reference to its multi-variate form [4]; Section 3 describes the non-linear aeroelastic bridge model assumed as reference; Section 4 shows the synthesis of its Volterra series approximation; Section 5 shows its numerical application for the dynamic analysis of a long-span bridge.

2 VOLTERRA SERIES: THEORETICAL BACKGROUND

Let us consider the nonlinear system represented by the following equation:

$$\mathbf{x}(t) = \mathscr{H}\left[\mathbf{u}(t)\right] \tag{1}$$

$\mathbf{u}(t)$ and $\mathbf{x}(t)$ being vectors with size n and m, respectively, representing the input and the output; t is the time. If the operator $\mathscr{H}[\bullet]$ is time-invariant and has finite-memory, its output $\mathbf{x}(t)$ can be expressed, far enough from the initial conditions, through the Volterra series expansion [e.g. 3, 4]:

$$\mathbf{x}(t) = \sum_{j=0}^{\infty} \int_{\boldsymbol{\tau}_j \in \mathbb{R}^j} \mathbf{h}_j\left(\boldsymbol{\tau}_j\right) \prod_{r=1}^{j} \mathbf{u}\left(t-\tau_r\right) \mathrm{d}\boldsymbol{\tau}_j \tag{2}$$

where $\boldsymbol{\tau}_j = [\tau_1 \ldots \tau_j]^{\mathrm{T}}$ is a vector containing the j integration variables; the functions $\mathbf{h}_j$ have values in $\mathbb{R}^{m \times n^j}$ and are called Volterra kernels. The product operator is interpreted as a sequence of Kronecker products, i.e.:

$$\prod_{r=1}^{j} \mathbf{u}\left(t-\tau_r\right) = \mathbf{u}\left(t-\tau_1\right) \otimes \cdots \otimes \mathbf{u}\left(t-\tau_j\right) \tag{3}$$

The 0th-order term of the Volterra series, $\mathbf{h}_0$, is a constant independent of the input; the 1st-order term is the convolution integral typical of the linear dynamical systems, with $\mathbf{h}_1$ being the impulse response function. The higher-order terms are multiple convolutions involving products of the input values for different time delays.

A Volterra system is entirely determined by its constant output and its Volterra kernels. An alternative representation is provided, in the frequency domain, by the Volterra frequency-response functions (VFRF), the multi-dimensional Fourier transforms of the Volterra kernels:

$$\mathbf{H}_j\left(\boldsymbol{\Omega}_j\right) = \int_{\boldsymbol{\tau}_j \in \mathbb{R}^j} \mathrm{e}^{-\mathrm{i}\boldsymbol{\Omega}_j^{\mathrm{T}}\boldsymbol{\tau}_j} \mathbf{h}_j\left(\boldsymbol{\tau}_j\right) \mathrm{d}\boldsymbol{\tau}_j \tag{4}$$

where $\boldsymbol{\Omega}_j = [\omega_1 \ldots \omega_j]^{\mathrm{T}}$ is a vector containing the j circular frequency values corresponding to $\tau_1, \ldots, \tau_j$ in the Fourier transform pair. The VFRFs are functions with values in $\mathbb{C}^{m \times n^j}$.

3 NON-LINEAR AEROELASTIC BRIDGE MODEL

In this section the non-linear model for the calculation of the aeroelastic response of bridges described in [2] is briefly recalled. For simplicity, the original model is reduced disregarding the effect of the longitudinal turbulence and of the sway degree of freedom; besides, the aerodynamic load is applied to the bridge deck according to the strip theory. These quite strict hypotheses

could be easily relaxed and are here adopted only because the added formal complexity introduced by a more sophisticated bridge model may hide the conceptual structure of the proposed technique. According to this formulation, the dynamic response of the bridge is provided by the differential equation:

$$\mathbf{M}\ddot{\mathbf{x}}+\mathbf{C}\dot{\mathbf{x}}+\mathbf{K}\mathbf{x}=\mathbf{f}_L+\mathbf{f}_H+\mathbf{f}_{se} \tag{5}$$

where $\mathbf{x} = [h, \alpha]^T$ is the displacement vector containing the heave displacement h (positive downwards) and the torsional rotation α (positive nose up), as shown in Fig. 1; the response $\mathbf{x}$ is divided into a low-frequency component $\mathbf{x}_L = [h_L, \alpha_L]^T$ and a high-frequency component $\mathbf{x}_H = [h_H, \alpha_H]^T$, separated by the frequency n_c. $\mathbf{M}$, $\mathbf{C}$ and $\mathbf{K}$ are the mass, viscous damping and stiffness matrixes, respectively; $\mathbf{f}_L$, $\mathbf{f}_H$ and $\mathbf{f}_{se}$ are, respectively, the low-frequency force modeled through a quasi-steady non-linear approach, the high-frequency buffeting force and the self-excited force.

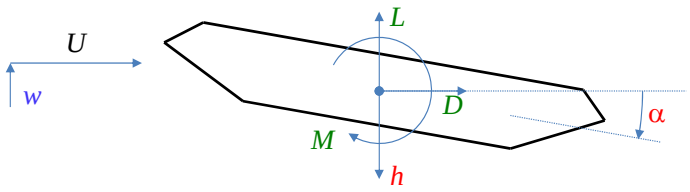

Figure 1. Bridge deck, incoming wind velocity, generalized forces and displacements.

The low-frequency force is defined as:

$$\mathbf{f}_L=\begin{bmatrix}-L\\ M\end{bmatrix}=\frac{1}{2}\rho B l V_r^2\mathbf{R}(\phi)\mathbf{C}(\alpha_e) \tag{6}$$

where ρ is the air density, B the deck width, l the length of the strip on which the load is applied, V_r is the wind-structure relative velocity expressed as:

$$V_r^2=U^2+\left(w_L+\dot{h}_L+m_1 B\dot{\alpha}_L\right)^2 \tag{7}$$

where U is the mean wind velocity, w_L is the low-frequency vertical turbulence (i.e. the vertical turbulence, w, low-pass filtered at the frequency $n = n_c$); $m_1 B$ is the leg for the reduction of the apparent velocity field generated by the torsional velocity; $\mathbf{R}$ is a rotation matrix defined as

$$\mathbf{R}(\phi)=\begin{bmatrix}-\sin\phi & \cos\phi & 0\\ 0 & 0 & 1\end{bmatrix} \tag{8}$$

where ϕ is the apparent (low-frequency) wind angle

$$\phi=\arctan\left(\frac{w_L+\dot{h}_L+m_1 B\dot{\alpha}_L}{U}\right) \tag{9}$$

The vector $\mathbf{C} = [C_D, -C_L, BC_M]^T$ contains the aerodynamic static coefficients, estimated for the effective angle of attack $\alpha_e = \phi + \alpha_L$ through static wind tunnel tests.

The high-frequency buffeting force is modeled as:

$$\mathbf{f}_H = \frac{1}{2}\rho U B l \mathcal{B}\left[w_H;\alpha_e\right] \tag{10}$$

Where w_H is the high-frequency vertical turbulence (i.e. w high-pass filtered at $n = n_c$) and $\mathcal{B}$ is a linear operator whose Frequency-Response Function (FRF) depends of the low-frequency response through the effective angle of attack α_e and is expressed as

$$\mathbf{B}(\omega;\alpha_e) = \begin{bmatrix} -C_D(\alpha_e) - C_L'(\alpha_e) & 0 \\ 0 & C_M'(\alpha_e) \end{bmatrix} \begin{bmatrix} \chi_{wL}(\omega;\alpha_e) \\ \chi_{wM}(\omega;\alpha_e) \end{bmatrix} \tag{11}$$

where C_L' and C_M' are the prime derivatives of C_L and C_M, respectively; χ_{wL} and χ_{wM} are the admittance functions weighting the effect of the vertical turbulence on the lift force and torsional moment, respectively; $\omega = 2\pi n$ is the circular frequency. Since α_e is variable in time due to w_L and $\mathbf{x}_L$, the operator $\mathcal{B}$ may be interpreted as a time-variant linear operator.

The self-excited forces are defined through the model:

$$\mathbf{f}_{se} = \frac{1}{2}\rho B^2 l \mathcal{A}\left[\mathbf{x}_H;\alpha_e\right] \tag{12}$$

where $\mathcal{A}$ is a linear operator whose FRF depends on α_e and is defined as

$$\mathbf{A}(\omega;\alpha_e) = \omega^2 \begin{bmatrix} H_4^*(k;\alpha_e) + \mathrm{i}\,\omega H_1^*(k;\alpha_e) & B\left(H_3^*(k;\alpha_e) + \mathrm{i}\,\omega H_2^*(k;\alpha_e)\right) \\ B\left(A_4^*(k;\alpha_e) + \mathrm{i}\,\omega A_1^*(k;\alpha_e)\right) & B^2\left(A_3^*(k;\alpha_e) + \mathrm{i}\,\omega A_2^*(k;\alpha_e)\right) \end{bmatrix} \tag{13}$$

where $H_j^*(k, \alpha)$ and $A_j^*(k, \alpha)$ are the flutter derivatives estimated at the reduced frequency $k = \omega B/U$ and for a mean angle of attack corresponding to α_e. Likewise the operator $\mathcal{B}$, also $\mathcal{A}$ is linear, but is time-variant because of the dependency on α_e.

4 SYNTHESIS OF A 3RD-ORDER VOLTERRA SYSTEM

In this section, the model described above is synthesized into a 3rd-order Volterra system whose FRFs are calculated adopting the topological assemblage scheme described in [3, 4]. Figure 2 shows a block diagram of the whole system. The input w is separated into w_L and w_H through the low-pass filter $\mathcal{P}_L$ and the high-pass filters $\mathcal{P}_H$, whose FRFs are $P_L(\omega)$ and $P_H(\omega)$, respectively. The output $\mathbf{x}$ is generated by the sum $\mathbf{x}_L$ and $\mathbf{x}_H$ obtained, respectively, as the outputs of the low-frequency and high-frequency stages of the system. A channel delivers the effective angle of attack α_e from the low-frequency stage of the system to its high-frequency stage. The rectangular boxes represent operators defined through a constitutive equation; the boxes with rounded corners are operators defined through experimental data; the triangles are gain blocks; $\mathbf{b}_1 = [1\ 0]$; $\mathbf{b}_2 = [1\ m_1 B]$. The operator $\mathcal{D}$ represents the left-hand side of Eq. (5) and its FRF is $\mathbf{D}(\omega) = -\omega^2\mathbf{M} + \mathrm{i}\omega\mathbf{C} + \mathbf{K}$. The operators $\mathcal{A}_j$ and $\mathcal{B}_j$ (j= 0,…,2) are linear operators whose FRFs, $\mathbf{A}_j$ and $\mathbf{B}_j$, are obtained by a polynomial approximation of $\mathbf{A}$ and $\mathbf{B}$ given by Eq. (11) and (13)

$$\mathbf{A}(\omega;\alpha_e) = \sum_{j=0}^{2} \mathbf{A}_j(\omega)\alpha_e^j; \qquad \mathbf{B}(\omega;\alpha_e) = \sum_{j=0}^{2} \mathbf{B}_j(\omega)\alpha_e^j \tag{14}$$

$\mathbf{A}_j$ and $\mathbf{B}_j$ (j = 0,..,2) are the FRFs of the time-invariant linear operators $\mathcal{A}_j$ and $\mathcal{B}_j$ and represented in Figure 2. Let us assume that the low-frequency and the high-frequency stages of the system can be represented by the operators

$$\mathbf{x}_L = \mathscr{L}[w]; \qquad \mathbf{x}_H = \mathscr{H}[w] \tag{15}$$

and assume that they can be expanded into convergent Volterra series, at least for the range of input amplitude relevant for the application.

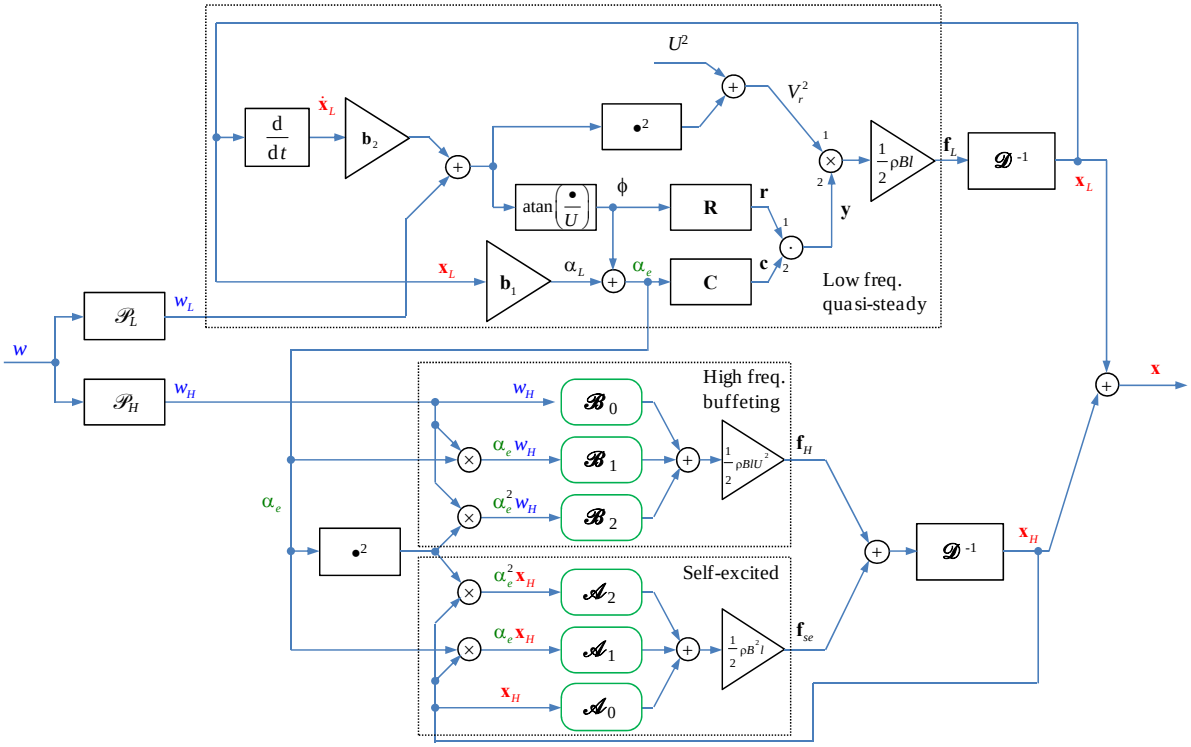

Figure 2. Block diagram of the nonlinear aeroelastic bridge model.

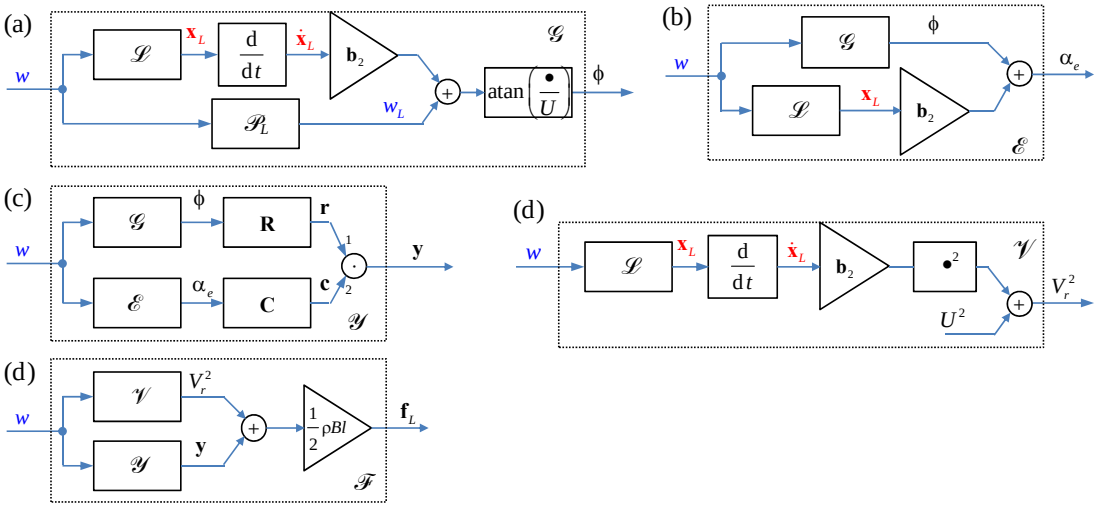

Figure 3. Block diagram of the sub-systems composing the low-frequency stage.

4.1 *Low-frequency stage*

Due to its topology, the identification of the system must start from the synthesis of the components of $\mathscr{L}$. Let $\mathscr{G}$ be the operator providing ϕ given w, described by the block diagram reported in Figure 3a. Its VFRFs G_j can be expressed as the sum of a direct term $G_j^{(d)}$ that does not depends on $\mathbf{L}_j$ and a feedback term $G_j^{(f)}$ that is linear in $\mathbf{L}_j$ [3, 4].

$$
\begin{aligned}
&G_0 = G_2^{(d)} = 0 \\
&G_1^{(d)}(\omega) = \frac{1}{U} P_L(\omega) \\
&G_3^{(d)}(\boldsymbol{\Omega}_3) = -\frac{1}{3U^3}\left[\prod_{r=1}^{3} P_L(\omega_r) + \prod_{r=1}^{3} \mathrm{i}\,\omega_r \mathbf{b}_2 \mathbf{L}(\omega_r)\right] \\
&G_j^{(f)}(\boldsymbol{\Omega}_j) = \frac{1}{U}\mathrm{i}\,\Sigma\boldsymbol{\Omega}_j \mathbf{b}_2 \mathbf{L}_j(\boldsymbol{\Omega}_j) \qquad (j = 1,2,3)
\end{aligned}
\tag{16}
$$

where $\Sigma\boldsymbol{\Omega}_j = \omega_1 + \ldots + \omega_j$. Figure 3b shows the block diagram of the operator $\mathscr{E}$ providing the effective angle of attack α_e. Its VFRFs $E_j = E_j^{(d)} + E_j^{(f)}$ are given as:

$$
\begin{aligned}
&E_0 = \mathbf{b}_1 \mathbf{L}_0 = \alpha_0 \\
&E_j^{(d)}(\boldsymbol{\Omega}_j) = G_j^{(d)}(\boldsymbol{\Omega}_j) \\
&E_j^{(f)}(\boldsymbol{\Omega}_j) = G_j^{(f)}(\boldsymbol{\Omega}_j) + \mathbf{b}_1 \mathbf{L}_j(\boldsymbol{\Omega}_j)
\end{aligned}
\qquad (j = 1,2,3)
\tag{17}
$$

where α_0 is the angle of attack obtained for $w = 0$. Figure 3c shows the block diagram of the operator $\mathscr{Y}$ providing the vector $\mathbf{y} = \mathbf{R}(\phi)\mathbf{C}(\alpha_e)$. The matrix $\mathbf{R}$ and the vector $\mathbf{C}$ are approximated by 3rd-order polynomials of ϕ and α_e, respectively.

$$
\mathbf{R}(\phi) = \sum_{j=1}^{3} \mathbf{R}_j \phi^j; \qquad \mathbf{C}(\alpha_e - \alpha_0) = \sum_{j=1}^{3} \mathbf{C}_j (\alpha_e - \alpha_0)^j
\tag{18}
$$

The VFRFs of $\mathscr{Y}$ are then in the form:

$$
\begin{aligned}
&\mathbf{Y}_0 = \mathbf{R}_0 \mathbf{C}_0 \\
&\mathbf{Y}_1^{(d)}(\omega) = \mathbf{R}_0 \bar{\mathbf{C}}_1^{(d)}(\omega) + \bar{\mathbf{R}}_1^{(d)}(\omega)\mathbf{C}_0 \\
&\mathbf{Y}_2^{(d)}(\boldsymbol{\Omega}_2) = \mathbf{R}_0 \bar{\mathbf{C}}_2^{(d)}(\boldsymbol{\Omega}_2) + \bar{\mathbf{R}}_1(\omega_1)\bar{\mathbf{C}}_1(\omega_2) + \bar{\mathbf{R}}_2^{(d)}(\boldsymbol{\Omega}_2)\mathbf{C}_0 \\
&\mathbf{Y}_3^{(d)}(\boldsymbol{\Omega}_3) = \mathbf{R}_0 \bar{\mathbf{C}}_3^{(d)}(\boldsymbol{\Omega}_3) + \bar{\mathbf{R}}_2(\omega_1,\omega_2)\bar{\mathbf{C}}_1(\omega_3) + \bar{\mathbf{R}}_1(\omega_1)\bar{\mathbf{C}}_2(\omega_2,\omega_3) + \bar{\mathbf{R}}_3^{(d)}(\boldsymbol{\Omega}_3)\mathbf{C}_0 \\
&\mathbf{Y}_j^{(f)}(\boldsymbol{\Omega}_j) = \mathbf{R}_0 \bar{\mathbf{C}}_j^{(f)}(\boldsymbol{\Omega}_j) + \bar{\mathbf{R}}_j^{(f)}(\boldsymbol{\Omega}_j)\mathbf{C}_0 \qquad (j = 1,2,3)
\end{aligned}
\tag{19}
$$

where $\bar{\mathbf{R}}_j = \bar{\mathbf{R}}_j^{(d)} + \bar{\mathbf{R}}_j^{(f)}$ are given as

$$
\begin{aligned}
&\bar{\mathbf{R}}_0 = \mathbf{R}_0 \\
&\bar{\mathbf{R}}_1^{(d)}(\omega) = \mathbf{R}_1 G_1^{(d)}(\omega) \\
&\bar{\mathbf{R}}_2^{(d)}(\boldsymbol{\Omega}_2) = \mathbf{R}_2 G_1(\omega_1) G_1(\omega_2) \\
&\bar{\mathbf{R}}_3^{(d)}(\boldsymbol{\Omega}_3) = \mathbf{R}_1 G_3^{(d)}(\boldsymbol{\Omega}_3) + 2\mathbf{R}_2 G_1(\omega_1) G_2(\omega_2, \omega_3) + \mathbf{R}_3 G_1(\omega_1) G_1(\omega_2) G_1(\omega_3) \\
&\bar{\mathbf{R}}_j^{(f)}(\boldsymbol{\Omega}_j) = \mathbf{R}_1 G_j^{(f)}(\boldsymbol{\Omega}_j) \qquad (j = 1,2,3)
\end{aligned}
\tag{20}
$$

The VFRFs $\bar{\mathbf{C}}_j = \bar{\mathbf{C}}_j^{(d)} + \bar{\mathbf{C}}_j^{(f)}$ can be obtained through Eq. (20) by replacing $\mathbf{R}_j$ with $\mathbf{C}_j$ and G_j with E_j. Figure 3d shows the block diagram of the operator $\mathscr{V}$ providing V_r^2. Its VFRFs are given as

$$
\begin{aligned}
&V_0 = U^2 \\
&V_1 = 0 \\
&V_2(\boldsymbol{\Omega}_2) = P_L(\omega_1) P_L(\omega_2) - \omega_1\omega_2 \mathbf{b}_2 \mathbf{L}_1(\omega_1) \mathbf{b}_2 \mathbf{L}_1(\omega_2) + 2P_L(\omega_1) \mathbf{b}_2 \mathbf{L}_1(\omega_2) \\
&V_3(\boldsymbol{\Omega}_3) = 2\mathrm{i} P_L(\omega_1)(\omega_2 + \omega_3) \mathbf{b}_2 \mathbf{L}_2(\omega_2, \omega_3) - 2\omega_1(\omega_2 + \omega_3) \mathbf{b}_2 \mathbf{L}_1(\omega_1) \mathbf{b}_2 \mathbf{L}_2(\omega_2, \omega_3)
\end{aligned}
\tag{21}
$$

Figure 3e shows the operator $\mathscr{F}$ providing the low-frequency force $\mathbf{f}_L$. Its VFRFs $\mathbf{F}_j = \mathbf{F}_j^{(d)} + \mathbf{F}_j^{(f)}$ are given as:

$$
\begin{aligned}
&\mathbf{F}_0 = \frac{1}{2}\rho B l V_0 \mathbf{Y}_0 \\
&\mathbf{F}_1^{(d)}(\omega) = \frac{1}{2}\rho B l V_0 \mathbf{Y}_1^{(d)}(\omega) \\
&\mathbf{F}_2^{(d)}(\boldsymbol{\Omega}_2) = \frac{1}{2}\rho B l \left(V_0 \mathbf{Y}_2^{(d)}(\boldsymbol{\Omega}_2) + V_2(\boldsymbol{\Omega}_2) \mathbf{Y}_0 \right) \\
&\mathbf{F}_3^{(d)}(\boldsymbol{\Omega}_3) = \frac{1}{2}\rho B l \left(V_0 \mathbf{Y}_3^{(d)}(\boldsymbol{\Omega}_3) + V_2(\omega_1, \omega_2) \mathbf{Y}_1(\omega_3) + V_3(\boldsymbol{\Omega}_3) \mathbf{Y}_0 \right) \\
&\mathbf{F}_j^{(f)}(\boldsymbol{\Omega}_j) = \frac{1}{2}\rho B l V_0 \mathbf{Y}_j^{(f)}(\boldsymbol{\Omega}_j) \qquad (j = 1,2,3)
\end{aligned}
\tag{22}
$$

The VFRFs of the operator $\mathscr{S}$ providing the low-frequency response can be obtained by equating the VFRFs of the operators $\mathscr{D}[\mathscr{D}[\bullet]]$ and $\mathscr{F}$, leading to the equations:

$$
\begin{aligned}
&\mathbf{L}_0 = \mathbf{D}(0)^{-1} \mathbf{F}_0 \\
&\mathbf{D}(\Sigma\boldsymbol{\Omega}_j) \mathbf{L}_j(\boldsymbol{\Omega}_j) - \mathbf{F}_j^{(f)}(\boldsymbol{\Omega}_j) = \mathbf{F}_j^{(d)}(\boldsymbol{\Omega}_j) \qquad (j = 1,2,3)
\end{aligned}
\tag{23}
$$

The 0^{th}-order equation is non-linear due to the dependency of the polynomial approximation of the aerodynamic coefficients from the α_0 (Eq. (18)). The other equations are linear in $\mathbf{L}_j$ ($\mathbf{F}_j^{(f)}$ is linear in $\mathbf{L}_j$) and contain lower-order solutions ($\mathbf{L}_k$ with $k < j$) in the term $\mathbf{F}_j^{(d)}$.

4.2 *High-frequency stage*

The synthesis of the high-frequency stage of the system requires the identification of the operators $\bar{\mathscr{A}}$ and $\bar{\mathscr{B}}$ providing, respectively the high-frequency buffeting force $\mathbf{f}_H$ and the self-excited force $\mathbf{f}_{se}$ (Figure 4). Their VFRFs, respectively, $\bar{\mathbf{A}}_j = \bar{\mathbf{A}}_j^{(d)} + \bar{\mathbf{A}}_j^{(f)}$ and $\bar{\mathbf{B}}_j$ are given as

$$
\begin{aligned}
&\bar{\mathbf{A}}_0 = \mathbf{0} \\
&\bar{\mathbf{A}}_1^{(d)}(\omega) = \mathbf{0} \\
&\bar{\mathbf{A}}_2^{(d)}(\boldsymbol{\Omega}_2) = \mathbf{A}_1(\Sigma\boldsymbol{\Omega}_2)\,\mathbf{H}_1(\omega_1)\,E_1(\omega_2) \\
&\bar{\mathbf{A}}_3^{(d)}(\boldsymbol{\Omega}_3) = \mathbf{A}_1(\Sigma\boldsymbol{\Omega}_3)\left[\mathbf{H}_1(\omega_1)\,E_2(\omega_2,\omega_3) + \mathbf{H}_2(\omega_1,\omega_2)\,E_1(\omega_3)\right] + \mathbf{A}_2(\Sigma\boldsymbol{\Omega}_3)\,\mathbf{H}_1(\omega_1)\,E_1(\omega_2)\,E_1(\omega_3) \\
&\bar{\mathbf{A}}_j^{(f)}(\boldsymbol{\Omega}_j) = \mathbf{A}_0(\Sigma\boldsymbol{\Omega}_j)\,\mathbf{H}_j(\boldsymbol{\Omega}_j) \qquad (j = 1,2,3)
\end{aligned}
\tag{24}
$$

$$
\begin{aligned}
&\bar{\mathbf{B}}_0 = \mathbf{0} \\
&\bar{\mathbf{B}}_1(\omega) = \mathbf{B}_0(\omega)\,P_H(\omega) \\
&\bar{\mathbf{B}}_2(\boldsymbol{\Omega}_2) = \mathbf{B}_1(\Sigma\boldsymbol{\Omega}_2)\,P_H(\omega_1)\,E_1(\omega_2) \\
&\bar{\mathbf{B}}_3(\boldsymbol{\Omega}_3) = \mathbf{B}_1(\Sigma\boldsymbol{\Omega}_3)\,P_H(\omega_1)\,E_2(\omega_2,\omega_3) + \mathbf{B}_2(\Sigma\boldsymbol{\Omega}_3)\,P_H(\omega_1)\,E_1(\omega_2)\,E_1(\omega_3)
\end{aligned}
\tag{25}
$$

The FRFs $\mathbf{H}_j$ of $\mathscr{H}$ can be obtained by equating, order by order, the VFRFs of the systems $\mathscr{D}[\mathscr{H}[\bullet]]$ and $\bar{\mathscr{A}} + \bar{\mathscr{B}}$, leading to the equations:

$$
\mathbf{D}(\Sigma\boldsymbol{\Omega}_j)\,\mathbf{H}_j(\boldsymbol{\Omega}_j) - \bar{\mathbf{A}}_j^{(f)}(\boldsymbol{\Omega}_j) = \bar{\mathbf{A}}_j^{(d)}(\boldsymbol{\Omega}_j) + \bar{\mathbf{B}}_j(\boldsymbol{\Omega}_j) \qquad (j = 1,2,3) \tag{26}
$$

which can be solved with respect to $\mathbf{H}_j$ since $\bar{\mathbf{A}}_j^{(f)}$ is linear in $\mathbf{H}_j$. It can be observed that the j^{th}-order high-frequency response is influenced by the low-frequency response up to the order j-1 through the VFRFs E_k (k = 1,..,j-1).

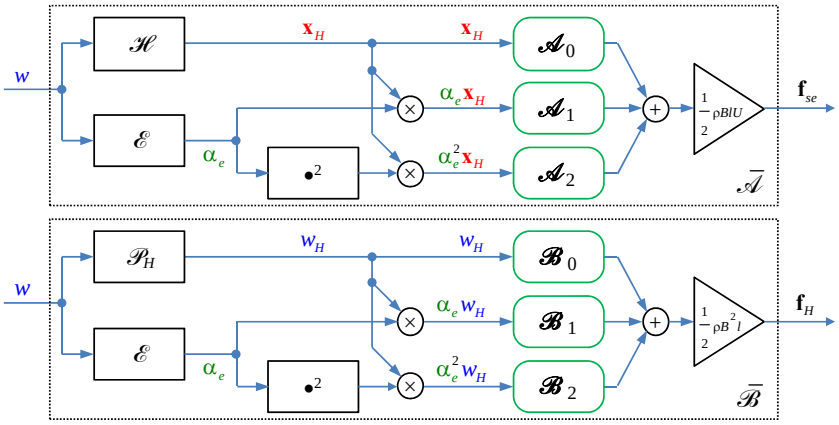

Figure 4. High-frequency stage.

5 NUMERICAL APPLICATION

The accuracy of the Volterra series representation of the non-linear aeroelastic bridge model described in Section 3 is demonstrated through the calculation of the response of a long-span bridge. The static coefficients of the cross section are measured for angle of attack between -10° and 10° with step 1°. These data are approximated through 3$^{\text{rd}}$-order polynomials through a mean-square error minimization procedure [3] (Figure 5a). The admittance function is modeled

through the Sears function and is independent of the angle of attack. The flutter derivatives are estimated for α = -3°, 0°, 3° and are interpolated, for each reduced velocity value, through a 2nd-order polynomial (Figure 5b). The natural frequency of the two considered modes is n_1 = 0.19 Hz and n_2 = 0.53 Hz. The frequency value dividing low and high-frequency components is n_c = 0.10 Hz.

Figure 6 shows the low-frequency response calculated through a Volterra model with order from 1 to 3, compared with the exact non-linear response calculated by a standard ODE solver. The result of the 3rd-order Volterra series appears quite accurate, in particular if compared to the linear model (1st-order Volterra series) which fails in reproducing the torsional response mainly due to its implicit symmetry.

Figure 7 shows the high-frequency response calculated through a Volterra model with order from 1 to 3, compared with the solution obtained by the time-domain procedure proposed in [2]. Also for this response component the 3rd-order Volterra series approximation provides a response very close to the time-domain solution.

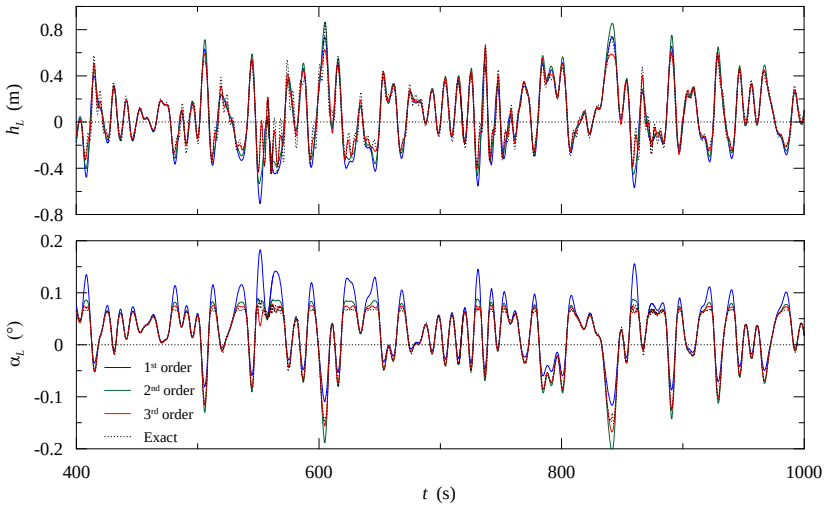

Figure 6. Low-frequency response.

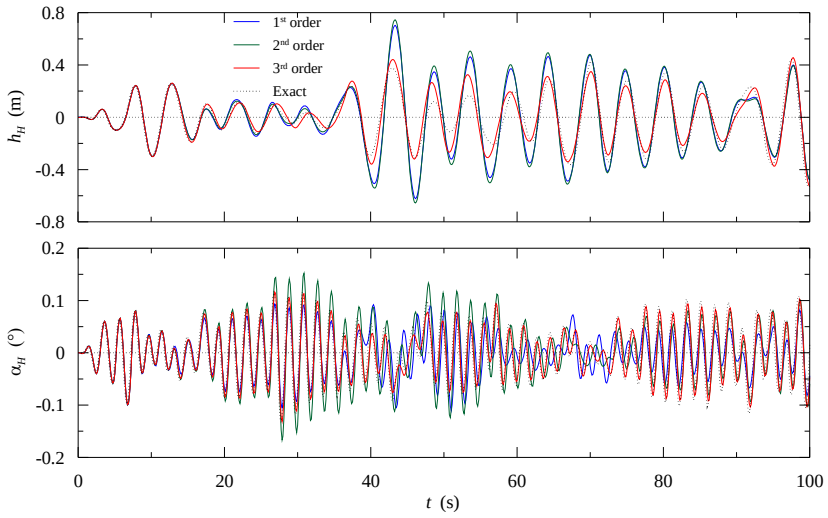

Figure 7. High-frequency response.

6 CONCLUSIONS

The proposed model is essentially the translation of an existing analysis procedure to the frequency domain, and therefore it inherits all its conceptual advantages and limitations (in particular, it is based on the hypothesis of small high-frequency oscillation of the bridge around a slow, possibly large, variation of the effective angle of attack). The added value of this new formulation is mostly related to its potential for deriving qualitative interpretations through this model. Besides, the functional structure of the proposed model may serve as a scaffolding to construct a fully-nonlinear model based on the Volterra series representation, to be identified from ad-hoc experimental procedures.

From a computational point of view, the implementation of the model in the framework of the Volterra series enables the formulation of a very efficient frequency-domain solution based on the concept of Associated Linear Equations (ALE). Accordingly, the model defined herein can be implemented through six linear frequency-domain equations that can be conveniently solvedin a cascade manner.

ABSTRACT: An approximate approach for the frequency- and time-domain aeroelastic analysis of bridge decks is presented. The aerodynamic transfer functions are approximated as a linear function with the coefficients determined through minimization of the weighted error between the exact and approximated transfer function. The weighting function in optimization is introduced for the improved approximation. Using the proposed method, the frequency dependence of the aerodynamic transfer function is eliminated, and a popular time marching algorithm is adopted for the aeroelastic analysis in the time domain. For the frequency domain analysis, a complete set of modal frequencies and modal shapes can be evaluated in a single eigenvalue analysis.

1 INTRODUCTION

For aeroelastic analyses of bridge decks under wind action, numerous approaches have been proposed since Scanlan and Tomko[1] defined self-excited forces using flutter derivatives. The difficulty in aeroelastic analysis basically arises from the frequency dependence of self-excited forces. For the frequency-domain aeroelastic analysis, an iterative procedure is required to solve the nonlinear eigenvalue problem, which is referred to as branch method[2]. The critical issue in the time-domain approach is the elimination of the frequency-dependent characteristics of the aerodynamic forces, for which the convolution integral is usually utilized. The impulse response functions are formed with the identified flutter derivatives through optimization in the frequency domain, and the aerodynamic forces are expressed as convolutions between the impulse response functions and the deck motion. The rational function approximation (RFA) has been the most popular approach for forming impulse response functions for the convolution integral[3]. Despite its popularity, however, Caracoglia and Jones[4] reported on the potential limitations of the RFA method on its applicability to bluff sections. Recently, Jung et al. [5] proposed a new algorithm for evaluating impulse response functions through a domain-discretization approximation to overcome the shortcomings of the RFA.

Although the convolution integral approach and the branch method can be successfully applied to time-domain and frequency-domain analyses, respectively, for various

types of sections, they are based on different approximations. The impulse response functions used for the convolution integral become inconsistent with the given flutter derivatives of a section through optimization, while the aerodynamic forces are evaluated at only one assumed frequency in the branch method. Therefore, the consistency between results of a time-domain analysis and a frequency-domain analysis cannot be generally guaranteed.

This paper presents a new unified approach for the aeroelastic analysis of a bridge structure by approximating each component of the aerodynamic transfer functions in frequency domain. Using this approximation, the equation of motion for an aeroelastic system becomes a set of simple second-order differential equations in the time domain. The coefficients of the second-order polynomial are determined through minimization of weighted errors between the exact and approximated aerodynamic transfer function in the frequency domain. The validity of the proposed method is demonstrated by applying to an idealized cable-supported structure.

2 AN APPROXIMATED APPROACH FOR THE AEROELASTIC ANALYSIS

2.1 *Equation of motion of a cable bridge under wind action*

The dynamic virtual work expression of a discretized structure under the action of wind is given as follows:

$$\delta\mathbf{U}^T\mathbf{M}\ddot{\mathbf{U}} + \delta\mathbf{U}^T\mathbf{C}\dot{\mathbf{U}} + \delta\mathbf{U}^T\mathbf{K}\mathbf{U} = \delta\Pi_{ad} + \delta\mathbf{U}^T\mathbf{P}_{ex} \tag{1}$$

where **M**, **C**, **K**, $\mathbf{P}_{ex}$ and **U** are the mass, damping, stiffness matrix of the discretized structural system, the equivalent nodal force vector and the nodal displacements vector, respectively, and δ, when placed in front of a variable, indicates a virtual quantity. The external virtual work done by wind-induced aerodynamic forces is denoted as $\delta\Pi_{ad}$ in Eq. (1), and defined as the summation of the contribution from each element.

$$\delta\Pi_{ad} = \sum_e \delta\Pi_{ad}^e = \sum_e \int_{l^e} (\delta h^e \cdot L_{ad}^e + \delta\alpha^e \cdot M_{ad}^e)dx \tag{2}$$

where and are the aerodynamic lift force and torsional moment per unit length in the local coordinate system for element e, respectively, while h^e and α^e are the vertical and torsional displacement defined also in the local coordinate system, respectively.

In accordance with the Scanlan and Tomko's formulation[1], the self-excited forces acting on a sinusoidally oscillating section in a single frequency are defined as:

$$L_{ae} = \frac{1}{2}\rho U^2 B[KH_1^*\frac{\dot{h}}{U} + KH_2^*\frac{B\dot{\alpha}}{U} + K^2H_3^*\alpha + K^2H_4^*\frac{h}{B}]$$
$$M_{ae} = \frac{1}{2}\rho U^2 B^2[KA_1^*\frac{B\dot{h}}{U} + KA_2^*\frac{B\dot{\alpha}}{U} + K^2A_3^*\alpha + K^2A_4^*\frac{h}{B}] \tag{3}$$

where ρ is the air density, U is the mean wind velocity, B is the width of the section model. $K=B\omega/U$ is the reduced frequency where ω is the angular frequency of the oscillation. The flutter derivatives are denoted as H_m^* and A_m^* (m=1,2,3,4), and are functions of the angular frequency. Because of this frequency dependence, the self-excited forces are usually defined in the frequency domain as follows [5]:

$$\begin{aligned}\begin{pmatrix} F(L_{ad}) \\ F(M_{ad}) \end{pmatrix} &= \frac{1}{2}\rho U^2 \begin{bmatrix} iK^2H_1^* + K^2H_4^* & B(iK^2H_2^* + K^2H_3^*) \\ B(iK^2A_1^* + K^2A_4^*) & B^2(iK^2A_2^* + K^2A_3^*) \end{bmatrix} \begin{pmatrix} F(h) \\ F(\alpha) \end{pmatrix} \\ &= \begin{bmatrix} \Psi_{hh} & \Psi_{h\alpha} \\ \Psi_{\alpha h} & \Psi_{\alpha\alpha} \end{bmatrix} \begin{pmatrix} F(h) \\ F(\alpha) \end{pmatrix} = \mathbf{\Psi}(\omega) F(\mathbf{u}^e) \end{aligned} \tag{4}$$

where F denotes the Fourier transform, and $\mathbf{u}^e$ is the displacement vector containing local displacement components h^e and α^e. Ψ_{mn} is the transfer function between the aeroelastic forces in the m direction and the motion in the n direction, and i is the imaginary unit. Using a standard finite element procedure for the interpolation and the coordinate rotation procedure, the displacement vector in Eq. (4) is expressed in terms of the nodal displacement vector of the discretized structure, **U**, defined in the structural coordinate system.

$$\mathbf{u}^e = \mathbf{N}^e \mathbf{\Gamma}^e \mathbf{T}^e \mathbf{U}$$

(5) $\mathbf{N}^e$ $\mathbf{\Gamma}^e$ $\mathbf{T}^e$

where , and are the shape function matrix for the local displacement vector, the transformation matrix between the local and structural coordinate system and the compatibility matrix that relates h^e and α^e to the structural displacement vector, respectively. The virtual work done by the aerodynamic forces in the frequency domain can easily be obtained using Eq. (4) and Eq. (5).

$$\begin{aligned} F(\delta\Pi_{ad}) &= F(\sum_e \delta\Pi_{ad}^e) = \sum_e \int_{l^e} (\delta h^e \cdot F(L_{ad}^e) + \delta\alpha^e \cdot F(M_{ad}^e)) dx \\ &= \sum_e \int_{l^e} (\delta\mathbf{u}^e)^T \mathbf{\Psi}^e F(\mathbf{u}^e)) dx = \delta\mathbf{U}^T \sum_e (\mathbf{\Gamma}^e\mathbf{T}^e)^T \int_{l^e} (\mathbf{N}^e)^T \mathbf{\Psi}^e \mathbf{N}^e dx \mathbf{\Gamma}^e \mathbf{T}^e F(\mathbf{U}) \\ &= \delta\mathbf{U}^T \mathbf{\Psi}(\omega) F(\mathbf{U}) \end{aligned} \tag{6}$$

where $\mathbf{\Psi}$ is referred to as the aerodynamic transfer function defining the aerodynamic force in terms of the displacement in the frequency domain.

The Fourier transform of Eq. (1) yields the dynamic virtual work expression of an aeroelastic system in the frequency domain.

$$F(\delta\Pi) = \delta\mathbf{U}^T([-\omega^2\mathbf{M} + i\omega\mathbf{C} + \mathbf{K} - \mathbf{\Psi}(\omega)]F(\mathbf{U}) - F(\mathbf{P}_{ex})) = 0$$

(7)

As Eq. (7) should hold for all admissible $\delta\mathbf{U}$, the equation of motion for a structure that is subject to the action of wind is derived in the frequency domain.

$$[-\omega^2\mathbf{M} + i\omega\mathbf{C} + \mathbf{K} - \boldsymbol{\Psi}(\omega)]F(\mathbf{U}) = F(\mathbf{P}_{ex})$$

(8)

The inverse Fourier transform of Eq. (9) yields the equation of motion in the time domain, which contains the well-known convolution expression for the aerodynamic force.

$$\mathbf{M}\ddot{\mathbf{U}} + \mathbf{C}\dot{\mathbf{U}} + \mathbf{K}\mathbf{U} = \mathbf{P}_{ex} + \int_0^t \boldsymbol{\Phi}(t-\tau)\mathbf{U}(\tau)d\tau \qquad (9)$$

Here, $\boldsymbol{\Phi}$ is the aerodynamic impulse response function matrix of the structural system, which is the inverse Fourier transform of the aerodynamic transfer function matrix, $\boldsymbol{\Psi}$. The convolution integral in Eq. (9) is valid if and only if the aerodynamic impulse response function vanishes for $t < 0$, which is referred to as the causality condition[5]. Several approaches have been proposed for forming approximated transfer functions that satisfy the casualty condition using the measured flutter derivatives[3,5].

The aerodynamic transfer functions used for the convolution integral approach and the branch method become different from those formed by the given flutter derivatives. The transfer functions of a section in Eq. (4) are modified in the optimization to enforce the causality condition in the convolution integral approach in Eq. (9). Meanwhile, the aerodynamic transfer functions of Eq. (6) in the branch method represent aerodynamic information related to only one assumed frequency rather than on the whole frequency range. Therefore, the results of an aerodynamic analysis in one analysis domain are generally inconsistent with those for the other analysis domain, which is a crucial drawback of methodologies that are currently used in aeroelastic analyses.

A new unified approach for the aeroelastic analysis can be formulated in case the aerodynamic transfer function matrix can be reasonably approximated by a linear function with respect to frequency as follows:

$$\boldsymbol{\Psi}(\omega) \approx \widetilde{\boldsymbol{\Psi}}(\omega) = i\omega\widetilde{\mathbf{C}} + \widetilde{\mathbf{K}}$$

$\widetilde{\boldsymbol{\Psi}}(\omega)$ (10) $\widetilde{\mathbf{C}}$ $\widetilde{\mathbf{K}}$

where is the approximated aerodynamic transfer function while and are unknown coefficient matrices. By use of Eq. (10) and the inverse Fourier transform of Eq. (8), the approximated equation of motion is defined as a usual second order differential equation in the time domain.

$$\mathbf{M}\ddot{\mathbf{U}} + \widetilde{\mathbf{C}}_{ae}\dot{\mathbf{U}} + \widetilde{\mathbf{K}}_{ae}\mathbf{U} = \mathbf{P}_{ex}$$

$\widetilde{\mathbf{C}}_{ae} = \mathbf{C} - \widetilde{\mathbf{C}}$ $\widetilde{\mathbf{K}}$ (11) $\mathbf{K} - \widetilde{\mathbf{K}}$

where and . The unknown coefficient matrices in Eq. (11) are determined through minimization in the frequency domain.

2.2 *Minimization of the weighted least square error*

The weighted error matrix of the approximation in Eq. (10) is defined by the modulus of a complex number of each component.

$$E_{kl} = \left|\Psi_{kl} - \widetilde{\Psi}_{kl}\right| w_{kl} = ((\Psi_{kl}^R - \widetilde{K}_{kl})^2 + (\Psi_{kl}^I - \omega\widetilde{C}_{kl})^2)^{0.5} w_{kl}$$

Ψ_{kl}^R Ψ_{kl}^I Ψ_{kl}

(12)

where w_{kl}, and are predefined weighting functions, the real and imaginary part of , respectively, while $|\cdot|$ denotes the modulus of a complex number. $\widetilde{K}_{kl}^{r}$ and are the *kl*-components of the corresponding coefficient matrices. The unknown coefficient matrices are determined by minimizing the norm of the weighted errors in Eq. (12).

$$\underset{\widetilde{C}_{kl},\widetilde{K}_{kl}}{\text{Min}}\,\Pi=\frac{1}{2}\int_0^{\omega_{\max}}E_{kl}^2 d\omega=\frac{1}{2}\int_0^{\omega_{\max}}(\Psi_{kl}^R-\widetilde{K}_{kl})^2 w_{kl}^2 d\omega+\frac{1}{2}\int_0^{\omega_{\max}}(\Psi_{kl}^I-\omega\widetilde{C}_{kl})^2 w_{kl}^2 d\omega \tag{13}$$

where $\omega_{\max}$ is the maximum frequency that defines the maximum frequency range of the aerodynamic transfer function. The first-order optimality condition yields the following linear algebraic equations:

$$\widetilde{C}_{kl}=\int_0^{\omega_{\max}}\omega\Psi_{kl}^I w_{kl}^2 d\omega\Big/\int_0^{\omega_{\max}}\omega^2 w_{kl}^2 d\omega,\quad \widetilde{K}_{kl}=\int_0^{\omega_{\max}}\Psi_{kl}^R w_{kl}^2 d\omega\Big/\int_0^{\omega_{\max}}w_{kl}^2 d\omega \tag{14}$$

The weighting functions in the error matrix are introduced to consider the responses of an aeroelastic system in the approximated transfer function of the aerodynamic forces. The approximation errors at frequencies where the responses of an aeroelastic system become small have little effect on the final solution of the aeroelastic analysis, regardless of their magnitude, and thus may be safely neglected in the minimization. Once the weighting functions are properly defined, the frequency-domain integrals in Eq. (14) can be evaluated by means of a numerical integration scheme such as the trapezoidal rule, and the *kl*-components of the coefficient matrices are easily obtained by solving the numerically integrated form of Eq. (14).

3 NUMERICAL EXAMPLES OF THE BRIDGE MODEL

The validity of the proposed method is demonstrated for an idealized model bridge with 8 stay cables, which simulates the center span of a cable-stayed bridge. The span length of the model bridge is assumed to be 200 m. Since the aeroelastic behaviors of a bridge are mainly dependent on the cross-sectional shape of the bridge deck, two extreme types of deck sections are considered. One is a thin rectangular section with a width-to-depth (B/D) ratio of 20 representing a streamlined box section, and the other is a bluff H-type section simulating a slab-on-stringer type girder.

3.1 *A thin rectangular section of B/D=20*

The proposed method is applied to the aeroelastic analysis of a bridge model with a thin rectangular section. Fig. 1 shows the damping ratios of the aeroelastic system obtained by the proposed method and by the branch method. The results obtained by the proposed method are in good agreement with the values obtained by the branch method. The time-domain aeroelastic analysis is performed for the forced vibration at a wind velocity of 55 m/s. Although the aeroelastic analysis is performed near the flutter onset velocity, the proposed method accurately yields displacements compared with those by the convolution integral.

3.2 *A bluff H-type section*

The aeroelastic analysis of the section model with a bluff H-type section is performed. Fig. 3 shows the damping ratios of the aeroelastic system, and Fig. 4 illustrates the free vibration responses at the wind velocity of 8 m/s. Even in the case of the bluff H-type section, the results obtained by the proposed method are also in good agreement with the values obtained by the branch method as well as the convolution integral.

4 CONCLUSIONS

A unified approach for the aeroelastic analysis is proposed. The aerodynamic transfer functions are approximated as a linear function with coefficients determined through the minimization of the weighted error between exact and approximated transfer functions.

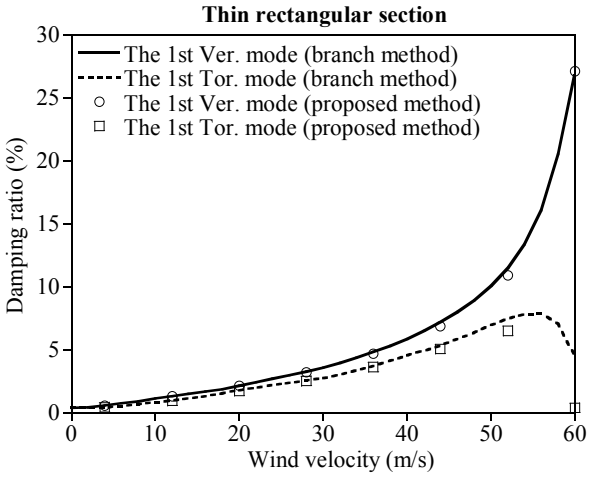

Fig. 1: Predicted damping ratio by the frequency-domain analysis of the bridge model

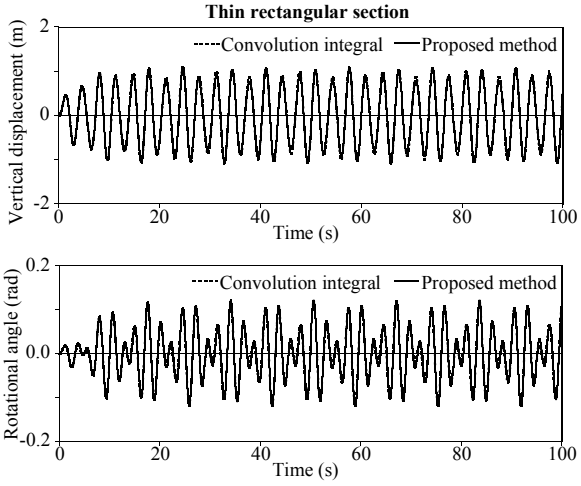

Fig. 2: Forced vibration responses for the wind velocity of 55m/s of the bridge model

With the proposed approximation, the frequency dependence of the aerodynamic transfer function is eliminated, and, as a result, the equation of motion for an aeroelastic system can be simply expressed as the same type of second-order differential equation in the time domain as that for a structural system. The validity of the proposed method is demonstrated for an section model with two extreme types of deck sections. Based on the results of the numerical simulations presented in this study, it can be concluded that the proposed approximation of the aerodynamic transfer function works well, even for the case of a bluff H-type section.

Comparison of various modeling schemes for bridge aerodynamics and aeroelasticity

Teng Wu [a], Ahsan Kareem [a]

[a] *Nathaz Modeling Laboratory, University of Notre Dame, Notre Dame, IN, USA*

ABSTRACT: This paper compares five analytical models available in the literature systematically together with a new developed model for bridge aerodynamic/aeroelastic analysis. The models under consideration are quasi-steady (QS) theory based model, corrected QS theory based model, linearized QS theory based model, semi-empirical linear model, hybrid model and the proposed modified hybrid model. Physical significances of each approach in capturing the bridge behavior are highlighted. The interaction between the turbulence and the bridge deck motions is investigated. All these models are utilized in the time domain for consistency.

KEYWORDS: Comparison; Model; Bridge; Aerodynamics; Aeroelasticity

1 INTRODUCTION

The catastrophic failure of the original Tacoma Narrows Bridge has been pivotal in drawing attention to research in the aerodynamic/aeroelastic behavior of long-span bridges. The intense oscillation of the deck of the original Tacoma Narrows Bridge is actually the galloping in torsional degree of freedom (usually refers to torsional flutter). As a result, it is convenient to illustrate this phenomenon based on the QS theory. However, an obvious shortcoming of the QS theory is that it cannot take into the unsteady effect of fluid-structure interaction.

A familiar approach to consider the fluid memory effects is to modify the steady-state coefficients based on the unsteady effects measured in the wind tunnel and hence to improve the simulation accuracy (Diana et al. 1993). On the other hand, in order to circumvent dealing with nonlinear differential equations, QS theory based formula is usually linearized to qualitatively evaluate the wind-induced aerodynamic/aeroelastic forces. The parameters (consists of steady-state coefficients and their first-order derivatives) of this linearized QS theory based formula has their corresponding unsteady analytical expressions for the structure with streamlined cross-section, such as Theodorsen function (Theodorsen 1935).

However, for the cross-sections of bluff body, it is questionable to obtain the analytical expressions for the parameters based on some basic, simplified mechanism (such as potential theory and Kutta condition) due to the flow separation and other bluff-body aerodynamic issues. As a result, the parameters based on the wind-tunnel tests (e.g., aerodynamic admittances and flutter derivatives) is commonly utilized (Scanlan and Tomko 1971). This semi-empirical, linear, unsteady scheme has been applied extensively to simulate bridge aerodynamic and aeroelastic behaviors since its invention. It is emphasized that the QS theory based model could take into account the nonlinearity but no fluid memory while the conventional semi-empirical model could account for the fluid memory but no nonlinearity. Hence, a hybrid scheme has been proposed to simulate both the unsteady and nonlinear effects in wind-bridge interaction (Chen and Kareem 2003). Though the hybrid model could reasonably account for the nonlinear effect, it compromises the consideration of unsteady effect in the low frequency part. A modified hybrid model is proposed in this research, where the steady-state coefficients are modified based on their hysteretic features observed in wind tunnel. As a result, this new model could involve the higher-order memory effect (represented by hysteretic loop) when QS theory (nonlinear effect) is utilized.

2 IMPLEMENT OF VARIOUS MODELS

The coordinate system of the wind-bridge interaction system for analysis in all these models is shown in Fig. 1. A unit-length section of a modern bridge deck subjected to a turbulent wind flow is considered here and the aerodynamic/aeroelastic loads are established based on "strip theory". The incident turbulent wind consists of mean wind velocity U and W and fluctuations u and w in horizontal and vertical direction, respectively. The bridge cross-section has horizontal motion p, vertical motion h, and torsional motion α under the turbulent wind. The wind-induced effects considered are lift force L, drag force D and moment M.

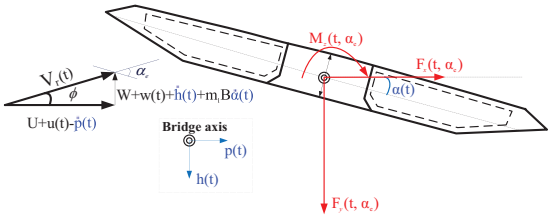

Figure 1: Coordinate system of the wind-bridge interaction system.

Suppose vertical translation and rotational motion are considered, the governing equations of the motion of bridge deck cross-section are modeled by a two-degree-of-freedom oscillator as

$$m\left(\ddot{h}+2\zeta_h\omega_h\dot{h}+\omega_h^2 h\right)=F_y\,;\quad I\left(\ddot{\alpha}+2\zeta_\alpha\omega_\alpha\dot{\alpha}+\omega_\alpha^2\alpha\right)=M_z \tag{1a; b}$$

where the over dot indicates the derivative with respect to time; ζ and ω represent the damping ratio and natural frequency, respectively; m is the effective mass and I the effective mass moment of inertia; F_y and M_z are wind-induced effects (aerodynamic/aeroelastic forces or moments) and the simulation of these effects is emphasized in this research.

2.1 *Quasi-steady (QS) theory based model*

QS theory based model describes the flow-structure interaction with a static nonlinear relationship between the status of the system (e.g., incident flow and structure) and the flow-induced forces exerted on the structure. Based on the QS theory, the lift force and torsional moment per unit span in the global bridge axes are expressed as (Miyata et al. 1995)

$$F_y=F_L\cos(\phi)-F_D\sin(\phi)\,;\quad M_z=M \tag{2a; b}$$

$$F_L=-\frac{1}{2}\rho V_r^2 BC_L(\alpha_e)\,;\quad F_D=\frac{1}{2}\rho V_r^2 BC_D(\alpha_e)\,;\quad M=\frac{1}{2}\rho V_r^2 B^2 C_M(\alpha_e) \tag{3a; b; c}$$

where ρ is air density; B is the bridge deck width; C_L, C_D and C_M are nondimensioanl steady-state coefficients which are conveniently obtained with static wind-tunnel tests, where C_M is respect to the center of the cross-section; V_r is the relative wind velocity calculated as

$$V_r=\sqrt{(U+u)^2+(W+w+\dot{h}+m_l B\dot{\alpha})^2} \tag{4}$$

and α_e is the dynamic angle of attack calculated as

$$\alpha_e=\alpha_s+\alpha+\phi \tag{5}$$

where α_s is the wind angle of attack when bridge deck is at the equilibrium position (also involving potential incident wind angle); α is the torsional displacement of the bridge deck under turbu-

lent wind; and ϕ is the "dynamic" angle of attack induced by the bridge deck motions and wind fluctuations (here the terminology "effective angle of attack" refers the situation that only deck motions contributes the angle of attack) and could be calculated as

$$\phi = \arctan\left(\frac{W + w + \dot{h} + m_1 B\dot{\alpha}}{(U+u)}\right) \tag{6}$$

The parameter m_1 value is selected to appropriately define a equivalent stationary state for the rotational motion.

2.2 *Corrected QS theory based model*

An obvious shortcoming of the quasi-steady theory based model is that it cannot take into account the unsteady effect. In order to improve this model, a corrected QS theory based model has been advanced where a coefficient is introduced to account for the unsteady effects (Diana et al. 1993). Based on the corrected QS theory, the lift force and torsional moment per unit span in the global bridge axes should be revised as

$$F_y = F_L\cos(\phi) - F_D\sin(\phi);\quad M_z = M \tag{2a; b}$$

$$F_L = -\frac{1}{2}\rho V_r^2 B\left\{C_L(\alpha_s) + \int_{\alpha_s}^{\alpha_e} k_{1L}\frac{d[C_L(\tilde{\alpha})]}{d[\tilde{\alpha}]}d\tilde{\alpha}\right\};\ F_D = \frac{1}{2}\rho V_r^2 B\left\{C_D(\alpha_s) + \int_{\alpha_s}^{\alpha_e} k_{1D}\frac{d[C_D(\tilde{\alpha})]}{d[\tilde{\alpha}]}d\tilde{\alpha}\right\};\ M = \frac{1}{2}\rho V_r^2 B^2\left\{C_M(\alpha_s) + \int_{\alpha_s}^{\alpha_e} k_{1M}\frac{d[C_M(\tilde{\alpha})]}{d[\tilde{\alpha}]}d\tilde{\alpha}\right\} \tag{7a; b; c}$$

The parameter k_1 is determined by the unsteady effect of the wind-bridge interaction.

2.3 *Linearized QS theory based model*

Both QS and corrected QS theory based model need to deal with nonlinear differential equations when implemented to calculate the bridge deck responses. In order to circumvent this complexity, QS theory based formula is usually linearized at the static equilibrium position to qualitatively evaluate the wind-induced aerodynamic/aeroelastic forces. Based on the linearized QS theory, the lift, drag and torsional coefficients should be approximated as

$$C_L(\alpha_e) \cong C_L(\alpha_s) + (\alpha+\phi)C_L'\big|_{\alpha_s};\quad C_D(\alpha_e) \cong C_D(\alpha_s) + (\alpha+\phi)C_D'\big|_{\alpha_s};\quad C_M(\alpha_e) \cong C_M(\alpha_s) + (\alpha+\phi)C_M'\big|_{\alpha_s} \tag{8a; b; c}$$

where prime indicates the derivative with respect to angle of attack. With some manipulations, the lift force and torsional moment per unit span based on the linearized QS theory in the global bridge axes could be expressed as

$$F_y = -\frac{1}{2}\rho U^2 B\left\{[C_L] + \left[(C_L' + C_D)\frac{w}{U} + 2C_L\frac{u}{U}\right] + \left[(C_L' + C_D)\frac{\dot{h} + m_1 B\dot{\alpha}}{U} + C_L'\alpha\right]\right\}\Big|_{\alpha_s};\quad M_z = \frac{1}{2}\rho U^2 B^2\left\{[C_M] + \left[C_M'\frac{w}{U} + 2C_M\frac{u}{U}\right] + \left[C_M'\frac{\dot{h} + m_1 B\dot{\alpha}}{U} + C_M'\alpha\right]\right\}\Big|_{\alpha_s} \tag{9a; b}$$

where the first term in the bracket represents static effect; the second term aerodynamic effect and the third term aeroelastic effect.

2.4 *Semi-empirical linear model*

In order to take into account the unsteady effect within a linear framework, the so-called semi-empirical scheme was developed by Scanlan (e.g., Scanlan and Tomko 1971) using wind tunnel tests of a sectional bridge model to account for the aeroelastic effects. On the other hand, the spectral analysis in this linear framework is developed by Davenport (e.g., Davenport 1962) to account for the aerodynamic effects, in which the coefficients of the corresponding linearized terms are also measured based on wind-tunnel test (or based on linearized QS theory). The lift force and torsional moment of frequency domain per unit span based on the semi-empirical linear model in the global bridge axes could be expressed as

$$F_y = -\frac{1}{2}\rho U^2 B\left\{\left[C_L\right]+\left[F_{L_b}\right]+\left[-F_{L_s}\right]\right\}\Big|_{\alpha_s};\quad M_z = \frac{1}{2}\rho U^2 B^2\left\{\left[C_M\right]+\left[M_b\right]+\left[M_s\right]\right\}\Big|_{\alpha_s} \tag{10a; b}$$

where the subscript "b" indicates the buffeting forces (or moment) while "s" indicates the self-excited forces (or moment). The buffeting forces (or moment) induced by turbulent wind are expressed as

$$F_{L_b} = (C_L^{'} + C_D)\chi_{Lw}\frac{w(t)}{U} + 2C_L\chi_{Lu}\frac{u(t)}{U};\quad M_b = C_M^{'}\chi_{Mw}\frac{w}{U} + 2C_M\chi_{Mu}\frac{u}{U} \tag{11a; b}$$

and the self-excited forces (or moment) induced by the bridge deck motions are expressed as

$$F_{L_s} = KH_1^*(K)\frac{\dot{h}}{U} + KH_2^*(K)\frac{B\dot{\alpha}}{U} + K^2H_3^*(K)\alpha + K^2H_4^*(K)\frac{h}{B};\quad M_s = KA_1^*(K)\frac{\dot{h}}{U} + KA_2^*(K)\frac{B\dot{\alpha}}{U} + K^2A_3^*(K)\alpha + K^2A_4^*(K)\frac{h}{B} \tag{12a; b}$$

where χ_{Lw}, χ_{Lu}, χ_{Mw} and χ_{Mu} are aerodynamic transfer functions (modulus is referred as aerodynamic admittance function) between wind fluctuations and buffeting forces (or moment), which are functions of K, wind angle of attack and deck shape; K=Bω/U is dimensionless reduced frequency with ω as circular frequency of bridge deck vibration; the coefficients $H_i^*(K)$ and $A_i^*(K)$ (i=1…4) are aeroelastic transfer function (flutter derivatives), which are also functions of K, wind angle of attack and deck shape.

2.5 *Hybrid model*

It should be noticed that it is intractable to determine the proper reduced wind velocity in the "corrected" quasi-steady theory. Therefore, usually only an unique value of the reduced velocity is utilized. In order to overcome this shortcoming of the corrected quasi-steady theory based model, band superposition model has been developed (Diana et al. 1995). However, this band superposition scheme is not easy to implement for the time-frequency mixed characteristics of the equations of motion and the measurement of the flutter derivatives under the incident wind condition with narrow-band turbulent fluctuations is not feasible. Besides, the interaction between each subrange cannot be considered. In order to further improve the "band superposition" scheme, a numerical analysis framework, which utilizes the rational function approximation scheme to obtain more efficient computational procedures, is proposed (Chen and Kareem 2003). Beside, this proposed scheme has a clear connection with the conventional linear analysis framework (here referred as semi-empirical linear model). This hybrid model simply combines "QS theory based model" and "semi-empirical linear model". Basically, the hybrid model linearizes the wind-induced force around a dynamic equilibrium angle of attack (or instantaneous angle of attack with low-frequency components) instead of a static angle of attack. Based on the hybrid model, the lift force and torsional moment per unit span in the global bridge axes are calculated by combining the forms of Eqs. (2) and Eqs. (10) and could be expressed as

$$F_y = -\frac{1}{2}\rho B\begin{Bmatrix} V_r^{l2}\left\{C_L(\alpha_e^l)\cos(\phi^l) + C_D(\alpha_e^l)\sin(\phi^l)\right\} \\ +U^2\left\{\left[C_L\right]+\left[F_{L_b}\right]+\left[-F_{L_s}\right]\right\}\Big|_{\alpha_e^l} \end{Bmatrix};\quad M_z = \frac{1}{2}\rho B^2\begin{Bmatrix} V_r^{l2}\left\{C_M(\alpha_e^l)\right\} \\ +U^2\left\{\left[C_M\right]+\left[M_b\right]+\left[M_s\right]\right\}\Big|_{\alpha_e^l} \end{Bmatrix} \tag{15a; b}$$

where superscript "l" indicate the low frequency part based on a pinpoint presupposed and

$$V_r^l = \sqrt{(U+u^l)^2 + (W+w^l+\dot{h}^l+m_1B\dot{\alpha}^l)^2};\quad \alpha_e^l = \alpha_s + \alpha^l + \phi^l;\quad \phi^l = \arctan\left(\frac{W+w^l+\dot{h}^l+m_1B\dot{\alpha}^l}{(U+u^l)}\right) \tag{17; 18; 19}$$

Theoretically, the parameters in high frequency part should be measured in the dynamic wind-tunnel tests with turbulent incident wind condition.

2.6 *Modified hybrid model (new)*

Typically, the "static" wind-tunnel tests are featured with the identification of steady-state coefficients while the "dynamic" wind-tunnel tests are featured with the identification of aerodynamic transfer functions or aeroelastic transfer functions in bridge aerodynamics/aeroelasticity. A convenient approach to describe the results from "static" and "dynamic" wind-tunnel tests is to utilize the similar parameters, namely, steady-state coefficients and dynamic-state coefficients, respectively. Both steady- and dynamic-state coefficients are nonlinear with respect to angle of attack, while the dynamic-state coefficients also presents the hysteretic loop feature. As the flutter derivatives (or aerodynamic admittances), the dynamic-state coefficients with hysteresis are dependent on the angle of attack of the equilibrium position and reduced wind velocity. Assume all the components of bridge deck motions and wind fluctuations have the equal weighting on the wind-bridge interaction behavior, as applied in QS theory based model, the bridge aerodynamic/aeroelastic behavior could be described utilizing the dynamic-state coefficients with hysteresis (Diana et al. 2010). However, this assumption is questionable and the error introduced by this assumption is not always acceptable. Some attempts of accounting for different weights for various components of the dynamic angle of attack is to use higher-order artificial neural network (ANN) (Wu and Kareem 2011a). However, as a nonparametric model it is difficult to elucidate the physical meaning of the various weighting functions employed in the ANN model. A critical issue when utilizing the dynamic-state coefficients in bridge aerodynamics/aeroelasticity is that it is very difficult to find a proper frequency to define the reduced wind velocity, especially when wind fluctuations involved. A feasible approach to deal with this issue is to determine an averaged frequency for defining the reduced wind velocity under each mean wind velocity. Another feasible way is to utilize the concept of "band superposition". Different reduced wind velocities could be defined at each subrange to apply the appropriate dynamic-state coefficients measured in wind tunnel. Besides, this approach could improve the hybrid model which compromises the consideration of unsteady effect in the low frequency part to account for the nonlinear turbulence effect on the aeroelastic instability. Based on the modified hybrid model, the lift force and torsional moment per unit span in the global bridge axes should be revised as

$$F_y=-\frac{1}{2}\rho B\begin{Bmatrix}U^2[C_L]+V_r^{I2}\left\{C_L^{hys}(\alpha_e^I)\cos(\phi^I)+C_D^{hys}(\alpha_e^I)\sin(\phi^I)\right\}\\ +V_r^{h_1\,2}\left\{C_L^{hys}(\alpha_e^{h_1})\cos(\phi^{h_1})+C_D^{hys}(\alpha_e^{h_1})\sin(\phi^{h_1})\right\}\Big|_{\alpha_e^I}\\ +\cdots\\ +V_r^{h_n\,2}\left\{C_L^{hys}(\alpha_e^{h_n})\cos(\phi^{h_n})+C_D^{hys}(\alpha_e^{h_n})\sin(\phi^{h_n})\right\}\Big|_{\alpha_e^I}\end{Bmatrix};\quad M_z=\frac{1}{2}\rho B^2\begin{Bmatrix}U^2[C_M]+V_r^{I2}\left\{C_M^{hys}(\alpha_e^I)\right\}\\ +V_r^{h_1\,2}\left\{C_M^{hys}(\alpha_e^{h_1})\right\}\Big|_{\alpha_e^I}\\ +\cdots\\ +V_r^{h_n\,2}\left\{C_M^{hys}(\alpha_e^{h_n})\right\}\Big|_{\alpha_e^I}\end{Bmatrix}\qquad (19a;\ b)$$

where superscript "hys" indicates the dynamic-state coefficients with hysteresis; "h_n" indicate the wind fluctuations of high frequency part are divided into n subranges, and

$$V_r^{h_n}=\sqrt{(U+u^{h_n})^2+(W+w^{h_n}+\dot{h}^{h_n}+m_1B\dot{\alpha}^{h_n})^2}\ ;\quad \alpha_e^{h_n}=\alpha_s+\alpha^{h_n}+\phi^{h_n}\ ;\quad \phi^{h_n}=\arctan\left(\frac{W+w^{h_n}+\dot{h}^{h_n}+m_1^{h_n}B\dot{\alpha}^{h_n}}{(U+u^{h_n})}\right)(20;\ 21;\ 22)$$

Due to a lack of the experimental data, only the dynamic-state coefficients with hysteresis in the subrange with low-frequency fluctuation components is utilized in this research.

3 RESPONSE ANALYSIS

In this section, the aeroelastic and aerodynamic responses of a long-span cable supported bridge have been calculated with the six models discussed in the preceding content. The time histories of wind fluctuations is simulated utilizing the spectral representation scheme with prescribed power spectral density (PSD) function and turbulence integral scales and intensities. Low-pass and high-pass elliptic filter are utilized to separate the wind fluctuation into low- and high- fre-

quency parts. The steady- and dynamic-state coefficients with angle of incidence are measured in wind tunnel and simulated based on the nonlinear least square and the Moore-Penrose pseudoinverse techniques, respectively. All the aerodynamic parameters in frequency domain are transferred into time domain based on the indicial function approximation.

3.1 *Aerodynamic analysis*

3.1.1 *Comparison of aerodynamic responses based on various models*

The aerodynamic responses of this bridge deck under turbulent wind condition are investigated based on the various models previously discussed. Fig. 2 presents the comparison of time histories of the calculated aerodynamic responses based on each model under the mean wind velocity 60 m/s with I_u=15% and I_w=8%.

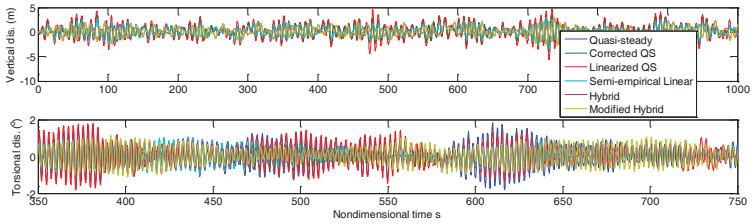

Figure 2. Time histories of the calculated responses based on each model.

Fig. 3 presents the root-mean-square (RMS) values of the vertical and torsional displacements. Since the semi-empirical linear model is the conventional model utilized for bridge aerodynmaics/aeroelasticity, it is treated as a reference model in this research. As discussed in the preceding section, for bridge aerodynamics/aeroelasticity, QS theory based model takes into account nonlinear effect but no fluid memory; corrected QS theory based model considers nonlinear effect with linear fluid memory at a fixed reduced frequency; linearized QS theory based model accounts for linear effect but no fluid memory; semi-empirical linear model considers linear effect with linear fluid memory; hybrid model considers nonlinear effect with linear fluid memory and modified hybrid model accounts for nonlinear effect with nonlinear memory (or higher-order memory featured by hysteresis).

Based on the results calculated by each model, in general it could be concluded that: (1) the aerodynamic responses based on the hybrid or modified hybrid models are close to the semi-empirical linear model, which indicates the nonlinearity or higher-order fluid memory effects captured by these two models in this case is small; (2) the aerodynamic responses based on the corrected QS model are closer to the semi-empirical linear model (larger for the vertical responses and smaller for the torsional responses in this case) compared to those based on the QS model, which indicates the corrected QS model could uncertainly improve the calculated responses by take into account the fluid memory at a fixed reduced frequency; (3) the fluid memory consideration has more significant effects on the torsional degree of freedom rather than the vertical degree of freedom as the relative difference between the torsional responses calculated by the linearized QS model and semi-empirical linear model is larger compared with the relative difference between the vertical responses; (4) the static nonlinearity consideration has more significant effects on the vertical degree of freedom rather than the torsional degree of freedom as the relative difference between the vertical responses calculated by the linearized QS model and QS theory based model is larger compared with the relative difference between the torsional responses. In a sense, the contribution to the aerodynamic responses from fluid memory effects is larger than that from nonlinear consideration based on this comparison. It should be noticed that the relative large torsional response based on the modified hybrid model is due in part to the contribution of

the limit cycle oscillation (LCO) response resulting from subcritical behavior, which indicates the aeroelastic instability resulting from the low-frequency part in the hybrid and modified hybrid models.

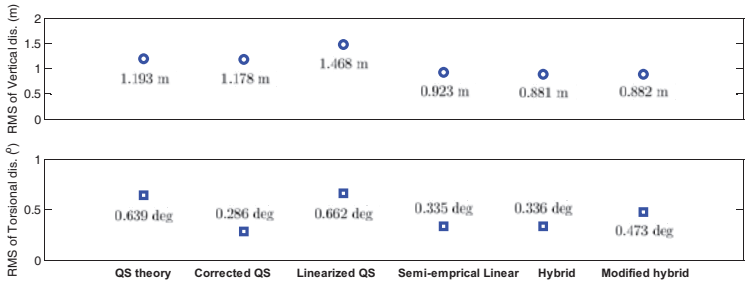

Figure 3. Aerodynamic responses under turbulent flow.

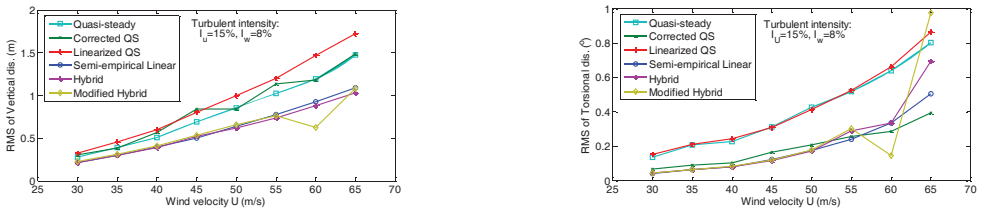
3.1.2 *Comparison of aerodynamic responses under various turbulent wind conditions*

Fig. 4 presents the RMS values of aerodynamics responses based on various models under different mean wind velocities with the turbulence intensity I_u=15% and I_w=8%.

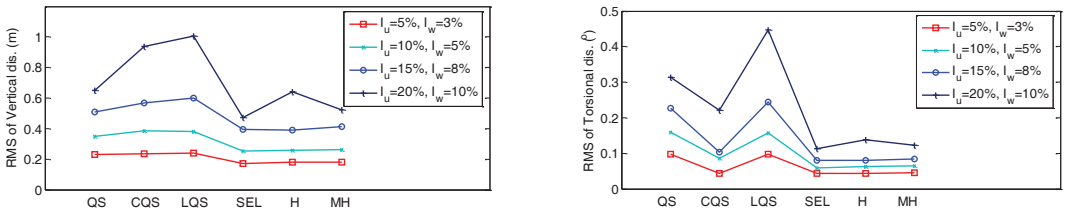


(a) RMS of vertical displacements (b) RMS of torsional displacements

Figure 4. RMS of various models under different wind velocity (I_w=8%).

As shown in this figure, it is obvious that these six model could be divided into two groups based on the calculated aerodynamic responses. One group cannot take into account the fluid memory effects (including QS theory based and linearized QS models) and the other group could account for the fluid memory effects (including semi-empirical linear, hybrid and modified hybrid models), while capability of the reasonable consideration for the fluid memory based on the corrected QS model is uncertain. The results based on no memory consideration group are obviously larger than those based on memory consideration group, which indicates the fluid memory effect consideration reduces the aerodynamic responses at various wind velocities. On the other hand, the hybrid model based results are close to those calculated from the semi-empirical linear model, which indicates that the hybrid model may not fully characterize the nonlinear effects at various wind velocities. Besides, the comparison of the responses based on QS theory and linearized QS theory at various wind velocities indicates that the static nonlinearity (without coupling fluid memory effect) has significant effects on the vertical aerodynamic responses at various wind velocity while it has less effects on the torsional responses in this case. However, it is not necessary that this observation is also applicable for the dynamic nonlinearity effects (with coupling fluid memory effect). The differences of the results based on various models are more significant at higher wind velocity. The ripples in the corrected QS theory based result at some wind velocities are due to the relatively intense change of the correct coefficient k_1 while the large oscillations of the modified hybrid based results at wind velocity 60 m/s and 65 m/s is due to the subcritical behaviors. It should be noted that the observations discussed in the preceding content is based on that all other models are compared with the selected reference model, i.e., the semi-empirical model, which may not provide the "true" answer for the bridge aerodynamics/aeroelasticity.

Fig. 5 presents the RMS values of aerodynamic responses based on various models under different turbulence intensities with the mean wind velocity 40 m/s. As indicated in this figure, in general the incremental values of the aerodynamic responses based on the models which can consider the fluid memory effect are less than those based on the models which cannot account for the fluid memory effect. Besides, as the turbulence intensity is larger than 15%, there is intense nonlinear increases of the aerodynamic responses for most of models.

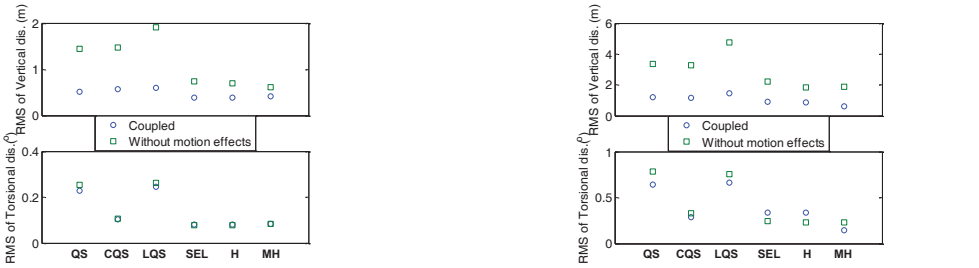


(a) RMS of vertical displacements (b) RMS of torsional displacements

Figure 5. RMS of various models under different turbulent conditions (U=40 m/s).

3.1.3 *Motion induced effects on the aerodynamic responses*

It is well known that the motion induced effects will change the effective structural dynamic parameters (mass, stiffness and damping ratio) and hence affect the aerodynamic responses. The aerodynamic responses discussed in the preceding content actually involves the aeroelastic effects. In order to investigate the motion induced effects on the aerodynamic responses for various models, the aerodynamic responses coupled with the aeroelastic responses are compared with the aerodynamic responses neglecting the motion induced effects as shown in the Fig. 6.



(a) RMS of vertical displacements (U=40 m/s) (b) RMS of torsional displacements (U=60 m/s)

Figure 6. RMS of aerodynamic responses (I_u=15%, I_w=8%) neglecting motion induced effects.

It is obvious that the motion induced effects are larger when the wind velocity increases. It seems there are more significant motion induced effects in the vertical degree of freedom in this case. In general, the motion induced effects will reduce the aerodynamic responses. However, for the torsional responses based on the semi-empirical linear and hybrid models the motion induced effects increase the aerodynamic responses. The errors of neglecting the motion induced effect for the aerodynamic responses based on the no memory consideration models are larger than those for the aerodynamic responses based on the memory consideration models.

3.2 *Aeroelastic analysis*

3.2.1 *Critical flutter wind velocities*

The stability issue is critical in bridge aeroelasticity as most researchers have attribute the catastrophic failure of the Tacoma Narrows Bridge to flutter behavior, which is a typical phenomenon of the bridge aeroelastic instability. Fig. 7 presents the critical flutter wind velocities U_{cr} cal-

culated utilizing these six models under the uniform wind condition. Based on the calculated U_{cr} of various models, in general it could be concluded that: (1) the linear memory effect consideration could increase the aeroelastic response (reduce the critical wind velocity of instability) since the U_{cr} calculated by linearized QS theory based model (no memory) is larger than semi-empirical linear model (linear memory); (2) the nonlinear memory effect consideration could reduce the aeroelastic response (increase the critical wind velocity of instability) since the U_{cr} calculated by modified hybrid model (nonlinear memory) is larger than hybrid model (linear memory); (3) the nonlinear effect consideration involved in the hybrid scheme could reduce the aeroelastic response (increase the critical wind velocity of instability) since the U_{cr} calculated by hybrid model (nonlinear) is larger than semi-empirical linear model (linear). In a sense, the contribution to the aeroelastic response from fluid memory effect is larger than that from nonlinear consideration based on the comparison of the results of these models. However, it should be noticed that while the fluid memory effect (especially linear) is considered well through the unsteady parameters (e.g., flutter derivatives) the nonlinear effects are not fully characterized with an appropriate approach.

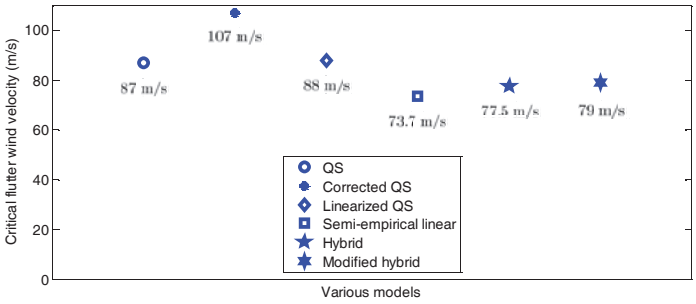


Figure 7. Critical flutter wind velocity under uniform flow.

3.2.2 *Turbulence effects on the instability*

Suppose the turbulence effects on instability are considered in two aspects: the effect on the nonlinearity and the effect on the fluid memory. As the linearized QS model cannot take into account either nonlinearity or fluid memory, the turbulence will not affect the instability based on the linearized QS model. However, though the semi-empirical linear model could take into account the fluid memory effect, the turbulence effects will not significantly change the instability based on this model since the aerodynamic and aeroelastic responses are simply summed based on the superposition theory. Generally, the turbulence consideration will increase the critical flutter wind velocities as its effects on the nonlinearity have more significant contribution on the aeroelastic responses, which is demostrated in the results based on the QS and corrected QS models as shown in Fig. 8. This observation indicates the turbulence effects reduce the aeroelastic responses due to static nonlinearity. On the other hand, if the turbulence effects on the fluid memory have more significant contribution on the aeroelastic responses, the situation becomes more complicated. In this situation, the turbulent fluctuations will reduce the critical flutter wind velocities generally. However, as the turbulence intensity increases, the critical flutter wind velocities slightly increase, as demostrated in the results based on the hybrid and modified hybrid models. This observation indicates the turbulence effects increases the aeroelastic responses due to fluid memory, and this effect is larger for the smaller turbulence intensity. Another possible mechanism for this complicated situation in the hybrid and modified hybrid models is that the turbulence effect on the nonlinearity involved in these model increase significantly as the turbulence intensity becomes larger, which results in the slight increase of the critical flutter wind velocities compared to those with smaller turbulence intensity. Besides, the higher-order fluid memory consideration will significantly reduce the instability based on QS

theory as the subcritical wind velocity in the modified hybrid model is 53 m/s under the uniform inflow condition while that in the hybrid model is 87 m/s. On the other hand, the low-frequency components of the wind fluctuations with small turbulence intensity (e.g., I_u=5%) will slightly change (either reduce or increase) the subcritical wind velocity (from 53 m/s to 52 m/s in the modified hybrid model and from 87 m/s to 88 m/s in the hybrid model) while the low frequency components of the wind fluctuations with larger turbulence intensity (e.g., I_u=15%) will increase the subcritical wind velocity (from 53 m/s to 59 m/s in the modified hybrid model and from 87 m/s to 91 m/s in the hybrid model).

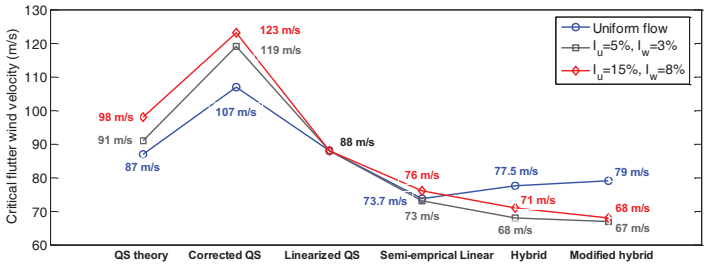

Figure 8. Critical wind velocity under various inflow conditions.

4 CONCLUDING REMARKS

Six models for bridge aerodynamics/aeroelasticity, namely the QS theory based model (nonlinear effect but no fluid memory), the corrected QS theory based model (nonlinear effect with linear fluid memory at a fixed reduced wind velocity), the linearized QS theory based model (linear effect but no fluid memory), the semi-empirical linear model (linear effect with linear fluid memory), the hybrid model (nonlinear effect with linear fluid memory) and the modified hybrid model (nonlinear effect with nonlinear fluid memory), are investigated in detail. It is noted that the consideration of the linear and nonlinear unsteadiness (fluid memory) and the nonlinearity in the wind-bridge interaction significantly changes the bridge aerodynamic/aeroelastic responses.

A new state-space model for self-exited forces and straight forward analysis of bridge deck flutter

Zeng-wei Guo [a], Yao-jun Ge [a]

[a] *State Key Laboratory of Disaster Reduction in Civil Engineering, Tongji Univercity, Shanghai, China*

ABSTRACT: Self-exited forces of bridge can be expressed in state space domain according to the state space description of dynamic system in modern control theory, and its formulation is depended on rational functions for approximating aerodynamic transfer function. In order to discuss time and frequency-domain response characteristics of state space formulation of self-exited force, flutter analysis of a simple supported beam with idealized thin plane section is conducted in frequency and time domain simultaneous, using the Roger's and Karpel's rational function approximations for aerodynamic transfer function. It is observed that frequency-response characteristics of the two formulations are both favorable, although flutter results based on Karpel's rational function approximations are more sensitive to residual of flutter derivatives. Besides, time-response characteristics of the two formulations are similar. As a result of unknown initial conditions of the aerodynamic state, structural response may be erroneous in first time period, which can be solved by restricting the lower limit of the aerodynamic parameters associated with aerodynamic states.

KEYWORDS: bridge, flutter, state-space, self-excited force, time and frequency characteristic.

1 INTRODUCTION

Flutter instability is one of the critical concerns for design and construction of long span bridges since it may lead bridge deck to oscillate divergently at some critical wind speed, and eventually result in a total collapse of structure. Since the collapse of Tacoma Narrow Bridge in 1940, great effort has been made to clarify the generation mechanism of this catastrophic aerodynamic behavior of bridge deck. Scanlan primarily proposed a formulation of self-excited force in terms of structural motions and introduced flutter derivatives to describe its unsteady fluid memory effect(Scanlan and Tomko, 1971). Subsequently, massive flutter analysis procedures through multimode or full mode technique have been developed based on this formulation (Ding et al, 2002b; Dung et al, 1998; Ge and Tanaka, 2000; Jain et al, 1996). These procedures must be conducted in frequency domain, since flutter derivatives obtained from sectional model wind tunnel tests are frequency dependent. However, Structural nonlinearities and turbulence effects, which may be prominent for long span bridges, cannot be considered in the frequency-domain analysis. It is necessary to cast the self-excited forces and governing equations of motion in the time domain to take account for structural nonlinearities and turbulence effects in flutter analysis. Corresponding to flutter derivatives, time-domain self-excited forces were expressed in terms of convolution integrals of impulse functions or indicial functions to take into account the effect that self-excited force variation lags behind structural motions. Most researchers (Caracoglia and Jones, 2003; Chen and Kareem, 2002; Costa and Borri, 2006; Wilde and Fujino, 1998) have dealt with convolution integrals of impulse or indicial functions using the following two methods: (1) adopting recursive algorithm similar to the famous Newmark-β method, (2) introducing additional aerodynamic state to represent this convolution integral and proposing state-space formulations.

The assessment of self-excited force in the time domain requires identification of aerodynamic impulse or indicial response functions. However, there are no theoretical solutions of the-

se functions for bluff bridge decks and it is also difficult to determinate these functions directly in wind tunnel tests. In aerospace engineering, Roger approximated the frequency-dependent Theodorsen function in terms of rational functions, and transformed the frequency-dependent aeroealstic forces of airplane into time domain based on the inverse Laplace transform. Analogously, these aerodynamic impulse or indicial response functions for bluff bridge sections can be determined by means of the inverse Laplace transform of Scanlan's formulation, if flutter derivatives can be approximated with continuous functions. Lin introduced rational functions for approximating flutter derivatives in bridge engineering(Lin and Yang, 1983), and there were mainly two formulations for these rational functions, which were noted as Roger's formulation and Karpel's formulation. However, time and frequency response characteristics of self-excited force state space model, which may influence the flutter analysis result both in frequency and time domain, have never been discussed in literatures.

The present paper derives the governing equations of flutter in state space domain based Roger's and Karpel's rational function approximations, and discusses their differences. Taking a simple supported beam with idealized thin plane section as example, we clarify the time and frequency response characteristics of these two state space model of self-excited force.

2 STATE-SPACE FORMULATIONS OF SELF-EXCITED FORCE

For complex sinusoidal motions with circular frequency ω, the self-excited forces per unit length are commonly expressed in terms of flutter derivatives as (Scanlan, 2001):

$$L = \frac{1}{2}\rho U^2 B\left(KH_1^* \frac{\dot{h}}{U} + KH_2^* \frac{B\dot{\alpha}}{U} + K^2 H_3^* \alpha + K^2 H_4^* \frac{h}{B} + KH_5^* \frac{\dot{p}}{U} + K^2 H_6^* \frac{p}{B} \right) \tag{1a}$$

$$D = \frac{1}{2}\rho U^2 B\left(KP_1^* \frac{\dot{p}}{U} + KP_2^* \frac{B\dot{\alpha}}{U} + K^2 P_3^* \alpha + K^2 P_4^* \frac{p}{B} + KP_5^* \frac{\dot{h}}{U} + K^2 P_6^* \frac{h}{B} \right) \tag{1b}$$

$$M = \frac{1}{2}\rho U^2 B^2\left(KA_1^* \frac{\dot{h}}{U} + KA_2^* \frac{B\dot{\alpha}}{U} + K^2 A_3^* \alpha + K^2 A_4^* \frac{h}{B} + KA_5^* \frac{\dot{p}}{U} + K^2 A_6^* \frac{p}{B} \right) \tag{1c}$$

where ρ=air mass density; U=wind velocity; B= bridge deck width; $K=\omega B/U$=reduced frequency; H^*i, A^*i, P^*i(i=1,2,⋯6)=frequency dependent flutter derivative; h, p, α=vertical, lateral and pitching displacement respectively, and the head dot denotes partial differentiation with respect to time t.

By taking the Laplace transform of Eq. (1), the self-excited force formulated utilizing flutter derivatives can be given in a matrix form by

$$\tilde{\mathbf{F}}_{se} = \frac{1}{2}\rho U^2 \mathbf{b}^T \mathbf{Q} \mathbf{b} \tilde{\mathbf{\Delta}} \tag{2}$$

where $\tilde{\mathbf{F}}_{se} = \begin{Bmatrix} \tilde{L} \\ \tilde{D} \\ \tilde{M} \end{Bmatrix}$; $\mathbf{b} = \begin{bmatrix} 1 & & \\ & 1 & \\ & & B \end{bmatrix}$; $\tilde{\mathbf{\Delta}} = \begin{Bmatrix} \tilde{h} \\ \tilde{p} \\ \tilde{\alpha} \end{Bmatrix}$; $\mathbf{Q} = \begin{bmatrix} K^2 H_4^* + pKH_1^* & K^2 H_6^* + pKH_5^* & K^2 H_3^* + pKH_2^* \\ K^2 P_6^* + pKP_5^* & K^2 P_4^* + pKP_1^* & K^2 P_3^* + pKP_2^* \\ K^2 A_4^* + pKA_1^* & K^2 A_6^* + pKA_5^* & K^2 A_3^* + pKA_2^* \end{bmatrix}$

=aerodynamic transfer function; $p=sB/U$, $s=(\xi+i)\omega$, ξ=damping ratio; the superscript indicates the Laplace transformation superscripts.

Approximation of unsteady aerodynamics forces as continuous rational functions allows self-excited forces to be cast in state space realization. The most common forms of these approximating functions used currently in bridge engineering for aerodynamic transfer matrix Q are(Chen and Kareem, 2002; Wilde and Fujino, 1998):

$$\hat{\mathbf{Q}} = \mathbf{A}_1 + \mathbf{A}_2 p + \mathbf{A}_3 p^2 + \sum_{l=1}^{m} \frac{\mathbf{A}_{l+3} p}{p + \lambda_l} \quad \text{(Roger's formulation)} \tag{3a}$$

$$\hat{\mathbf{Q}} = \mathbf{A}_1 + \mathbf{A}_2 p + \mathbf{A}_3 p^2 + \mathbf{D}\left(p\mathbf{I} + \mathbf{\Lambda}\right)^{-1}\mathbf{E}p \quad \text{(Karpel's formulation)} \tag{3b}$$

Where $\mathbf{Q}$ =rational function approximation of aerodynamic transfer function $\mathbf{Q}$; $\mathbf{A}_1,\ldots\mathbf{A}_{l+3}$, $\mathbf{D}$, $\mathbf{E}$, $\mathbf{\Lambda}$, $\lambda_1,\ldots\lambda_m$=frequency-independent ration function coefficients; m indicates the number of the partial fractions.

By defining the partial fractions as follows:

$$\tilde{\mathbf{\Phi}}_{se,l} = \frac{\mathbf{b}^T\mathbf{A}_{l+3}\mathbf{b}}{p+\lambda_l}\left(p\tilde{\mathbf{\Delta}}\right) \quad \text{(Roger's formulation)} \tag{4a}$$

$$\tilde{\mathbf{\Phi}}_{se} = \left(p\mathbf{I} + \mathbf{\Lambda}\right)^{-1}\mathbf{E}\mathbf{b}\left(p\tilde{\mathbf{\Delta}}\right) \quad \text{(Karpel's formulation)} \tag{4b}$$

and substituting Eq. (3) and (4) into Eq. (2), subsequently inverse Laplace transform of Eq. (4), the following state space formulation of self-excited forces can be obtained:

$$\begin{Bmatrix}\mathbf{F}_{se}\\ \mathbf{0}\\ \mathbf{0}\\ \mathbf{0}\end{Bmatrix} = \frac{1}{2}\rho U^2\left(\begin{bmatrix}\mathbf{b}^T\mathbf{A}_1\mathbf{b} & \frac{B}{U}\mathbf{b}^T\mathbf{A}_2\mathbf{b} & \mathbf{I} & \mathbf{I} & \mathbf{I}\\ & & \frac{\lambda_1 U}{B}\mathbf{I} & & \\ & & & \ddots & \\ & & & & \frac{\lambda_l U}{B}\mathbf{I}\end{bmatrix}\mathbf{X}_R + \begin{bmatrix}\mathbf{0} & \left(\frac{B}{U}\right)^2\mathbf{b}^T\mathbf{A}_3\mathbf{b} & \mathbf{0} & \mathbf{0} & \mathbf{0}\\ -\mathbf{b}^T\mathbf{A}_4\mathbf{b} & & \mathbf{I} & & \\ \vdots & & & \ddots & \\ -\mathbf{b}^T\mathbf{A}_{l+3}\mathbf{b} & & & & \mathbf{I}\end{bmatrix}\dot{\mathbf{X}}_R\right)$$

(Roger's formulation) (5a)

$$\begin{Bmatrix}\mathbf{F}_{se}\\ \mathbf{0}\end{Bmatrix} = \frac{1}{2}\rho U^2\left(\begin{bmatrix}\mathbf{b}^T\mathbf{A}_1\mathbf{b} & \frac{B}{U}\mathbf{b}^T\mathbf{A}_2\mathbf{b} & \mathbf{b}^T\mathbf{D}\\ \mathbf{0} & \mathbf{0} & \frac{U}{B}\mathbf{\Lambda}\end{bmatrix}\mathbf{X}_K + \begin{bmatrix}\mathbf{0} & \left(\frac{B}{U}\right)^2\mathbf{b}^T\mathbf{A}_3\mathbf{b} & \mathbf{0}\\ -\mathbf{E}\mathbf{b} & \mathbf{0} & \mathbf{I}\end{bmatrix}\dot{\mathbf{X}}_K\right) \text{(Karpel's formulation)} \tag{5b}$$

Additional aerodynamic states are introduced to express the aerodynamic phase lag behind structural motions. Obviously, addition of each partial fraction for approximating flutter derivatives may result in an additional new aerodynamic state in the state space equations of bridge deck flutter. Since there are three nonzero components of each nodal self-excited force vector, the number of additional aerodynamic state may be 3m and m for Roger's formulation and Karpel's formulation respectively. For Roger's formulation, variance of each aerodynamic state influences only one self-excited force component, and each self-excited force component is determined by only m independent aerodynamic states. However, for Karpel's formulation, variance of each aerodynamic state may influence all self-excited force components, and each self-excited force component may be influenced by all aerodynamic states.

3 FLUTTER ANALYSIS BY STATE SPACE APPROACH

The governing equations of flutter of a bridge deck in the smooth flow are given in matrix form as:

$$\mathbf{M}\ddot{\mathbf{Y}} + \mathbf{C}\dot{\mathbf{Y}} + \mathbf{K}\mathbf{Y} = \mathbf{F}_{se} \tag{6}$$

where $\mathbf{M}$, $\mathbf{C}$, and $\mathbf{K}$=mass, damping, stiffness matrices, respectively; $\mathbf{Y}$=nodal displacement vector; $\mathbf{F}_{se}$= nodal self-excited force vector.

Substituting Eq. (5) into Eq. (6) yields the following state space equations in flutter analysis

$$\dot{\mathbf{X}} = \mathbf{A}\mathbf{X} \tag{7}$$

where A=system matrix, for Roger's formulation, $\mathbf{A} = \begin{bmatrix}\mathbf{0} & \mathbf{I} & \mathbf{0} & \cdots & \mathbf{0}\\ -\bar{\mathbf{M}}^{-1}\bar{\mathbf{K}} & -\bar{\mathbf{M}}^{-1}\bar{\mathbf{C}} & \frac{1}{2}\rho U^2\bar{\mathbf{M}}^{-1} & \cdots & \frac{1}{2}\rho U^2\bar{\mathbf{M}}^{-1}\\ \mathbf{0} & \mathbf{b}^T\mathbf{A}_4\mathbf{b} & \frac{\lambda_1 U}{B}\mathbf{I} & \cdots & \mathbf{0}\\ \vdots & \vdots & \vdots & \ddots & \vdots\\ \mathbf{0} & \mathbf{b}^T\mathbf{A}_{m+3}\mathbf{b} & \mathbf{0} & \cdots & \frac{\lambda_m U}{B}\mathbf{I}\end{bmatrix}$,

and for Karpel's formulation of approximating flutter derivatives $\mathbf{A}=\begin{bmatrix} \mathbf{0} & \mathbf{I} & \mathbf{0} \\ -\bar{\mathbf{M}}^{-1}\bar{\mathbf{K}} & -\bar{\mathbf{M}}^{-1}\bar{\mathbf{C}} & \frac{1}{2}\rho U^2\bar{\mathbf{M}}^{-1}\mathbf{b}^T\mathbf{D} \\ \mathbf{0} & \mathbf{Eb} & -\frac{U}{B}\mathbf{\Lambda} \end{bmatrix}$;

$\mathbf{X}=\begin{Bmatrix}\mathbf{Y} & \dot{\mathbf{Y}} & \mathbf{X}_{se}\end{Bmatrix}^T$; $\bar{\mathbf{K}}=\mathbf{K}-\frac{1}{2}\rho U^2\mathbf{b}^T\mathbf{A}_1\mathbf{b}$; $\bar{\mathbf{C}}=\mathbf{C}-\frac{1}{2}\rho UB\mathbf{b}^T\mathbf{A}_2\mathbf{b}$; $\bar{\mathbf{M}}=\mathbf{M}-\frac{1}{2}\rho B^2\mathbf{b}^T\mathbf{A}_3\mathbf{b}$.

Flutter analysis can be conducted in both frequency and time domain using this preceding frequency independent state space equation.

3.1 *Flutter analysis in frequency domain*

Flutter analysis in frequency domain can be converted to be an algebraic eigenvalue problem, since real part of each complex eigenvalues of system matrix **A** indicates the logarithm decay rates of corresponding modal of structure, which represents its dynamic stability. As the system matrix **A** is frequency independent and parameterized only by wind velocity, complex analysis can be carried out straightforward without frequency iterative to determine the critical flutter wind speed.

The diagonal elements of system matrix **A** determine the behavior of structural states and aerodynamic states, and the non-diagonal elements represent coupling effects between structural states and aerodynamic states. If wind speed is not so high, the coupling effects between structure and fluid may be not significant, the non-diagonal terms of system matrix A are close to zero and A can be appropriately considered to a diagonal matrix. Therefore, eigenvalues of **A** generally consist of 2*n* complex-conjugate pairs of eigenvalues corresponding to structure itself and *m* real values corresponding to aerodynamic states, since structural governing equations are second order differential equations, while governing equations of aerodynamic states are of first order. However, if wind speed is close to critical flutter wind velocity, aeroelastic effects may be significant and the non-diagonal elements are far from zero, so some eigenvalues corresponding to aerodynamic states may become complex, which may be mixed up with structural eigenvalues. Therefore, the inherent eigenvalues corresponding to structure should be sorted out in flutter analysis in frequency domain (Xie and Xiang, 1985).

We identify structural inherent eigenvalues based on the fact that natural mode shape of structures may not change a lot at different wind velocities, especially at two adjacent wind speeds. The procedures of identification of structural inherent eigenvalues at a certain wind speed can be summarized as follows:

(1) Conduct structural damped eigenvalue analysis at zero wind speed, and sort the eigenvalues and their corresponding eigenvectors according to the image part of eigenvalues in descending order, and then store the first *n* complex eigenvalues $\mathbf{\Lambda}_0$ and their corresponding eigenvectors $\mathbf{\Phi}_0$ as structural inherent eigenvalues and eigenvectors.

(2) Assume a wind speed increment ΔU, and set current wind speed $U_i=i*\Delta U$ (i=1,⋯n).

(3) Carry out damped eigenvalue analysis at current wind speed U_i, and hunt for the first *n* natural eigenvectors of structure in sequence according to the sorted structural eigenvectors $\mathbf{\Phi}_{i-1}$ using an evaluating indicator of mode similarity *MSI*, which is defined as

$$MSI=\frac{\left(\mathbf{\Theta}_{j,i}^T\mathbf{\Phi}_{j,i-1}\right)^2}{\left(\mathbf{\Theta}_{j,i}^T\mathbf{\Theta}_{j,i}\right)\left(\mathbf{\Phi}_{j,i-1}^T\mathbf{\Phi}_{j,i-1}\right)} \tag{8}$$

Where $\mathbf{\Phi}_{j,i-1}$=the *j*th column of sorted eigenvectors $\mathbf{\Phi}_{i-1}$ at wind speed U_{i-1}, $\mathbf{\Theta}_{j,i}$=the *j*th column of unsorted eigenvectors $\mathbf{\Phi}_{i-1}$ at wind speed U_i, and the superscript ^{T} indicates vectors or matrix transpose.

(4) Sort the identified structural eigenvalues and their corresponding vectors according to $\mathbf{\Phi}_{i-1}$ at wind speed U_{i-1}, and store the structural eigenvalues $\mathbf{\Lambda}_i$ and eigenvectors $\mathbf{\Phi}_i$ at current wind speed.

If real parts of structural eigenvalues are all negative bridge will be dynamically stable, and if real part of any structural eigenvalue is positive bridge will be dynamically unstable. So the critical flutter wind speed can be defined as the wind velocity at which bridge system has only one eigenvalue λ with zero real part, and the imaginary part of this complex eigenvalue λ is flutter circular frequency.

3.2 *Flutter analysis in time domain*

Flutter analysis can also be conducted in time domain, in which structural and aerodynamic nonlinearities may be incorporated. In the present paper, buffeting force caused by the turbulence existing inherently in natural wind in conjunction with the structural-induced signature turbulence is not considered, and it is taken for granted that governing equation of bridge deck flutter (Eq. (6)) is homogeneous. Free vibration response to a certain initial condition of structure can be readily obtained by any time integration scheme, and subsequently damping ratio can be determined. Flutter instability of bridge deck will be happened when free vibration amplitude is constant or even increasing with time. The initial condition of structure should be given according to its flutter mode shape in order to seek out the critical flutter wind speed more precisely, with the reason that free vibration amplitude might be still decay with time at some wind speed a little larger than critical flutter wind speed with improper initial condition.

4 CASE STUDY

In this section, a simply supported line-like bridge with thin-airfoil cross section is taken as a case study. Since theoretical solution of flutter frequency and flutter wind velocity for this structure is available, this example can be used to verify the state space approach of flutter analysis and investigate the time and frequency domain response characteristics of two state-space formulations of self-excited force. The structural parameters are as follows: span l=300m; width of the bridge deck B=40m; vertically bending rigidity EI_z=2.1×10^{6}MPam^4; laterally bending rigidity EI_y=1.8×10^{7}MPam^4; torsional rigidity GI_t=4.1×10^{5}MPam^4; mass m=20,000kg/m; mass moment of inertia I_m=4.5×10^{6}kgm^2/m and air mass density ρ=1.248kg/m^3. The structural damping is not considered in this example to make a theoretical comparison.

Theodorson functions have been adopted for expressing self-excited forces acting on this simply supported bridge with thin-airfoil cross section, and it should be approximated by rational function firstly before flutter analysis with state space approach. The aerodynamic coefficients in rational function approximation are obtained by minimizing the optimization target J, which is defined as:

$$J\left(A_l,\lambda_l\right)=\sum_{i=1}^{N}w_i\left\|\mathbf{Q}_{\mathrm{Re}}\left(\nu_i\right)-\hat{\mathbf{Q}}_{\mathrm{Re}}\left(\nu_i\right)\right\|_F+\sum_{i=1}^{N}w_i\left\|\mathbf{Q}_{\mathrm{Im}}\left(\nu_i\right)-\hat{\mathbf{Q}}_{\mathrm{Im}}\left(\nu_i\right)\right\|_F \tag{9}$$

where $\mathbf{Q}_{\mathrm{Re}}=\begin{bmatrix}H_4^* & H_3^*\\ A_4^* & A_3^*\end{bmatrix}$, $\mathbf{Q}_{\mathrm{Im}}=\begin{bmatrix}H_1^* & H_2^*\\ A_1^* & A_2^*\end{bmatrix}$ = real and image part of aerodynamic transfer function, respectively ; $\hat{\mathbf{Q}}_{\mathrm{Re}}=\left(\frac{\nu}{2\pi}\right)^2\mathbf{A}_1-\mathbf{A}_3+\sum_{l=1}^{m}\mathbf{A}_{l+3}\frac{\nu^2}{\lambda_l^2\nu^2+4\pi^2}$, $\hat{\mathbf{Q}}_{\mathrm{Im}}=\frac{\nu}{2\pi}\mathbf{A}_2+\sum_{l=1}^{m}\mathbf{A}_{l+3}\frac{\lambda_l\nu^3}{2\pi\lambda_l^2\nu^2+8\pi^3}$ = real and image part of Roger's rational function approximation of aerodynamic transfer function, respectively; $\hat{\mathbf{Q}}_{\mathrm{Re}}=\left(\frac{\nu}{2\pi}\right)^2\mathbf{A}_1-\mathbf{A}_3+\nu^2\mathbf{D}\left(4\pi^2\mathbf{I}+\mathbf{\Lambda}^2\nu^2\right)^{-1}\mathbf{E}$, $\hat{\mathbf{Q}}_{\mathrm{Im}}=\frac{\nu}{2\pi}\mathbf{A}_2+\nu^3\mathbf{D}\left(8\pi^3\mathbf{I}+2\pi\nu^2\mathbf{\Lambda}^2\right)^{-1}\mathbf{\Lambda E}$ = real and

ly; $\hat{\mathbf{Q}}_{\mathrm{Re}} = \left(\frac{\nu}{2\pi}\right)^2 \mathbf{A}_1 - \mathbf{A}_3 + \nu^2 \mathbf{D}\left(4\pi^2\mathbf{I} + \mathbf{\Lambda}^2\nu^2\right)^{-1}\mathbf{E}$, $\hat{\mathbf{Q}}_{\mathrm{Im}} = \frac{\nu}{2\pi}\mathbf{A}_2 + \nu^3\mathbf{D}\left(8\pi^3\mathbf{I} + 2\pi\nu^2\mathbf{\Lambda}^2\right)^{-1}\mathbf{\Lambda E}$ = real and image part of Karpel's rational function approximation of aerodynamic transfer function, respectively; M = the number of elements in aerodynamic matrix Q; n = the number of reduced wind velocity; w_i= weight factor; $\|\cdot\|_F$=F norm of matrix.

Simulated annealing algorithm is applied to solve this optimization problem, and the rational function coefficients of two formulations extracted by approximating Theodorson functions with reduced wind velocity ranging from 0 to 20 are listed in Table 1.

Table 1 Rational function coefficients extracted by approximating Theodorson functions

Figure 1 gives the comparison of flutter derivatives based on Theodorson function and its rational function approximation results. It is shown that four groups of aerodynamic coefficients in table 1 can all accord well with flutter derivatives.

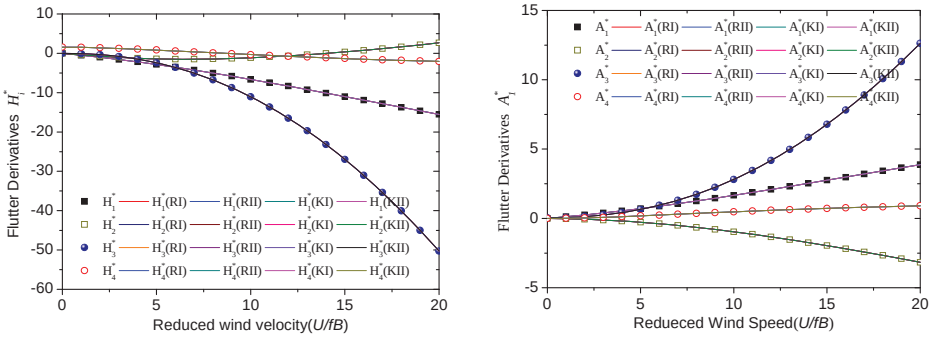

Figure 1 Rational function approximation of flutter derivatives

Applying the aerodynamic coefficients listed in Table 1 and following the identification procedures of structural inherent eigenvalues described in section 3.1, damped complex eigenvalue analysis is conducted under wind velocities from 0 to 150m/s. The critical flutter wind speed and flutter frequencies of this simple supported beam with four groups of rational function coefficients are given in Table 2.

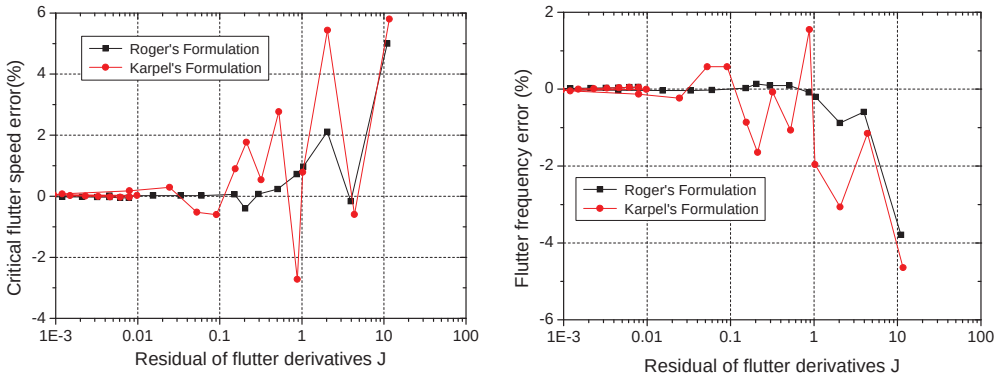
Table 2 Flutter analysis results of the simply supported beam with four groups of rational function coefficients

	Theoretical solutio	Flutter derivatives	Roger I	Roger II	Karpel I	Karpel II
Critical flutter speed(m/s)	139.90	139.79	139.79	139.72	139.86	139.75
Flutter frequency (Hz)	0.3801	0.3800	0.3800	0.3802	0.3799	0.3802

Apparently, critical flutter wind speed and flutter frequency using state space approach with four groups of coefficients are almost the same as the theoretical solution and full order solution (Ding et al, 2002a)directly using flutter derivatives. Choosing group I coefficients of Roger's formulation as an example, the first 10 conjugate pairs of structural complex eigenvalues and complex eigenvectors are also obtained, and the variation of these complex eigenvalues versus wind velocity is plotted in Fig. 1. It is observed that (i) the vibration frequencies of modes except for the first torsional and vertical modes all alert little or even remain unchanged with the increase in wind velocity; (ii) for the first vertical and torsional mode, the frequency increases and decreases in the wind velocity range, respectively; (iii) the vibration damping of first torsional mode firstly increases and then decreases with increasing wind velocities, while damping of the other modes with increasing wind velocities. As shown in Fig. 1(b), the damping of first torsional mode becomes zero at a wind velocity of 139.79 m/s, and the corresponding torsional frequency becomes 0.3940 Hz, namely flutter frequency.

4.1 *Frequency-domain response characteristics of two formulations*

As it is still difficult to identify aerodynamic coefficients in rational function approximation of aerodynamic transfer function of self-excited forces directly in wind tunnel test, these aerodynamic coefficients are usually obtained by fitting flutter derivatives. However, this rational function approximation of aerodynamic transfer function cannot fit flutter derivatives without residual. Precision of flutter analysis results may be determined by frequency response characteristics of two formulations and fitting residual. In order to investigate frequency response characteristics of two formulations, we chose 22 groups of aerodynamic coefficients for two formulations with fitting residual ranging from 1.0×10^{-3} to 10.0 to conduct flutter analysis in frequency domain by state-space approach. For each group of aerodynamic coefficients, the initial iterative values and stopping criteria are identical and ultimate residual is in the same level for both two state-space formulations to confirm that the difference between flutter analyses results based on two formulations is not induced by self-difference of aerodynamic coefficients. Fig. 3 gives the variation of flutter analysis results to approximation residual of flutter derivatives, in which the relative errors of critical flutter wind speed and flutter frequencies are compared with that of full order solution directly using flutter derivatives, not with theoretical solution. It is observed that (i) relative errors of critical flutter wind speed and flutter frequency for both two formulations are no larger than 10% even for approximation residual larger than 10.0; (ii) the flutter analysis results based on Karpel's formulation are more sensitive to approximation errors than that of Roger's formulation although the number of additional aerodynamic states introduced in Karpel's formulation is half of Roger's formulation.



(a) critical flutter wind speed (b) flutter frequency

Figure 3 Variation of flutter analysis results to approximation residual of flutter derivatives

4.2 *Time-domain response characteristics of two formulations*

It is necessary to assume an initial condition of flutter governing equation in smooth wind flow before conducting flutter analysis in time domain. However, it is difficult to determine initial condition of aerodynamic states corresponding to the given initial condition of structural states. With these factitious initial conditions, structural responses may be erroneous in the first time period, although this incorrect response will gradually converge to physical solution with the prolonging of calculating time. Hence, it is essential to investigate the time response characteristic of two state-space formulations of self-excited forces.

In order to study time response characteristics of two self-excited force formulations, time-domain analyses of this simple supported beam have been carried out using the four groups of aerodynamic coefficients listed in table 1, respectively. For a given velocity, the time-domain structural response subjected to an initial excitation can be readily computed using a high precision direct integration time integration scheme. For convenience of comparison, time step size is assumed as 0.1s, while torsional and vertical displacement with value of 1deg and 0.01m respectively are employed as the initial conditions and applied to every node on the beam, and initial conditions of aerodynamic states are set as zero.

Under respective critical wind velocity of four groups of aerodynamic coefficients, the response time histories of mid-point of this simple supported beam are shown in Fig. 4. It is observed that time-domain response characteristics of two state-space formulations of self-excited force are almost identical and structural responses are incorrect in a long period time corresponding to the second group of coefficients for both state-space formulations. It can be noticed that the two groups of aerodynamic coefficients are basically the same except for those related to aerodynamic states no matter for Roger's formulation and Karple's formulation. Therefore, those coefficients related to aerodynamic states may determine the time-domain response characteristics of state-space formulations of self-excited forces.

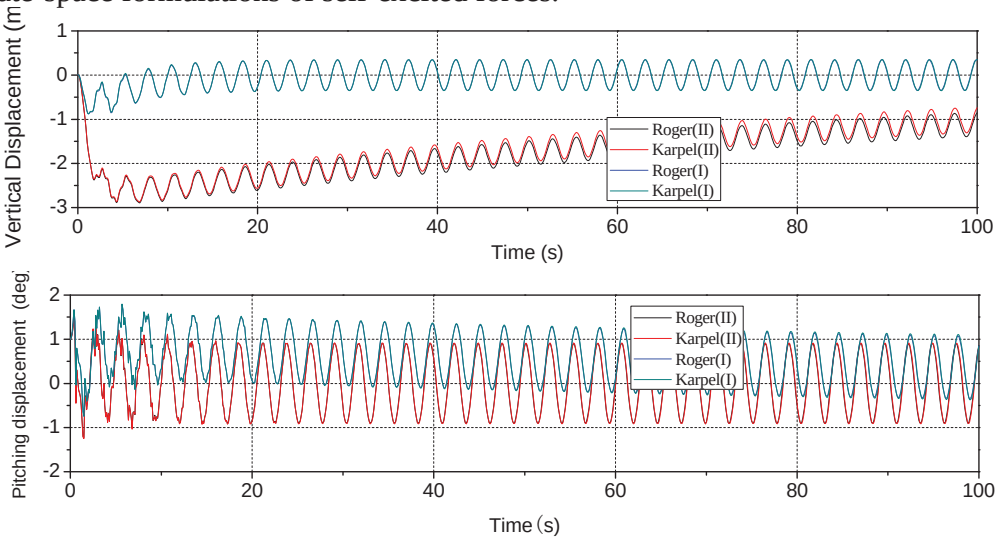


Figure 4 Time history of displacements at center span of simple supported beam

This incorrect response in first time period is mainly caused by improper initial conditions of aerodynamic states. Since these initial conditions of aerodynamic states cannot be determined in advance, it is alternative to make this incorrect response converge to physical solution as soon as possible. As the time-domain response characteristics of these two state-space formulations of self-excited force are almost identical and mainly determined by the characteristic of aerodynamic states, we choose aerodynamic states in Roger's formulation to cast around for solutions to make this initial incorrect response attenuate as soon as possible.

In the critical state of flutter, the motion of bridge deck can be viewed as a simple harmonic motion. Based on this assumption and by taking inverse Laplace transform of Eq. (4a), the aerodynamic state related to self-excited force component F caused by bridge deck motion Δ can be expressed as:

$$X_{sel}^{F\Delta}=A_{l+3}^{F\Delta}\int_{-\infty}^{t}e^{-\frac{\lambda_l U}{B}(t-\tau)}\omega\cos(\omega\tau)\,d\tau=\frac{A_{l+3}^{F\Delta}\omega e^{-\frac{\lambda_l U}{B}t}}{\left(\frac{\lambda_l U}{B}\right)^2+\omega^2}\left[e^{\frac{\lambda_l U}{B}\tau}\left(\omega\sin\omega\tau+\frac{\lambda_l U}{B}\cos\omega\tau\right)\Big|_{-\infty}^{t}\right]=\frac{A_{l+3}^{F\Delta}}{\sqrt{(\lambda_l/K)^2+1}}\sin(\omega t+\theta) \tag{10}$$

where $\theta=\arctan(\lambda_l/K)$. However, the lower limit of this convolution integral must be larger than zero in calculation, namely convolution integral in Eq. (10) is forced to be expressed as:

$$\begin{aligned}X_{sel,0}^{F\Delta}&=A_{l+3}^{F\Delta}\frac{\omega e^{-\frac{\lambda_l U}{B}t}}{\left(\frac{\lambda_l U}{B}\right)^2+\omega^2}\left[e^{\frac{\lambda_l U}{B}\tau}\left(\omega\sin\omega\tau+\frac{\lambda_l U}{B}\cos\omega\tau\right)\Big|_{0}^{t}\right]\\&=A_{l+3}^{F\Delta}\frac{1}{\sqrt{(\lambda_l/K)^2+1}}\sin(\omega t+\theta)-A_{l+3}^{F\Delta}\frac{\lambda_l/K}{(\lambda_l/K)^2+1}e^{-\frac{\lambda_l}{K}\frac{2\pi t}{T}}=X_{sel}^{F\Delta}+X_{sel,a}^{F\Delta}\end{aligned} \tag{11}$$

where $T=1/2\pi\omega$. Obviously, an additional term is introduced if this convolution integral is calculated from zero, and it can be viewed as the initial conditions of aerodynamic states. In flutter analysis, this additional term of aerodynamic state is usually unknown in advance, and it will cause the incorrect structural response. Fortunately, if λ_l is larger than zero this additional term will decay exponentially with time at a rate depending on λ_l/K and ω. The incorrect response may attenuate more quickly by increasing λ_l/K and ω. When this addition term is smaller than five percent of aerodynamic state response, the effect can be neglected. Therefore, the influence of additional term on aerodynamic state response will be smaller than 5% if Eq. (13) is satisfied,

$$\frac{X_{sel,a}^{F\Delta}}{X_{sel}^{F\Delta}}=\frac{\frac{\lambda_l/K}{(\lambda_l/K)^2+1}e^{-\frac{\lambda_l}{K}\frac{2\pi t}{T}}}{\frac{1}{\sqrt{(\lambda_l/K)^2+1}}}<\frac{\lambda_l/K}{(\lambda_l/K)^2+1}e^{-\frac{\lambda_l}{K}\frac{2\pi t}{T}}<\frac{1}{2}e^{-\frac{\lambda_l}{K}\frac{2\pi t}{T}}<5\% \tag{12}$$

which demands that λ_l is larger than $0.366K/n$,and n indicates the number cycles.

5 CONCLUSION

The self-excited force of bridge deck can be descripted in state space domain by using rational function approximations of unsteady aerodynamic forces. This state space equation of bridge deck motion makes flutter analysis straightforward and simplifies the design of efficient vibration suppression systems. The present paper mainly focuses on the time and frequency-domain response characteristics of Roger's and Karpel's state-space formulations of self-excited force and discusses detailed operation techniques of flutter analysis by state-space approach in frequency and time domain. Flutter analysis of a simple supported beam bridge with idealized thin plane section has been conducted as a case study. The concluding remarks can be summarized as follows:

(1) The additional aerodynamic states introduced in Roger's state-space formulation are twice than that of Karpel's formulation.

(2) Frequency-domain response characteristics of two state-space formulations are both favorable, although flutter results based on Karpel's formulation are more sensitive to residual of flutter derivatives than Roger's formulation.

(3) Time-domain response characteristics of two state-space formulations are almost identical; with restricting the lower limit of the coefficients related to aerodynamic states, the time period of incorrect transient response of structure can be shorten.

ABSTRACT: Long-span cable supported bridges are prone to aerodynamic instabilities caused by wind and this phenomenon is usually a major design criterion. If the wind speed exceeds the critical flutter speed of the bridge, this constitutes an Ultimate Limit State. The prediction of the flutter boundary therefore requires accurate and robust models. This paper aims at studying various combinations of models to predict the flutter phenomenon. Since flutter is a coupling of aerodynamic forcing with a structural dynamics problem, different types and classes of models can be combined to study the interaction. Here, both numerical approaches and analytical models are utilised and coupled in different ways to assess the prediction quality of the hybrid model. Models for aerodynamic forces employed are the analytical Theodorsen expressions for the motion-induced aerodynamic forces of a flat plate and Scanlan derivatives as a Meta model. Further, Computational Fluid Dynamics (CFD) simulations using the Vortex Particle Method (VPM) were used to cover numerical models.

KEYWORDS: Suspension bridge, flutter, CFD, aerodynamic derivatives, numerical simulation

1 INTRODUCTION

Long-span bridges are highly flexible, light weight and have low structural damping. They can be subjected to large dynamic motion due to wind actions. The assessment of aerodynamic behaviour, therefore, plays very important role in the design of long-span bridges. For this reason, flutter is also viewed as essential aeroelastic phenomenon to be studied for these structures. The aeroelastic stability of long-span bridges against flutter is checked by calculating a wind speed at which flutter occurs which is known as the flutter limit. The required aeroelastic properties of the bridge deck section are usually determined in wind tunnel tests.

Scanlan introduced mathematical treatment of flutter in 1960s whereas for the last couple of decades, numerical methods are becoming more popular due to the increasing use of computers in the field of Structural Engineering. In this paper, the study is made on the aerodynamic phenomena, the methods available for flutter analysis for bridges, and to apply the analytical and numerical based analysis on the Lillebælt suspension bridge to calculate ultimately its flutter limit.

2 METHODS OF AERODYNAMIC ANALYSIS

Analytical approaches play very important role in Wind Engineering whereas numerical methods are gaining importance. All methods apply simplifications to a certain extent such as assuming two-dimensionality of the flow or the shedding process like the wake oscillator model for the

case of vortex induced vibration [1]. There are three main types of analysis to for aerodynamic problems:

- Experimental methods
- Analytical methods
- Numerical methods

The last two methods have been used in this study. Analytical solution based on potential flow theory for the motion induced forces on a flat plate exerting sinusoidal heave and pitch motion was given by Theodorsen [2]. In most cases, the empirical models are available which are based on the results of experimental studies. These models are mostly based on 2D situations but in reality the 3D effects are present. Also in analytical models, the basic physical causes are attended but the Fluid-structure Interaction is not addressed. The experimental methods are considered relatively accurate compared to the other methods. Wind tunnel testing and full scale models are the examples of experimental methods.

The wind tunnel testing is very expensive for parametric studies but the numerical approach makes it relatively cheaper. With the advancement in the computer modelling and the processing power and by using the principles of CFD, it is now possible to study wind effects on structures in relatively less time. These methods are also efficient, repeatable and economical. Numerical simulations can be used in place of wind tunnel investigation for the fundamental studies. The accuracy of results from these methods not only depends on the quality of the solver but also on the modelling itself. Therefore, the numerical method must be reliable and robust to be used in place of wind tunnel tests.

3 REFERENCE OBJECT

The Lillebælt suspension bridge, Denmark, has been used as a reference object to employ the various model combinations. The data about the bridge is available in [3] and the structural parameters used for this reference object are given in Table 1. For simplicity in the calculation, the railing and other attachments on the deck are not considered in this study.

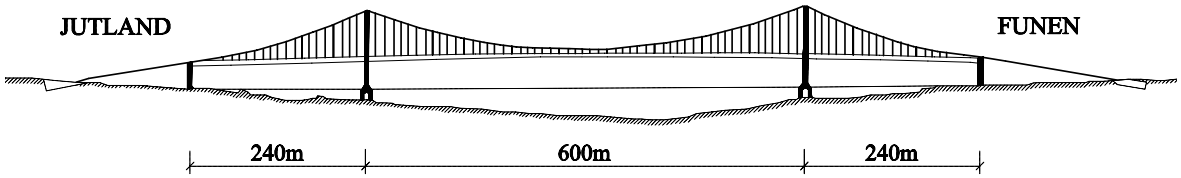

Figure 1. Elevation of the Lillebælt suspension bridge, Denmark used as a reference object in this study.

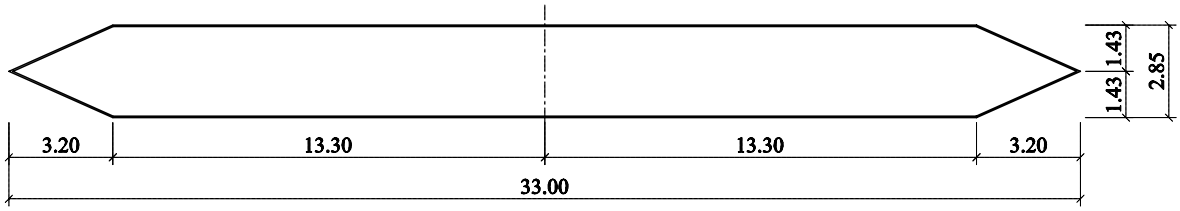

Figure 2. Simplified Lillebælt suspension bridge deck section geometry used in this study (Dimensions: [m]).

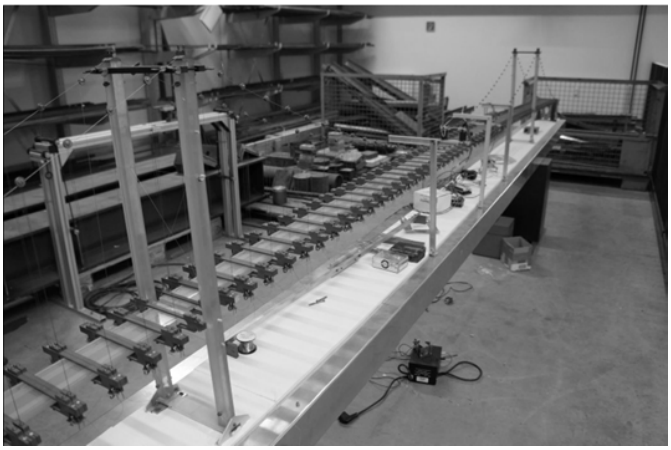

Figure 3. Physical model of the Lillebælt suspension bridge.

Table 1. Basic data and structural properties of the Lillebælt suspension bridge section used in this study.

4 COUPLING OF MODELS

Flutter is a coupling of aerodynamic forcing with a structural dynamics problem. Therefore, different types and classes of models can be combined to study the interaction. In this study, both numerical approaches and analytical models are utilised and coupled in different ways to assess the prediction quality of the hybrid model.

The structural representations were dimensionally reduced to two degree of freedom section models calibrated from global models as well as a fully three-dimensional Finite Element (FE) model. A two degree of freedom system was analysed analytically as well as numerically. The following models were thus derived and analysed: Fully analytical, CFD Derivatives-Analytical and Numerical 2D Structural, CFD Derivatives-Numerical 3D Structural, Fully coupled CFD Numerical 2D Structural. This has allowed to investigate a very broad range of model combinations and to study their merits and drawbacks.

4.1 *Analytical Approach (Theodorsen Theory)*

Theodorsen investigated the flutter phenomenon for aircraft wings and gave a very popular approach for the flutter analysis. This approach is independent of the shape of the body but on the other hand it neglects the effect originating from the simplification to the flat plate. From the basic principle of potential flow theory, Theodorsen showed that for thin airfoils in incompressible flow, the expressions for F_L and F_M are linear in displacement h and α and their first and second derivatives [2].

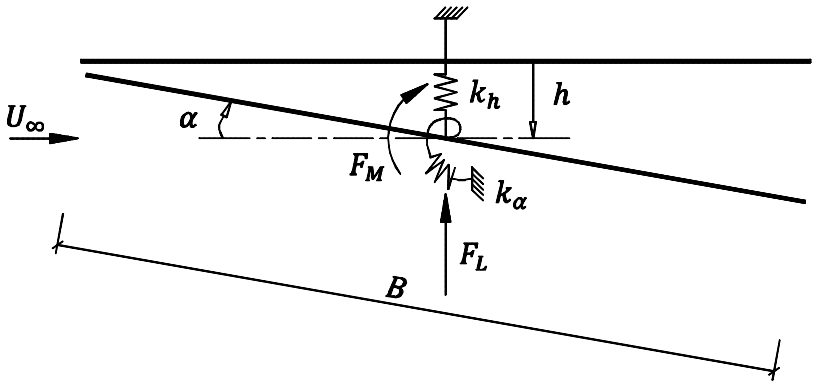

Figure 4. Definition of degrees of freedom (heave h and pitch α) for flutter analysis.

where F_L and F_M are the lift and moment, k_h and k_α are the vertical and rotational spring stiffness and h and α are the vertical displacement and rotation respectively. U_∞ is the oncoming wind speed. The equations of motion can be written

$$F_L = m\ddot{h} + 2m\xi_h\omega_h\dot{h} + m\omega_h^2 h \tag{1}$$

$$F_M = I\ddot{\alpha} + 2I\xi_\alpha\omega_\alpha\dot{\alpha} + I\omega_\alpha^2\alpha \tag{2}$$

where ω_h and ω_α are the natural circular frequencies in heave and pitch degree of freedom respectively. The theoretical expressions on a flat plate airfoil for sinusoidal oscillating lift F_L and moment F_M are

$$F_L = -\rho b^2 U_\infty \pi\dot{\alpha} - \rho b^2\pi\ddot{h} - 2\pi\rho C U_\infty^2 b\alpha - 2\pi\rho C U_\infty b\dot{h} - 2\pi\rho C U_\infty b^2 \tfrac{1}{2}\dot{\alpha} \tag{3}$$

$$F_M = -\rho b^2\pi\tfrac{1}{2}U_\infty b\dot{\alpha} - \rho b^4\pi\tfrac{1}{8}\ddot{\alpha} + 2\rho U_\infty b^2\pi\tfrac{1}{2}CU_\infty\alpha + 2\rho U_\infty b^2\pi C\dot{h} + 2\rho\tfrac{1}{2}U_\infty b^3\pi C\dot{\alpha} \tag{4}$$

where ρ is the air density, C is the Theodorsen's circulation function and $b = B/2$. The system of differential equations (1), (2), (3) and (4) can be written as

$$\begin{bmatrix}\dot{h}\\ \ddot{h}\\ \dot{\alpha}\\ \ddot{\alpha}\end{bmatrix} = \begin{bmatrix}0 & 1 & 0 & 0\\ a_{21} & a_{22} & a_{23} & a_{24}\\ 0 & 0 & 0 & 1\\ a_{41} & a_{42} & a_{43} & a_{44}\end{bmatrix}\begin{bmatrix}h\\ \dot{h}\\ \alpha\\ \dot{\alpha}\end{bmatrix} \tag{5}$$

This is of the form

$$\dot{X} = AX \tag{6}$$

and assuming the response X is of the form

$$X = \boldsymbol{R}.e^{\lambda t} \tag{7}$$

where $\boldsymbol{R}$ is real. This simplifies to Eigenvalue problem as follows:

$$[\boldsymbol{A} - \lambda \boldsymbol{I}]\boldsymbol{R}.e^{\lambda t} = 0 \tag{8}$$

The solution for $h(t)$ and $\alpha(t)$ is of an exponential form. The Eigenvalues of λ_i of the matrix $\boldsymbol{A}$ characterize the response of the system as follows:

- Positive real part: Increasing response
- Negative real part: Decaying response
- Imaginary part: Oscillating response

The system will become unstable when an Eigenvalue has a positive real part. When the imaginary part goes towards zero, the oscillatory part vanishes and the phenomenon of static divergence is observed. In this situation, there will be pure heave or pitch motion which can be interpreted as loss of vertical stiffness. The system is solved successively for increasing U_∞ until at least one Eigenvalue becomes positive real. The code for solving the Theodorsen's equations was written in Matlab. Using the structural parameters for the Lillebælt bridge (see Table 1), the flutter limit was found 93.8m/s.

4.2 *Meta Model (Scanlan Representation)*

Scanlan proposed a set of expressions for the aerodynamic forces on a bridge cross section. It assumes that the self-excited lift F_L and moment F_M for a bluff body may be treated as linear in displacement h and rotation α and their first derivatives [4]. Below is commonly used linearized form.

$$F_L = \frac{1}{2}\rho U_\infty^2 B\left[KH_1^*\frac{\dot{h}}{U_\infty} + KH_2^*\frac{B\dot{\alpha}}{U_\infty} + K^2H_3^*\alpha + K^2H_4^*\frac{h}{B}\right] \tag{9}$$

$$F_M = \frac{1}{2}\rho U_\infty^2 B^2\left[KA_1^*\frac{\dot{h}}{U_\infty} + KA_2^*\frac{B\dot{\alpha}}{U_\infty} + K^2A_3^*\alpha + K^2A_4^*\frac{h}{B}\right] \tag{10}$$

$$K = \frac{B\omega}{U_\infty} \tag{11}$$

where the non-dimensional coefficients H_i^* and A_i^* are known as aerodynamic or flutter derivatives. The frequency of the bridge oscillation under aerodynamic forcing is known as reduced frequency. As the aerodynamic derivatives are the function of this frequency therefore they can only be measured when the bridge is in the oscillatory state. Normally these are measured in special wind tunnel tests.

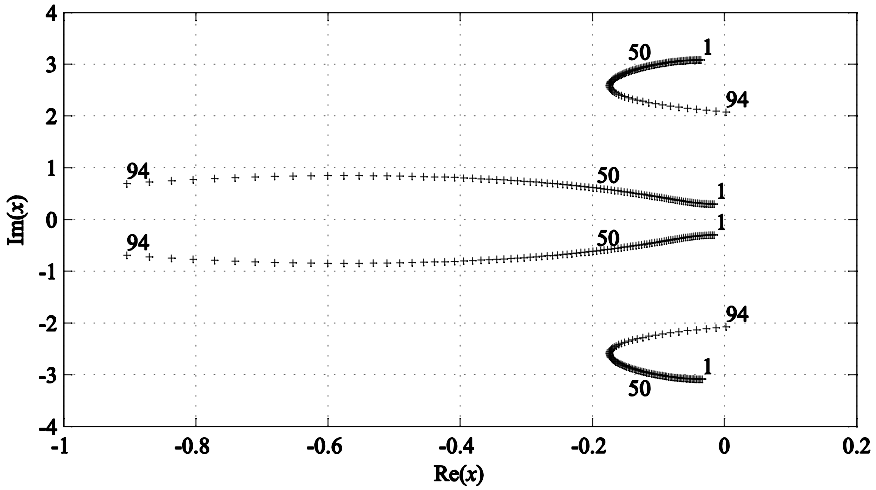

Figure 5. Eigenvalue paths for increasing wind speed U_∞.

The formulation to the Eigenvalue problem in this case is similar as described in Section 4.1. The flutter limit is determined when the real part of at least one Eigenvalue becomes positive as shown in Figure 6. The flutter limit was determined as 93.8m/s using the structural parameters of the Lillebælt bridge given in Table1.

4.3 *Forced Vibration Simulation*

Forced vibration simulations are used to determine motion-induced forces. The resulting lift and moment time histories are used to compute the aerodynamic derivatives. A computer code, VXFlow, based on VPM has been used here to compute these derivatives. Forced vibration simulations were performed on the Lillebælt section and the flat plate (aspect ratio 1:100) in sinusoidal heave and pitch motion over a range of reduced frequencies. The reduced frequency is controlled by changing the period of heave and pitch forcing motion.

$$v_r = \frac{2\pi U_\infty}{b\omega} \tag{12}$$

where v_r is reduced frequency. These simulations are performed in heave and pitch motion separately and the aerodynamic derivatives are computed from the resulting force time histories. The simulation gives time histories for $\overline{\boldsymbol{F}}_{\boldsymbol{L}}$ and $\overline{\boldsymbol{F}}_{\boldsymbol{M}}$ corresponding to known displacement traces $\boldsymbol{h}$. Equations (9) and (10) (with $\alpha = 0$) thus constitutes a system of equations as

$$\overline{\boldsymbol{F}}_{\boldsymbol{L}} = \boldsymbol{C}_h^L \boldsymbol{H}_h^* \tag{13}$$

$$\overline{\boldsymbol{F}}_{\boldsymbol{M}} = \boldsymbol{C}_h^M \boldsymbol{A}_h^* \tag{14}$$

where

$$\boldsymbol{C}_h^L = \frac{1}{2}\rho U_\infty^2 BK \begin{bmatrix} \frac{\dot{\boldsymbol{h}}}{U_\infty} & K\frac{\boldsymbol{h}}{B} \end{bmatrix} \text{ and } \boldsymbol{C}_h^M = B\boldsymbol{C}_h^L \tag{15}$$

$$\boldsymbol{H}_h^* = \begin{bmatrix} H_1^* \\ H_4^* \end{bmatrix}, \ \boldsymbol{A}_h^* = \begin{bmatrix} A_1^* \\ A_4^* \end{bmatrix} \tag{16}$$

System (13) can be solved in the least-squares sense by left-multiplying with the $\boldsymbol{C}$ matrix:

$$\boldsymbol{C}_h^{L^T} \bar{F}_L = \boldsymbol{C}_h^{L^T} \boldsymbol{C}_h^L \boldsymbol{H}_h^* \tag{17}$$

$$\boldsymbol{C}_h^{M^T} \bar{F}_M = \boldsymbol{C}_h^{M^T} \boldsymbol{C}_h^M \boldsymbol{A}_h^* \tag{18}$$

This gives two sets of derivatives in lease-square sense. The procedure to calculate these aerodynamic derivatives can be found in [5] and is summarized as follows:

- perform forced vibration tests in either heave or pitch motion
- calculate a best-fit harmonic of the same forcing frequency to obtain lift coefficient and phase shift
- calculate derivatives

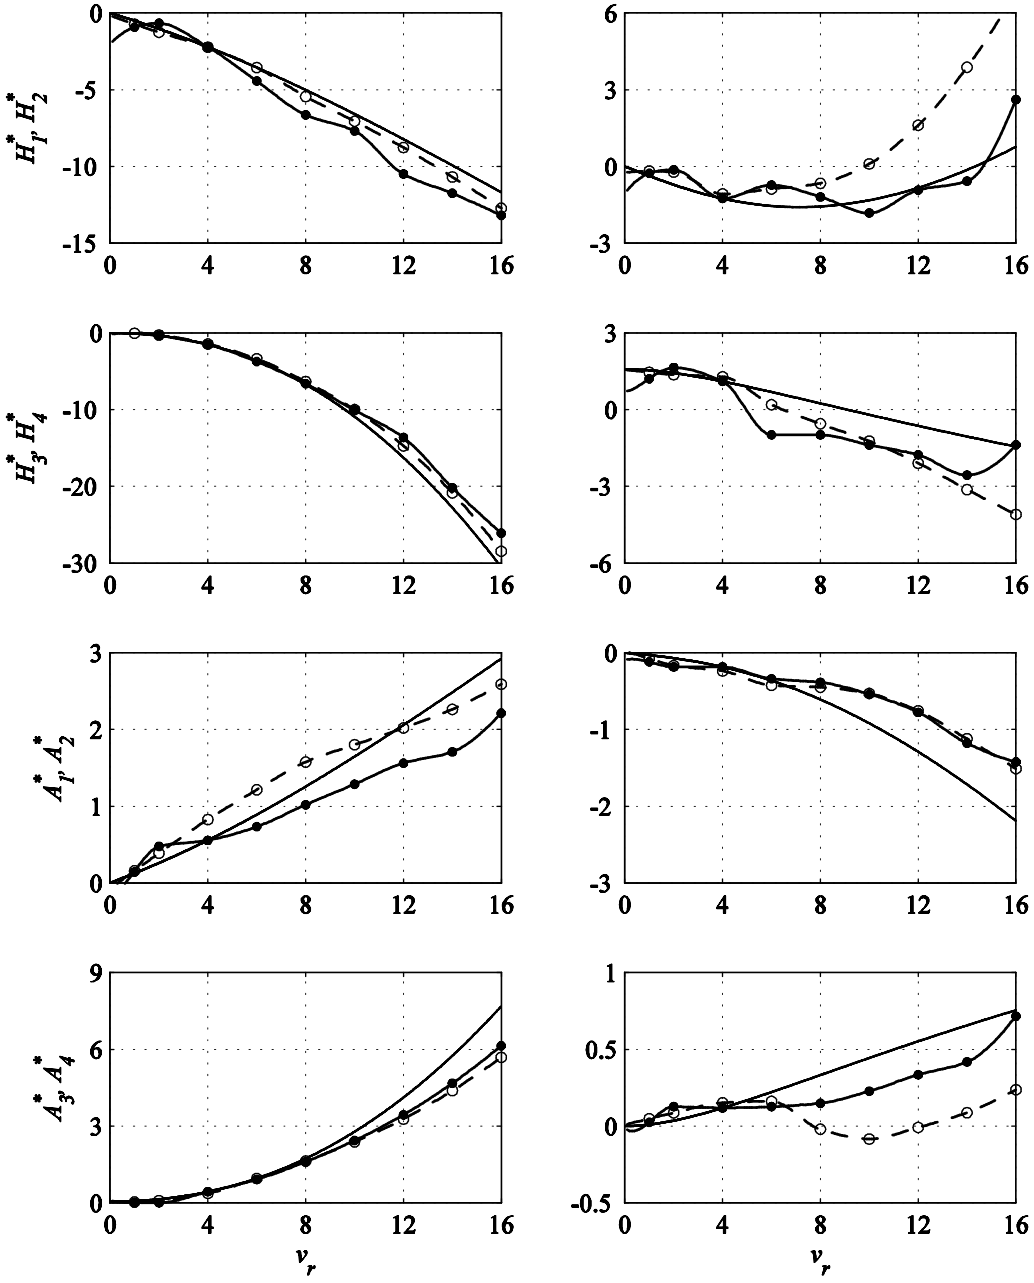

Figure 6. Aerodynamic derivatives (H_i^* and A_i^* where i =1, 2, 3, 4) w.r.t. the reduced speed (v_r): flat plate by Theodorsen theory (——), interpolated values from forced vibration analysis on the Lillebælt section (—•—) and the flat plate (- -o- -).

The resulting aerodynamic derivatives can be used to calculate flutter limit of the bridge. The forced vibration simulation was performed for the Lillebælt section shown in Figure 2 and the flat plate of the same width with aspect ratio of 100. For both these cases, structural parameters given in Table 1 were used. The flutter limit for the Lillebælt section was calculated as 94.2m/s and for flat plate as 88.7m/s.

4.4 *Fluid-structure Interaction Simulation*

VXFlow has been used here for the coupled analysis of the vertical motion and rotation of a 2 degree of freedom spring supported section model. The coupling of fluid dynamics solution and the structural dynamics is done at every time step. The pressure on the surface of the body is integrated to get the resultant force in terms of lift and twisting moment. These are associated with the two degrees of freedom of the structural system. The equations of motion for the system are solved by time marching structural dynamics solution. A stiffness matrix is then created and solution is performed. Rayleigh damping is used to model structural damping, for which the damping matrix is proportional to the combination of mass and stiffness matrices.

Structural parameters, given in Table 1 for the Lillebælt suspension bridge, were used for the bridge section (see Figure 2) and the flat plate of aspect ratio 100. The simulations were performed at various wind speed to identify the flutter instability. It was observed that just before the flutter limit, the section goes in the loss of vertical stiffness stage having extreme heave condition. At 95m/s the bridge section becomes unstable after a few hundred time steps. The flutter limit for the plate section was found as 98m/s.

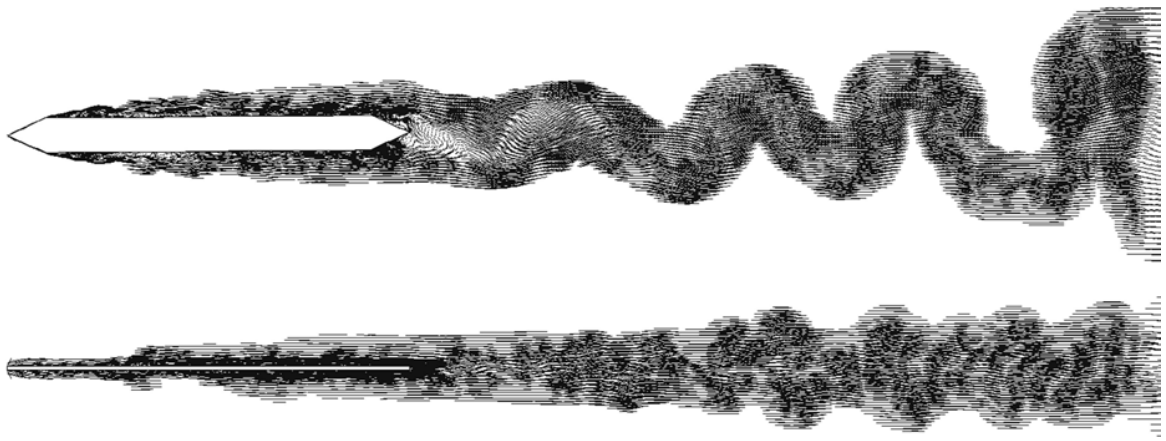

Figure 8. Instantaneous vortex pattern with streak lines for the Lillebælt section (Top) and the flat plate (Bottom).

4.5 *Finite Element Model*

The section of the Lillebælt suspension bridge deck was modelled as a two degree of freedom beam element of unit length in a Finite Element software. The system was supported on springs with vertical and rotational degrees of freedom. The reduced model was calibrated to represent the first bending and first torsional mode of the full bridge model. The dimensional reduction to a 2 degree of freedom system is a simplification but on the other hand it neglects the effects coming from the higher modes. The aerodynamic derivatives obtained through forced vibration analysis (see Section 4.3), for the Lillebælt section and the flat plate, were used to calculate the aerodynamic forces. Dynamic wind history analysis was performed on the system. The flutter limit both for the Lillebælt section and the flat plate was found to be 58.5m/s.

A 3D Finite Element model of the Lillebælt suspension bridge was made and calibrated to represent the structural properties of the bridge given in Table 1. In the calibration process some discrepancies were found and the target frequencies were not achieved exactly. The mode shapes of first bending and first torsional mode with their achieved frequencies are shown in Figure 10. The approach from the two degree of freedom model was implemented to the full 3D model of the bridge and the resulting flutter limits were calculated. The effect of higher modes was observed in the deformed model of the bridge at flutter limit. The flutter limit calculated was 49.0m/s both for the Lillebælt section and the flat plate.

5 CONCLUSIONS

The flutter phenomenon was studied employing various combinations of analytical and numerical prediction models. Lillebælt suspension bridge was used as a study object. Generally, all models were able to predict the flutter phenomenon and relatively close agreement was found for the particular bridge. Fully coupled CFD analyses have the advantage that no prior knowledge as to the phenomenon needs to be inserted into the model. Three-dimensional structural representations are superior over dimensionally reduced models in that no prior knowledge as to the modes participating in the flutter coupling is required. Fully analytical models are more direct models and allow a better insight into the force coupling. Simplified aerodynamic models need to be critically assessed with respect to their ability to predict the aerodynamic behaviour of the real cross section. The paper presents in detail all the models used and shows the analysis results.

Interference effect on local peak pressure between two high-rise buildings with rectangular shape

Yi Hui [a], Akihito Yoshida [a], Yukio Tamura [a]

[a]*Department of Architectural Engineering, Tokyo Polytechnic University, Atsugi, Kanagawa, Japan*

ABSTRACT: This study investigates the interference effects between two rectangular-section high-rise buildings by wind tunnel experiments, focusing on local peak pressure coefficients. Wind tunnel experiments were carried out under all possible wind incidence angles for many configurations. The parallel building arrangements were considered. To evaluate the interference effects for local peak pressures in detail, interference factors for maximum positive and minimum negative peak pressures are presented and discussed. The results show that interference effects greatly depend on the configurations. The interfering building has stronger effects on the smallest minimum negative peak pressure of the principal building than the largest maximum positive peak pressure. The wind direction that causes the largest peak pressure varies with the changing of interfering building's location.

KEYWORDS: high-rise building; interference effects; wind tunnel experiment; Local peak pressure.

1 INTRODUCTION

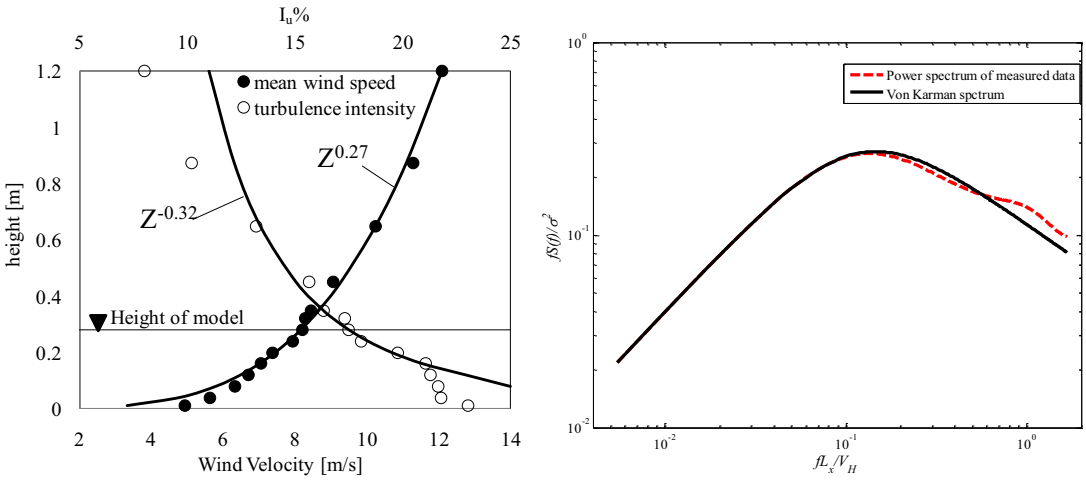
Modern tall buildings are often built in groups in urban areas. This results in flow interference and wind loads on buildings are modified from the isolated building situation. Catastrophic incidents may result if the interference effect on load has is not considered in design. An investigation of interference effect is complicated by the large number of variables needed to describe the broad set of possible situations – sizes and shapes of buildings, relative locations of adjacent building(s), wind directions, upstream terrain conditions and so on.

Tang and Kwok (2004) investigated interference excitation mechanisms of translational and torsional responses of a pair of identical tall buildings. They found that amplified along-wind, cross-wind and torsional responses were largely induced by the wake of an upstream interfering building. Lam et al. (2011) studied wind-induced interference effects on a row of five square-plan tall buildings arranged in close proximity, and clarified that the design values of peak dynamic responses of a tall building are not significantly magnified when placed in a row. Kim, et al., (2009) discussed interference effect on local peak pressures between two identical square-section tall buildings from the viewpoint of cladding design. They found that the local peak pressure coefficients on the walls of a principal building largely depended on the location of an interfering building.

However, investigating only buildings with the same cross section is not enough for a comprehensive understanding of interference effect. It is apparent that the flow pattern surrounding two buildings will change with building shapes, and this will lead to a change in local peak pressures on buildings. In the present study, in order to obtain more information about the interference effects between two high-rise buildings on the local peak pressure, two rectangular-section building were used to conducted wind tunnel experiments. The experimental results are presented and discussed in this paper.

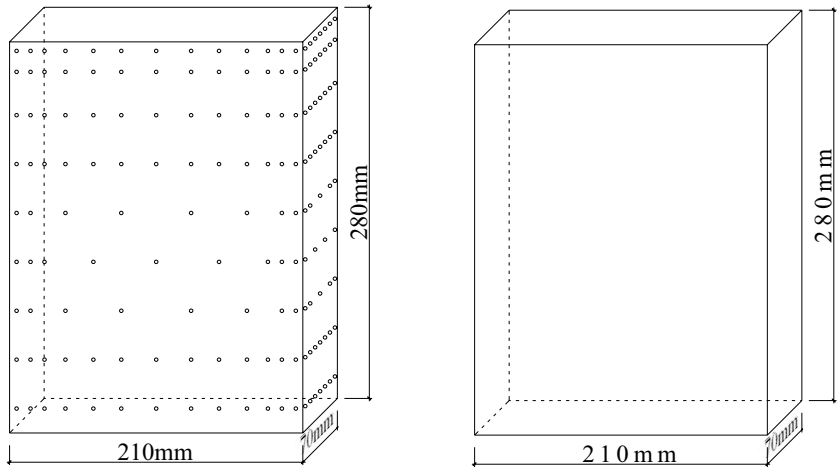
2 WIND TUNNEL EXPERIMENTS

Wind tunnel experiments were carried out in a Boundary Layer Wind Tunnel located at Tokyo Polytechnic University, Japan. The test section of the wind tunnel was 2.2m wide and 1.8m high. The approaching flow represented an urban wind exposure using the spire-roughness technique with a power law exponent of 0.27. The wind speed and turbulence intensity at the roof height of the model were 8m/s and 17%, respectively. The velocity scale was set to 1/5. Measured longitudinal mean wind velocities and turbulence intensity profiles are shown in Fig. 1. Fig. 1 also shows the power spectrum of longitudinal wind speed at the roof height.



(a) wind profiles of experiment (b) wind power spectrum

Fig. 1. Characteristics of longitudinal wind in experiment.



(a) Principal building models (b) Interfering building models

Fig. 2. Building models for pressure measurement.

The model size was 210mm wide, 70mm deep and 280mm high. Two models of the same shape were used (Fig. 2). The one with pressure taps was used as the principal building, the one without pressure taps was used as the interfering building. A total of 318 pressure taps were installed on the walls of the principal building: 103 on each wide face and 56 on each narrow face. The target geometric scale was set to 1:400, so that the models represented full-scale buildings 112m high and 84m×28m in plan.

The parallel and perpendicular arrangements were considered, as shown in Fig. 3. Both models were rigidly mounted on a turn-table. The distance between the two models was varied longitudinally, Y/*b*, and laterally, X/*b*, on the Cartesian coordinates shown in Fig. 3, where "*b*" indicates the depth of the model. Wind tunnel tests were carried out on 54 different configurations by moving the interfering building's location from one spot to another shown in Fig. 3. For each configuration, the angle of incidence wind was varied from 0° to 360° at 5° intervals and the fluctuating wind pressures on the building faces were simultaneously measured at all taps using a multi-channel simultaneous fluctuating pressure measurement system for each wind direction.

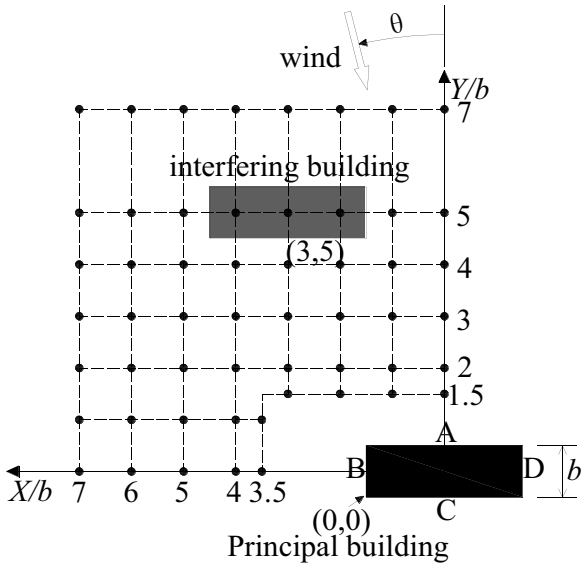


Fig. 3. Experimental arrangements

The sampling frequency for the pressure data was 781Hz. For each wind direction, fifteen 7.5s-long samples were collected, which corresponded to fifteen 10min-long samples in full scale. The time histories of fluctuating pressure were filtered by means of a moving average filter (Holmes 1997) as follows:

$$\tau = 1.0 \times L / \overline{U}_H \tag{1}$$

where τ is the averaging time corresponding to 0.2s in full scale, L is the length of the cladding diagonal in full scale (6m in this study) and $\overline{U}_H$ is the mean wind speed at the roof height of the principal building.

The Cook-Mayne method (Cook and Mayne, 1979) was adopted to obtain the extreme pressure coefficient. The extreme pressure coefficient representing the 50-year return period was calculated using Eq. (2).

$$\hat{C}_p = C_p + 1.4 / a_c \tag{2}$$

where C_p and $1/a_c$ are the mode and scale parameter of the extreme pressure coefficient.

3 RESULTS AND DISCUSSION

3.1 *Interference factor for local peak pressures and unfavorable regions*

As mentioned, the interference effects on the local peak pressures were studied. And it's known that an interfering building might cause different effects on different faces of a principal building. Thus, in order to check in detail and find the difference among them, the interference effects on different faces were checked individually in terms of the largest maximum peak pressure coefficient of Wall-X— $\hat{C}_p^{\mathrm{X}}$ and smallest minimum peak pressure coefficient of Wall-X— $\check{C}_p^{\mathrm{X}}$, where X∈(A, B, C, D). Interference Factor (IF) was introduced into this study as follows:

$$\hat{IF}(\mathrm{X}) = \frac{\hat{C}_p^{\mathrm{X}} \text{ with interferin g building}}{\hat{C}_p^{\mathrm{X}} \text{ without interferin g building}} \tag{3}$$

$$\check{IF}(\mathrm{X}) = \frac{\check{C}_p^{\mathrm{X}} \text{ with interferin g building}}{\check{C}_p^{\mathrm{X}} \text{ without interferin g building}} \tag{4}$$

Based on our experiment, the value $\hat{C}_p^{\mathrm{X}}$ of isolated condition was 2.6. $\check{C}_p^{\mathrm{X}}$ of isolated condition was -4.6 for Wall-A and Wall-C (the narrow faces), and it was -5.7 for Wall-B and Wall-D (the wide faces). These results were used as the basic reference values for evaluating the interference factor.

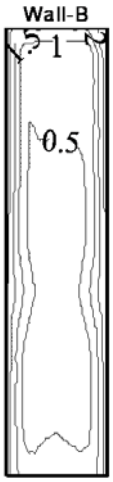
(a) $\hat{C}_p^{\mathrm{A}}(i)$ of case (0, 1.5b)



(b) $\hat{C}_p^{\mathrm{B}}(i)$ of case (3.5b, 0)

Fig. 5. $\hat{C}_p^{\mathrm{X}}(i)$ distributions of some configurations in parallel arrangement.

3.1.1 *Interference effects for positive peak pressure*

Fig. 4 clearly shows that the interfering building only slightly affects the $\hat{C}_p^{\mathrm{X}}$ value on the principal building. Most of the $\hat{IF}(\mathrm{X})$ values are in the range of 0.9 to 1.1. Even when the interfering building is located just in front of the principal building with small separation, there is no dramatic decrease in $\hat{C}_p^{\mathrm{A}}$, which was assumed to appear due to the shielding effects. The $\hat{C}_p^{\mathrm{A}}(i)$ distribution shown in Fig. 5(a) shows that the $\hat{C}_p^{\mathrm{A}}(i)$ values are very low, around 0.5, except in

small regions near the edges and corners when the interfering building was at (0, 1.5*b*). Similar results are also obtained for Wall-B when the interfering building was located at (3.5*b*, 0) which was just beside the principal building (Fig. 5(b)). Fig. 5 indicates that the interfering building decreases most of the $\hat{C}_p^{\mathrm{X}}(i)$ values on the face facing it when the two buildings are placed in a row with the same orientation. However, the principal building's edges and corners cannot be totally under the shielding offered of the upstream building at all wind angles.

3.1.2 *Interference effects for negative peak pressure*

The results of the interference factor of each face are shown in Fig. 6. It can seen that the interfering building had significant interference effects on the $\check{C}_p^{\mathrm{X}}$ of the principal building, especially on Wall-A and Wall-B, which faced the interfering building. The maximum value of $\check{IF}(\mathrm{A})$ can be larger than 1.5 when the interfering building is located at (3*b*, 2*b*), and the maximum value of $\check{IF}(\mathrm{B})$ can also be larger than 1.3 when the interfering building is at (3*b*, 2*b*) and (5*b*, 5*b*). However, the $\check{IF}(\mathrm{C})$ and $\check{IF}(\mathrm{D})$ values are all between 0.9 and 1.1, which means that the effects on Wall-C and Wall-D are weaker than on the other two faces.

In this study, the region where $\hat{IF}(\mathrm{X})$ or $\check{IF}(\mathrm{X})$ is greater than 1.1 is nominated as the unfavorable region of Wall-X. If the interfering building is located in an unfavorable region for Wall-X, that means the tested largest maximum peak pressure or smallest minimum peak pressure of Wall-X is more than 10% larger than the design value which is obtained based on the isolated condition, and the design value of the pressure coefficients on Wall-X of the principal building should be modified for safety. The unfavorable regions of Wall-A and Wall-B can also be much larger than those of the other two faces for the parallel arrangement.

(c) Contour of $\overset{\vee}{IF}(\mathrm{C})$ (d) Contour of $\overset{\vee}{IF}(\mathrm{D})$

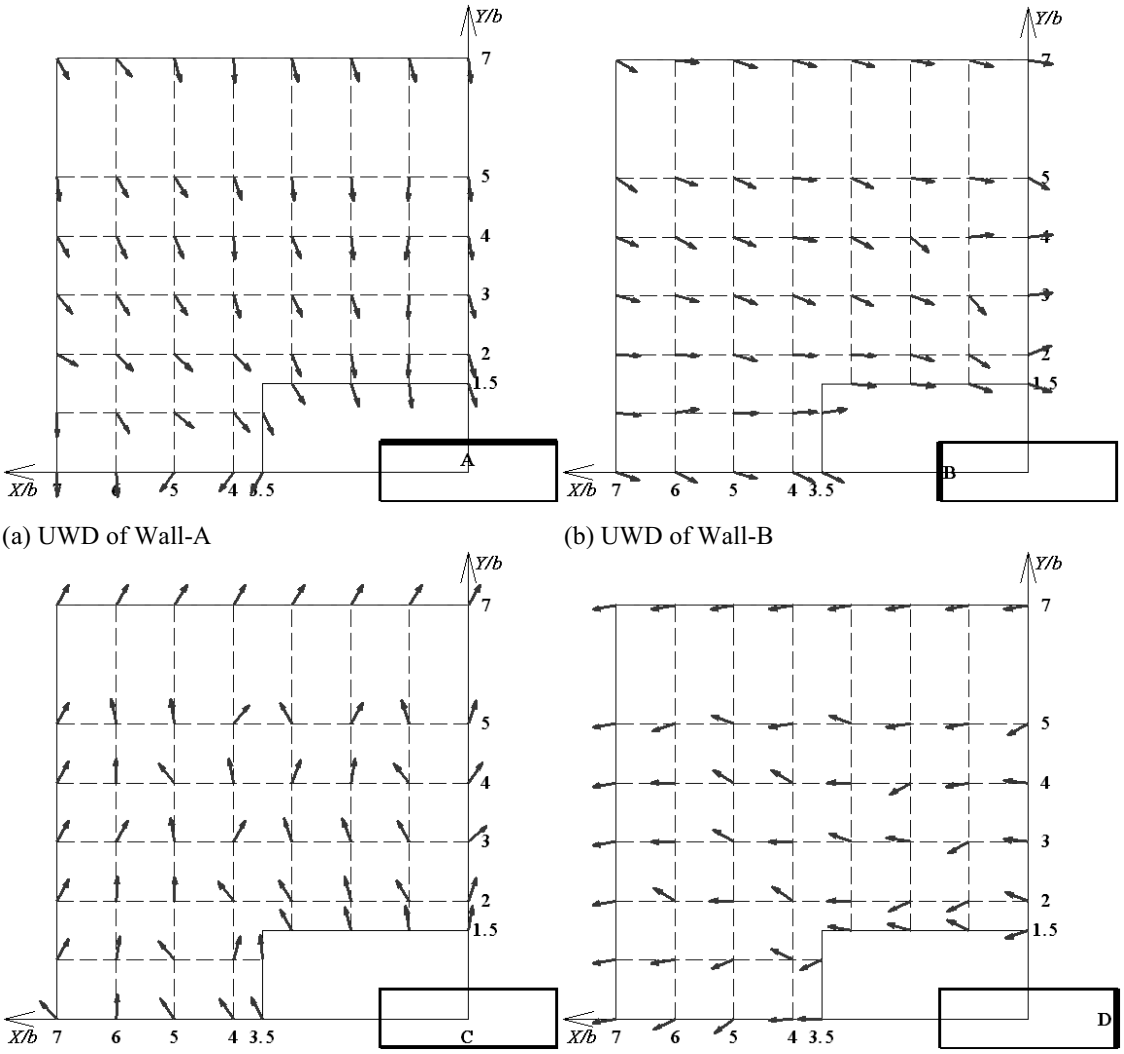
Fig. 6. $\overset{\vee}{IF}(\mathrm{X})$ results of experiment.

3.2 *Effect of wind direction*

Wind direction is a very important parameter as well. Engineers are not only interested in $\hat{C}_p^{\mathrm{X}}$ and $\check{C}_p^{\mathrm{X}}$, but also want to know what wind directions cause these $\hat{C}_p^{\mathrm{X}}$ and $\check{C}_p^{\mathrm{X}}$ values. In this study, the wind direction under which the $\hat{C}_p^{\mathrm{X}}$ or $\check{C}_p^{\mathrm{X}}$ of Wall-X is observed is defined as the Unfavorable Wind Direction (UWD) of Wall-X, where $\mathrm{X} \in (\mathrm{A,B,C,D})$.

3.2.1 *Unfavorable wind direction for positive peak pressure*

Fig. 7 gives the positive UWD of four faces of parallel arrangement. The arrow at each position indicates the unfavorable wind direction of the target wall when the interfering building is located there. For Wall-A and Wall-B, the UWD varies with change of the interfering building's position. For most cases of the two faces, the unfavorable winds tilts towards the interfering building from the direction normal to the target face, that means the wind causing high positive pressure attacks the principal building after passing the interfering building. But for the other two faces (Wall-C and Wall-D), it can be seen that although the unfavorable winds also shift a little from the direction normal to the target face, the direction of shifting are random and doesn't depend on the location of the interfering building. This is because when the wind blows directly to the Wall-C and Wall-D, the interfering building is mainly at the downstream direction of the principal building in this experimental setup. Thus the interfering building couldn't affect the coming wind of the principal building.



(a) UWD of Wall-A

(b) UWD of Wall-B

(c) UWD of Wall-C

(d) UWD of Wall-D

Fig. 7. Positive UWD of four faces.

3.2.2 *Unfavorable wind direction for positive peak pressure*

Fig. 8 shows the UWD of the parallel arrangement. According to these figures, for Wall-A and Wall-B, the unfavorable wind mostly attacks the principal building from the direction approximately along with the target face after passing the upstream interfering building. The UWD also changes with changing position of the interfering building. But for the other two faces the dependence of unfavorable wind direction on the location of interfering building cannot be clearly found.

Some results in Fig. 8(b) show that in the parallel arrangement when the interfering building is located in the area along the Y-axis where $X \in (0, 2b)$ the unfavorable wind always comes from the back side of Wall-A. But when it is out of the range where $X>2b$, the unfavorable wind changes almost 180º which comes from the front side of Wall-A. This is because when the interfering building is located in the range where $X \in (0, 2b)$, Wall-B is just in the wake of interfering building if wind comes from the front side of Wall-A and consequently the negative pressure on

it is low. If the wind comes from the back side of Wall-A, there is no shielding from the interfering building to protect Wall-B, so the negative peak pressure on Wall-B becomes higher. From Fig. 6(b), it can be checked that the $\overset{\vee}{IF}(\mathrm{B})$ values are all lower than 1 when X$\in$(0, 2*b*). The smallest value among them is only 0.7 when the interfering building is at (2*b*, 1.5*b*). These results imply that even when the interfering building is located in the downstream direction it also affects the $\overset{\vee}{C}_p^{\mathrm{B}}$ value by changing the flow field around the principal building.

4 CONCLUDING REMARKS

Experiments were carried out to investigate the interference effect on local peak pressures between two identical rectangular-cross-section high-rise buildings. The aspect ratio of the build-

ings was Width: Depth: Height=3:1:4. Parallel arrangement of the two buildings was checked. The interference effects on the external local peak pressures were evaluated and analyzed.

Based on the study, on one hand, the interfering building doesn't have a significant effect on maximum positive peak pressure. For most configurations of the interfering building, the interference factors for the largest maximum positive peak pressure were in the range of 0.9-1.1. On the other hand, the interfering building has a strong effect on the smallest minimum negative peak pressure. The unfavorable regions on Wall-A and Wall-B of the two arrangements were very large. The largest interference factor was greater than 1.5, which means the absolute value of the smallest minimum negative peak pressure coefficient is 50% higher than the design value of the isolated building situation.

Wind direction is one of the most crucial parameters. For most cases, the interference effect was stronger when the interfering building was located upstream of the principal building. The unfavorable wind directions depend strongly on the configurations of the two buildings.

Interference effect on wind pressure of two buildings

Ning Han [a], Ming Gu [a], Peng Huang [a]

[a] *State Key Laboratory of Disaster Reduction in Civil Engineering, Tongji University, Shanghai, China*

ABSTRACT: The interference effect on wind pressure between two identical buildings was analyzed by wind tunnel tests for different locations of the interfering building .The results show that for the tandem configurations, mean pressure on windward face of the principal building is suction when spacing ratio is less than 3.0, otherwise it is positive. The magnitude of mean negative pressure on the side and leeward faces and fluctuating pressure on all faces get maximums when spacing ratio is 3.0.With an increase in spacing ratio for the side-by-side arrangements, the maximum value of mean and fluctuating pressure coefficient interference factor decreases on the inner and outer face while slightly increases on the front and rear face. Notably, the fluctuating pressure coefficient interference factor on the inner face grows visibly and the maximum value is 2.2 on the top leading corner when the spacing ratio is 2.0.

KEYWORDS: Tandem; side-by-side; interference factor; spacing ratio; square building

1 INTRODUCTION

The wind pressure on isolated building has significant change or even becomes quite complex due to the surrounding tall buildings. Interference effect among tall buildings has been studied by many researchers over the past several decades. Khanduri et al. [1] gave a review of interference effect before 1998.After this; Xie & Gu [2-5] reported interference effect on dynamic response and correlation among three tall buildings. For the side-by-side arrangements, Kumar et al. [6] studied wind-induced responses of the principal building caused by interfering building which was located in different positions and had 4 different size ratios such as 0.5, 1.0,1.5 , 2.0.Then they reported that the critical size ratio is 1.0, the response amplitude has no significant differences when size ratio is smaller than 1.0, but it will increase remarkably when the size ratio is greater than 1.0 and reduced velocity is larger than 12. Interference effect on wind pressure of two buildings placed in staggered arrangements has been studied numerically and experimentally by Zhang et al. [7], but only certain points on certain heights were focused on. Wong et al. [8] reported aerodynamic distribution and flow around two side-by-side square buildings with different cross–section, the spacing ratio is between 1.12 and 2.5. Analogously, Chen et al. [9] found that the spacing ratio has a threshold value; a biased gap flow pattern appears when spacing ratio is smaller than this value. But three dimensional effects of interference between two high-rise buildings haven't been considered in this paper. Sakamoto et al. [10] reported changes on fluctuating pressure of two tandem buildings. They found that fluctuating pressure on principal building increases when the spacing ratio is larger than 3.0. Lam et al. [11] investigated interference effects on three closely arranged buildings in oblique wind direction. Mean pressure contours of the principal building in certain spacing ration and wind direction were given. They pointed out that high suction appears on leeward side, but they didn't analyze the effect of changing spacing ratio.

This paper focuses on local wind pressure on walls of the principal building with wind pressure coefficient interference factor. Various locations of an identical interfering building are considered.

2 EXPERIMENTAL SETUP AND DATA ANALYSIS

2.1 *Wind tunnel tests*

Wind tunnel tests were conducted in TJ-2 Boundary Layer Wind Tunnel at Tongji University. Its working section is 3.0m in width, 2.5m in height and15.0m in length. Wind field of Type C at a length scale of 1/400 which is in accordance with the Chinese code [12] was simulated by passive simulation method. The exponents of the mean wind profile for the terrain category C is 0.22, and the corresponding gradient height is 400m. Figure 1 shows the simulated mean wind speed profile and the longitudinal component profile of turbulence intensities. The figures show that both the experimental mean velocity and turbulence intensity are in agreement with the target profiles from Chinese code and A.I.J. [13], respectively. Figure 2 shows the power spectra of longitudinal fluctuating wind speeds.

The experimental models were a pair of identical square buildings. One was referred as the test building and another was referred as the interfering building which was located at various positions. The test building, at a length scale of 1:400, was B×D×H=150mm × 150mm × 900mm. A total of 496 pressure taps, 124 on each face were installed, especially the top and leading edges of the test building as shown in Figure 3.

Figure 4 shows the detailed experimental plan indicating the different locations of the interfering building and wind directions in wind tunnel. The interfering building was orientated with its face normal to the test building and was placed in 16 different arrangements with respect to the test building at origin of coordinates (0, 0). The center-to-center spacing between them was varied by spacing ratio Sx=x/B longitudinally and Sy=y/B laterally. The wind direction was varied in 15° steps in the range from 0° to 345°.

In this paper, only tandem and side-by-side arrangements at wind direction 0° were investigated. The sampling frequency and sampling time of the wind pressure were 312.5 Hz and 48s.

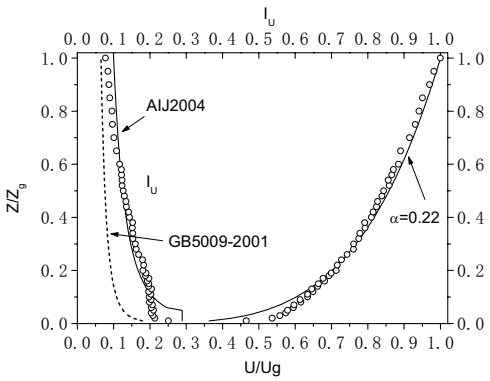

Figure 1. Mean velocity and longitudinal turbulence intensity profile.

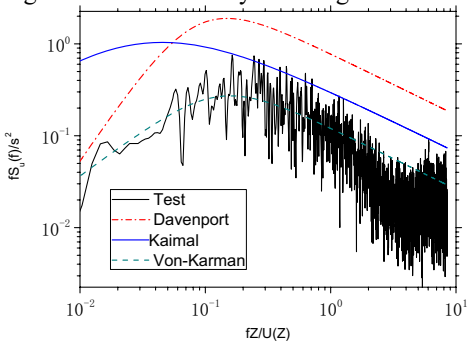

Figure 2. Longitudinal fluctuating velocity spectrum.

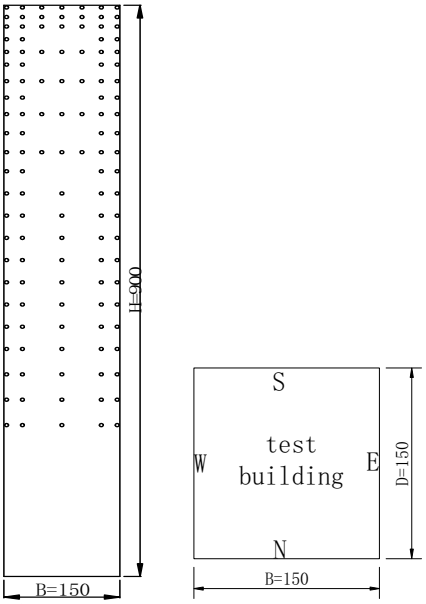

Figure 3. Locations of pressure taps on the test building.

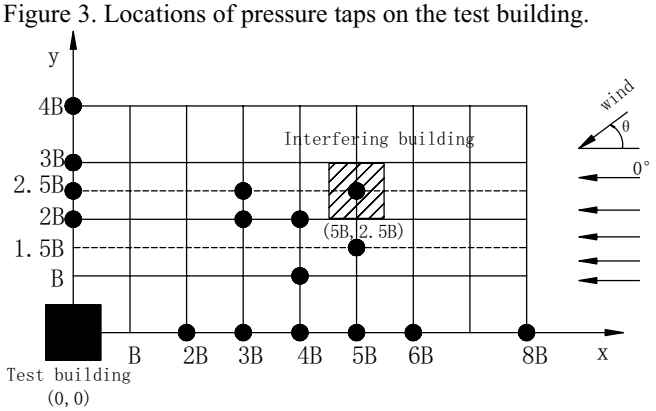

Figure 4. Configurations of interfering building and wind directions.

2.2 *Test data processing*

The pressure coefficient is defined as [14]

$$\overline{C}_p = \left(\overline{p} - p_0\right) \Big/ 0.5\rho\overline{u_r}^2 \tag{1}$$

$$C'_p = \sqrt{\overline{p'^2}} \Big/ 0.5\rho\overline{u_r}^2 \tag{2}$$

Where $\overline{C}_p$ is mean pressure coefficient, $\overline{p}$ is mean pressure, C'_p is r.m.s. fluctuating pressure coefficient, $\sqrt{\overline{p'^2}}$ is r.m.s. fluctuating pressure, p_0 is static pressure, ρ is the density of air, $\overline{u_r}$ is mean longitudinal velocity at the reference point . The reference height is selected at the top of the building.

Interference effect is presented in the form of non-dimensional Interference Factor (IF). IF can be expressed as

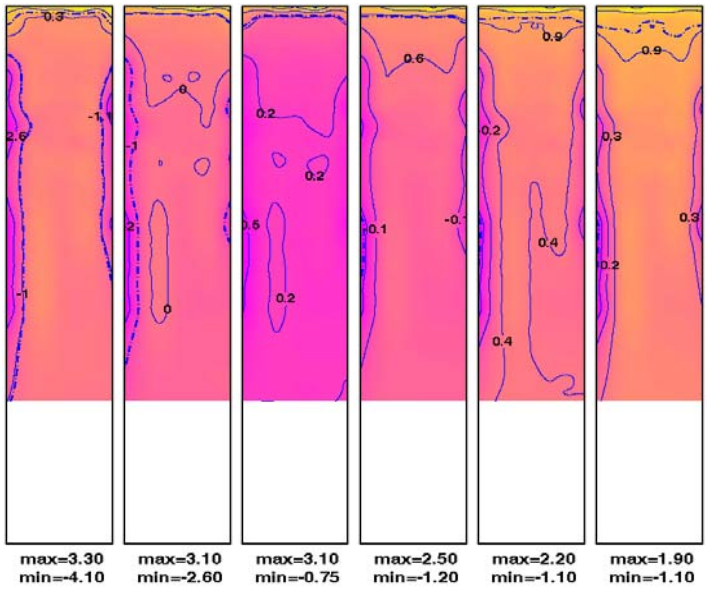
$$IF = \frac{C_{p\_\mathrm{inf}er}}{C_{p\_iso}} \tag{3}$$

Where $C_{p\_\inf er}$ represents the mean or R.M.S. pressure coefficients on the building with interference, C_{p_iso} is relative to the mean or R.M.S. pressure coefficients on the isolated building.

$|IF|>1$ represents the increase and $|IF|<1$ represents decrease on the test building due to interference. $IF=1$ suggests that interfering building has no effect on the test building. $IF=-1$ suggests that the sign of wind pressure on the test building changes, but the value doesn't change.

3 RESULTS AND DISCUSSION

3.1 *Mean pressure in tandem configurations*

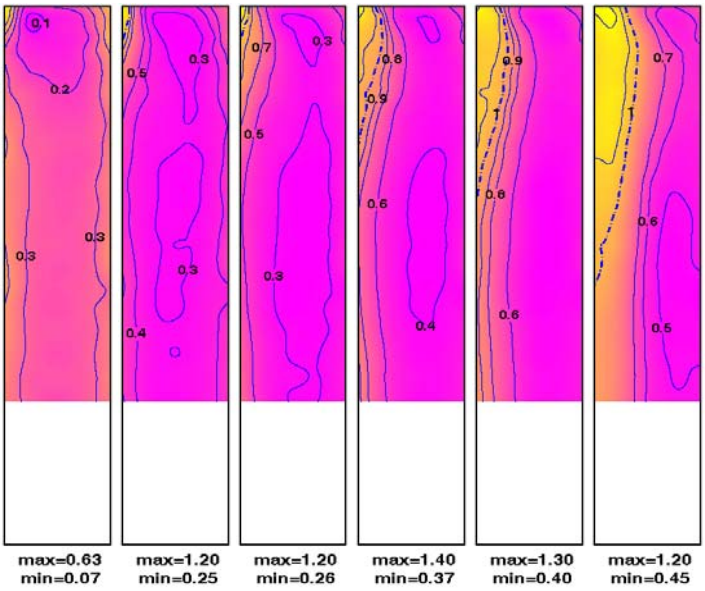


(a)Sx=2.0 (b)Sx=3.0 (c) Sx=4.0 (d)Sx=5.0 (e)Sx=6.0 (f)Sx=8

Figure 5. IF contours of mean pressure coefficient on face N for the test building (θ =0°, Sy=0).

Figure 5 shows IF contours for mean pressure coefficient on face N for the test building at different spacing ratio Sx at 0° wind angle. From the figure we can see that the critical Sx is 3.0, when Sx is smaller than3.0, IF on most part of face N is negative, otherwise negative IF only appears on leading edges. Therefore, there are two different flow patterns when spacing ratio changes in tandem arrangements. When spacing ratio is smaller than the critical value, vortex streets behind the upstream building are inhibited, otherwise vortex streets are formed behind each building and lead to complex vortex street interactions. This is in accordance with the results of Chen et al.[15] and Hasebe et al.[16].As spacing ratio Sx is smaller than3.0, negative pressure appears on face N and IF for mean pressure coefficient lies between -1.0 and 0 on most parts of the face. When spacing ratio Sx is beyond 3.0, the range of 0<IF<1.0 appears on face N and increases with Sx. IF lies between0.3 and 1.0 when Sx is equal to8.0. It is noteworthy that extrema of IF appear mainly on top and leading edges of face N, respectively. The extremum is beyond 1.0 and becomes smaller with the larger Sx. In a word, mean pressure on most zones of front face of the test building decreases due to the upstream building. Khanduri et al. [17] reported similar results. Differently, in this paper the mean pressure is amplified significantly on certain local zones on front face, for example, the top and leading edges.

As against front face N, interference effect on mean pressure of face E follows a regular trend when spacing ratio changes. IF is positive for all tandem configurations as shown in Figure 6. This indicates that mean pressure on face E is still negative when the interfering building is around. It is worth noting that the IF on top leading corner of face E has greater values which are larger than 1. An increase in mean pressure coefficient of 40% is obtained when Sx is equal to5.0. The reason of this situation is that with spacing ratio increasing, the separated flow from upstream building impinges on top of face N which leads to re-separation of the separated flow from the leading top corner of face E. As a result, velocity of the separated flow from the leading edge of face E increases and suction on face E becomes larger.



(a)Sx=2.0 (b)Sx=3.0 (c) Sx=4.0 (d)Sx=5.0 (e)Sx=6.0 (f)Sx=8

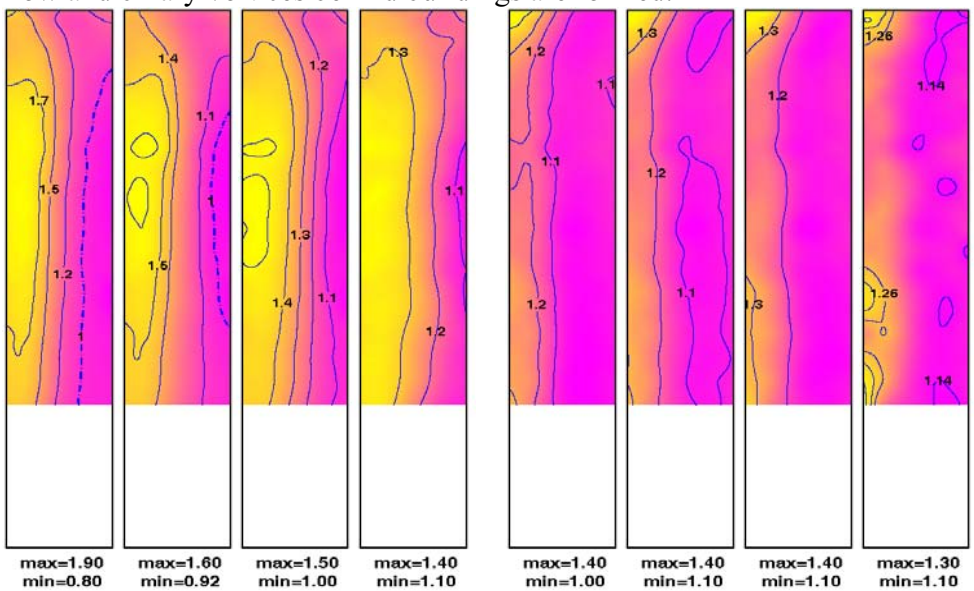
Figure 7. IF contours of mean pressure coefficient on face S for the test building (θ =0°, Sy=0).

Figure 7 shows IF contours for mean pressure coefficient on face S for the test building at different Sx at 0° wind angle. From the figure we can see that IF is positive and smaller than 1 at any spacing ratio. This indicates that mean pressure on face S is still negative, but it shows a reduction compared with that of the isolated building. This maybe ascribe to the presence of interfering building which leads to decrease in wake velocity from the test building.

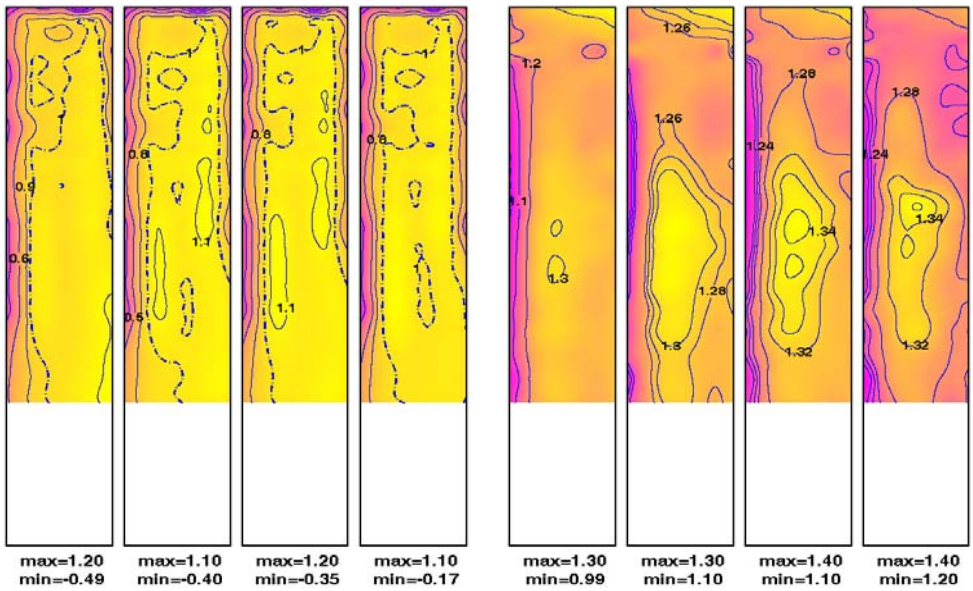
3.2 *Mean pressure in side-by-side configurations*

Figure 8 shows IF contours for mean pressure coefficient of the test building at different Sy at 0° wind angle. In Figure8a, IF on face E decreases gradually from leading edge towards trailing edge and the intensity of decrease is mild with an increase of spacing ratio. This is because gap flow forms between the two buildings. The smaller the spacing ratio, the faster the gap flow passes through the channel which leads to larger suction. The extremum of IF becomes smaller with the larger Sy and it gets maximal value 1.9 which locates on the (2/3) H of face E when Sy=2.0. Figure8b shows IF of face W. From the figure we can see that IF gets extremum on trailing top corner. This maybe ascribe to presence of the interfering building which changes the flow pattern of the test building that aggravates the vortex shedding from trailing top corner on face W. Chen et al. [9] reported similar results.

As against the side faces, changes on spacing ratio have little influence on IF on face N. The value of IF has a little increase on most zones of face N. Mean pressure coefficients increase by about 10%~20% compared with those of the isolated building, as shown in Figure8c. In Figure8d, values of IF on face S are larger than 1.0 at any spacing ratio. This indicates that suction on face S increases due to the interfering building. Changes on spacing ratio have little influence on IF on face S as that on face N. It shows that flow pattern behind the test building doesn't change qualitatively. This is in accordance with the results of literatures [8-9].There is a critical spacing ratio less than 2.0 for two buildings placed side-by-side. As spacing ratio is larger than the threshold, flow patterns have transition from asymmetric flow to symmetrical flow and binary vortices behind buildings are formed.



(a) Face E Sy=2.0, 2.5, 3.0, 4.0 (b) Face W Sy=2.0, 2.5, 3.0, 4.0

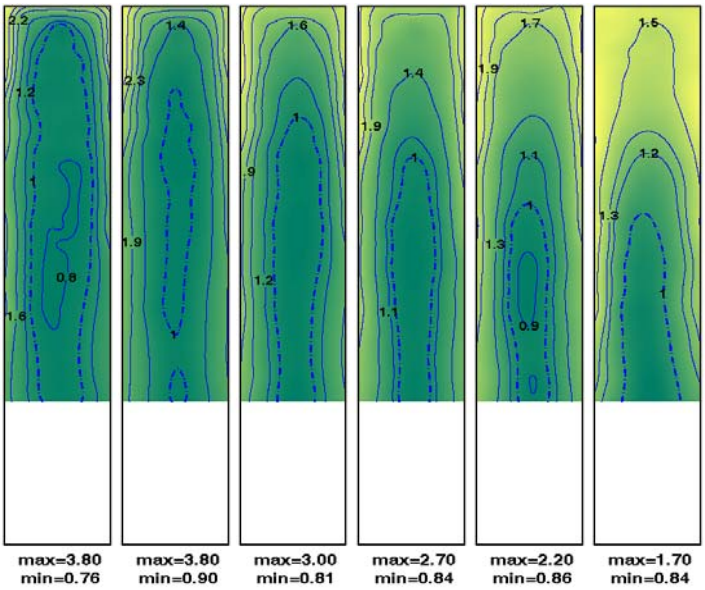


(c) Face N Sy=2.0, 2.5, 3.0, 4.0 (d) Face S Sy=2.0, 2.5, 3.0, 4.0

Figure 8. IF contours of mean pressure coefficient for the test building (θ =0°, Sx=0).

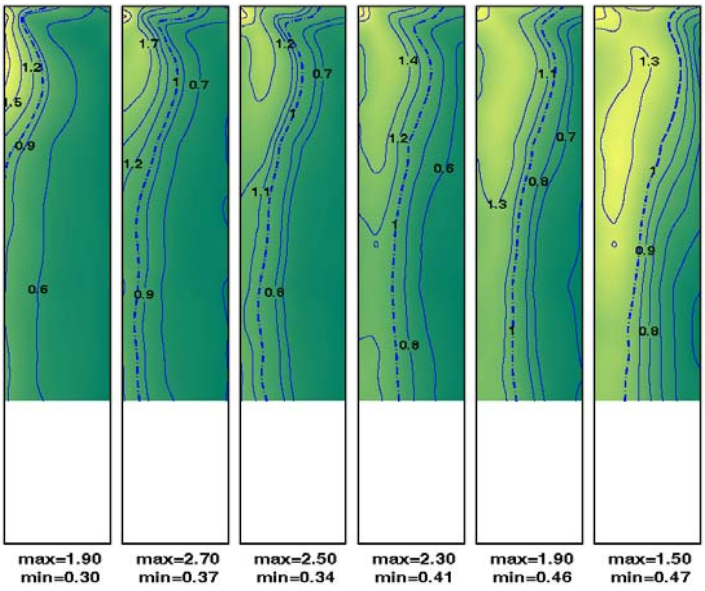
3.3 *Fluctuating pressure in tandem configurations*

Figure 9 shows IF contours for fluctuating pressure coefficient on face N for the test building at different Sx at 0° wind angle. From the figure we can see that the zone of IF>1.0 increases with Sx. It is noteworthy that extremum of IF decreases with Sx and it gets maximal value3.8 which locates on top leading edges of face N when Sx is equal to3.0. The reason for this situation is that when spacing ratio Sx is smaller than3.0, steady vortex zones form between the two buildings. Shear layers separated from the leading edges of the interfering building reattach fast to the side faces of the test building due to the closely spacing, then re-separation happens at the trailing edge of the test building which forms quasi-periodic vortex shedding behind it. This can be observed in Figures10a-10b, the value of IF is larger than 1.0 on the leading edge of face E due to reattachment of shear layers. Vortex shedding forms behind upstream and downstream building respectively when spacing ratio Sx is beyond3.0, fluctuating pressure on face N increases compared with that of the isolated building due to the turbulent of the incoming flow increases. So the zone of IF>1.0 expands as shown in Figures 9c-9f. Fluctuating pressure on face E increases correspondingly. The reason is, vortices in the wake of the upstream interfering building impinge directly on the front face N of the downstream test building which increases the velocity of shear layer separation and leads to intense turbulences as shown in Figures 10c-10f. The zone of IF>1.0 on face E expands when the spacing ratio increases. The extremum of IF becomes smaller with the larger Sx and gets maximal value 2.7 when Sx is equal to3.0.



(a)Sx=2.0 (b)Sx=3.0 (c) Sx=4.0 (d)Sx=5.0 (e)Sx=6.0 (f)Sx=8

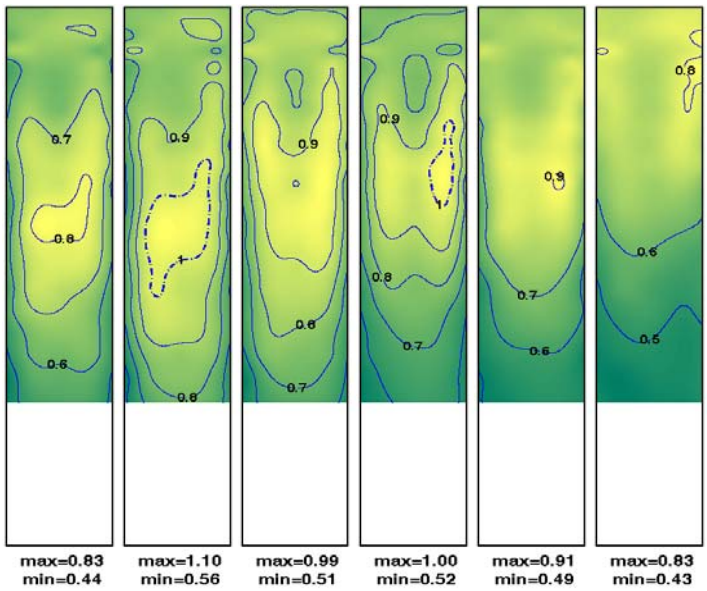
Figure 9. IF contours of fluctuating pressure coefficient on face N for the test building (θ =0°, Sy=0).



(a)Sx=2.0 (b)Sx=3.0 (c) Sx=4.0 (d)Sx=5.0 (e)Sx=6.0 (f)Sx=8

Figure 10. IF contours of fluctuating pressure coefficient on face E for the test building (θ =0°, Sy=0).

Figure 11 shows IF contours for fluctuating pressure coefficient on face S of the test building at different Sx at 0° wind angle. From the figure we can see that the value of IF which is larger than 1.0 only appear on the middle part of face S when Sx is equal to 3.0. The value of IF is less than 1.0 on other cases. The results illustrate that the vortex shedding intensity behind the test building becomes smaller compared with that of the isolated building due to the upstream building. As a result, the fluctuating pressure on face S reduces.



(a)Sx=2.0 (b)Sx=3.0 (c) Sx=4.0 (d)Sx=5.0 (e)Sx=6.0 (f)Sx=8

Figure 11. IF contours of fluctuating pressure coefficient on face S for the test building (θ =0°, Sy=0).

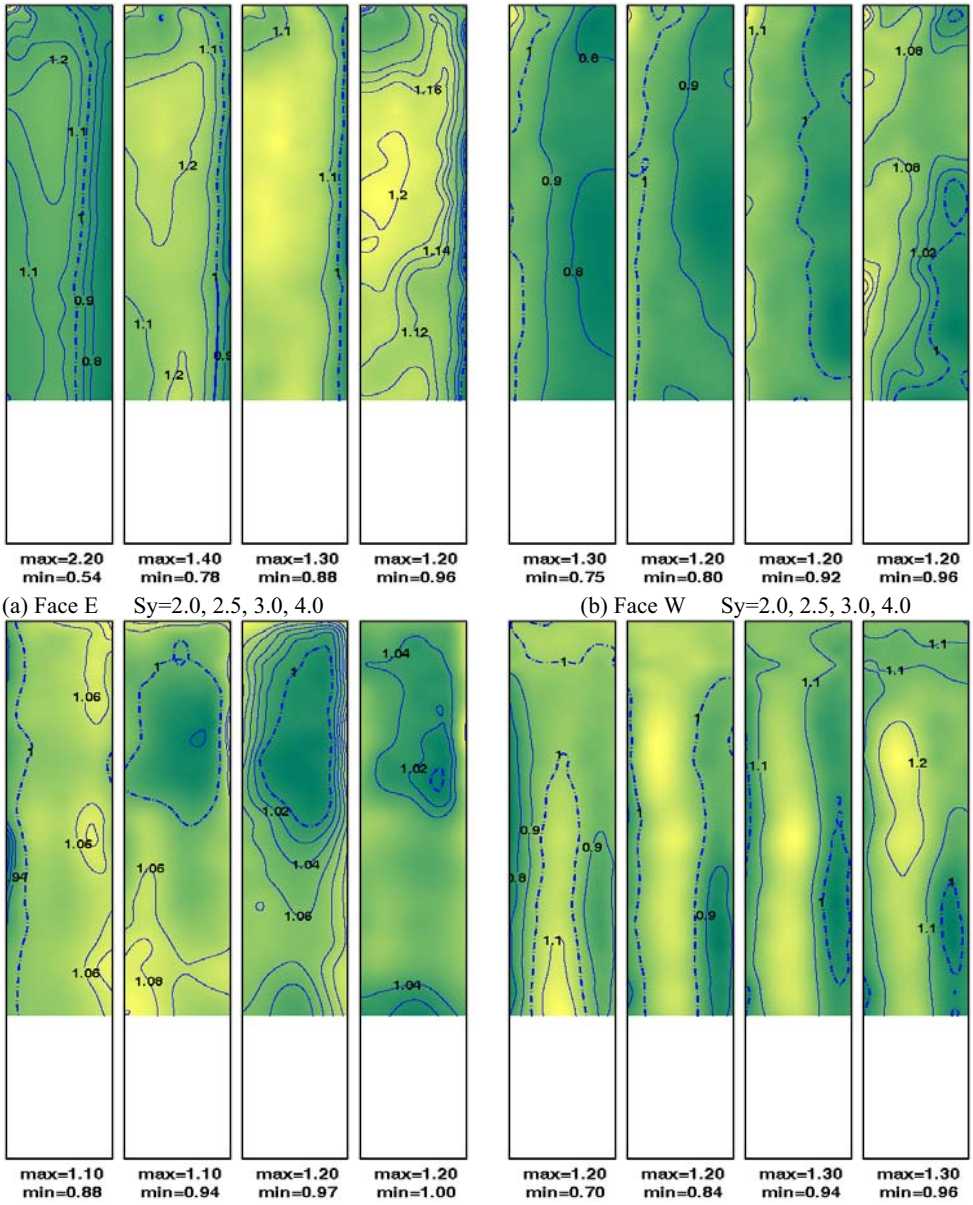
3.4 *Fluctuating pressure in side-by-side configurations*

Figure 12 shows IF contours for fluctuating pressure coefficient on walls of the test building at different Sy at 0° wind angle. In Figure12a, IF on face E is the same as that for mean pressure coefficient on face E which decreases gradually from leading edge towards trailing edge. The extremum of IF becomes smaller with the larger Sy and locates mainly on leading top corner and (0.6~0.8) H on face E. Interference effect tends to average overall as spacing ratio increases. IF on face E gets maximal value 2.2 which locates on leading top corner of face E when Sy=2.0. This is because the position lies in the high-velocity region due to fast separation which leads to the turbulent increases. So these positions are dangerous zones and should be paid much attention to. As against face E, in Figure12b, changes on spacing ratio have little influence on the extremum of IF which mainly lies in the trailing top corner on face W. It is around 1.2. In addition, the flow separated from the leading edges of face N tends to symmetry, as a result, the zone of IF>1.0 increases slightly with Sy increases.

Changes on spacing ratio have little influence on IF for fluctuating pressure coefficient on face N, as shown in Figure12c. The value of IF mostly lies between 0.9 and 1.1, which are very uniform distribution when spacing ratio is equal to4.0. It illustrates that the interference effect decrease with spacing ratio increases. In Figure12d, the zone of IF>1.0 expands slightly with spacing ratio increases and the location on which IF gets extremum gradually approaches the (2/3) H on face S. The value of IF on most part of face S is still larger than 1.0 when Sy is equal to 4.0. This is because the three-dimensional interference leads to turbulences around the test building increase, that is to say interference effect is still significant when spacing ratio is 4.0.

4 CONCLUSIONS

The interference effect for mean and fluctuating pressure on the test building for various locations of an identical interfering building at 0° wind direction has been studied by interference factor contours. The following results were obtained:



(a) Face E Sy=2.0, 2.5, 3.0, 4.0 (b) Face W Sy=2.0, 2.5, 3.0, 4.0

(c) Face N Sy=2.0, 2.5, 3.0, 4.0 (d) Face S Sy=2.0, 2.5, 3.0, 4.0

Figure 12. IF contours of fluctuating pressure coefficient for the test building (θ =0°, Sx=0).

1 In tandem configurations, mean pressure on front face of the test building is negative as spacing ratio is smaller than 3 and positive when spacing ratio is larger than3.0. The test building experiences considerable shielding due to an upstream interfering building and the extent of shielding is obviously weakened with spacing ratio increases. IF for mean pressure coefficient on front and leeward face is positive, in addition, it gets maximal value when spacing ratio Sx is 3.0. Fluctuating pressure has moderate change with spacing ratio compared with that of mean pressure.Variations of IF for fluctuating pressure coefficient on all faces are similar,they all get maximal value as spacing ratio Sx is 3.0.

2 In tandem configurations, the leading top corner on side faces of the test building should be pay special attention to, especially when spacing ratio Sx is 3.0.

3 In side-by-side configurations, the extrema of IF for mean and fluctuating pressure coefficient on outer and inner face of the test building decrease with spacing ratio increase. However, the extremum of IF for fluctuating pressure coefficient was influenced significantly by the interfering building and gets maximal value 2.2 on inner face when spacing ratio Sy is 2.0. Changes on spacing ratio have little influence on the extrema of IF on front and leeward faces , but IF on leeward face which gets maximal value 1.4 is greater than that on front face.
4 In side-by-side configurations, pressure on inner face of the test building changes significantly, especially on leading top corner of the inner face. So, envelops of these positions in which mean and fluctuating pressure is obviously enlarged should be strengthened when there are adjacent buildings.

ABSTRACT: Wind pressure characteristics of a twin-tower high-rise structure disturbed by surrounding buildings were investigated using large eddy simulation (LES). The computational simulation technique were described initially. Studies have been performed in detail for the mean and fluctuating pressure coefficients. Detail explanations of each analysis results were given in the paper. To study further on the pressure coefficients on the building surfaces, parameter studies on shape coefficient and spatial correlation were performed and investigated subsequently. The numerical obtained in this study are expected to provide practicing engineers a better understanding of wind field around buildings.

1 INTRODUCTION

Computational fluid dynamics has been a widely-used method of wind flow simulation around buildings for more than 20 years. Rapid development is observed especially in recent studies. Traditional standard turbulence models, such as eddy viscosity-based models and various second-order stress models, were found to be inadequate in predicting unsteady flows around bluff bodies (Castro and Graham, 1999; Cowan, 1997; Lim et al, 2009; Leschziner, 1993). Unsteady techniques such as discrete vortex methods and, particularly, large eddy simulation (LES) are found to be much more appropriate for simulating unsteady flow features (Murakami and Mochida, 1995; Shah and Ferziger, 1997; Murakami, 1998; Fasel et al, 2002; Nozawa and Tamura, 2002; Fureby, 2007; Tominaga, 2008). Rodi (1997) compared the performance of LES and Reynolds-Averaged Navier-Stokes (RANS) calculations of vortex-shedding flow passing a square cylinder at Reynolds number, Re=22,000 and that of the 3D flow passing a surface-mounted cube at Re=40,000. Results showed that turbulence fluctuations were severely under-estimated by RANS, while LES was found more suitable and had great potential for complex flow calculations. Validation of LES in predicting flow around an obstacle under turbulent flow condition was also confirmed by Nozawa and Tamura (2002). Breuer et al (2003) investigated the variations of the predicted results among RANS, DES (detached-eddy simulation) and LES for the separated flow around a flat plate at high incidence. The RANS computations were not able to capture the unsteady vortex shedding behaviour and both two- and three-dimensional RANS predictions led to the same steady-state results. The asymmetric vortex shedding motion was well reproduced by DES and LES. But the free shear layer originating from the leading edge of the plate was not well reproduced by DES. Kose and Dick (2010) presented a numerical study of the flow around a cubical building by RANS, hybrid RANS/LES and LES in Re=4×106. Results obtained by LES were the most accurate for coarse grid simulations. Detailed comparison between LES and experiment of both the inflow boundary layer and the flow field around a cube

was performed by Lim et al (2009). Results confirmed that LES is a viable tool for use in wind engineering problems concerning flow over isolated bodies.

It is well-known that there is rarely a case that only one single high-rise building is built in a city district. Many more regional groups of high-rise buildings are built in major cities, which cause structural wind characteristics become much more complex because of interaction and obstruction effects among buildings. Moreover, existing study results on wind characteristics of flow around single building and also some design parameters stipulated in international design codes may not be applicable to buildings under such wind condition. So, the structural wind characteristics influenced by surrounding buildings have been a subject of interest to researchers and engineers because of its significance for the evaluation of building designs. Zhou (2011) studied wind characteristics around a tall structure, which is disturbed by surrounding buildings, using experimental and numerical methods. Results showed that pressure coefficients were greatly disturbed by surrounding buildings. Cheng et al (2003) discussed the predictive performance of LES with various dynamic subgrid-scale models for a fully developed turbulent flow around a matrix of cubes. Su and Chen (2006) predicted the wind-induced surface pressures and wind environment around a complex-shaped high-rise building with annex by the standard k-ε model and the RNG k-ε model. Ma et al. (2007) investigated the wind environment around a single building and a building complex based on and the Reynolds averaged N-S equations and the RNG k-ε turbulence model. Wang et al. (2003) predicted wind-induced pressures on a low-rise single house with gable roofs and a building complex consisting of six low-rise houses with gable roofs by numerical simulation.

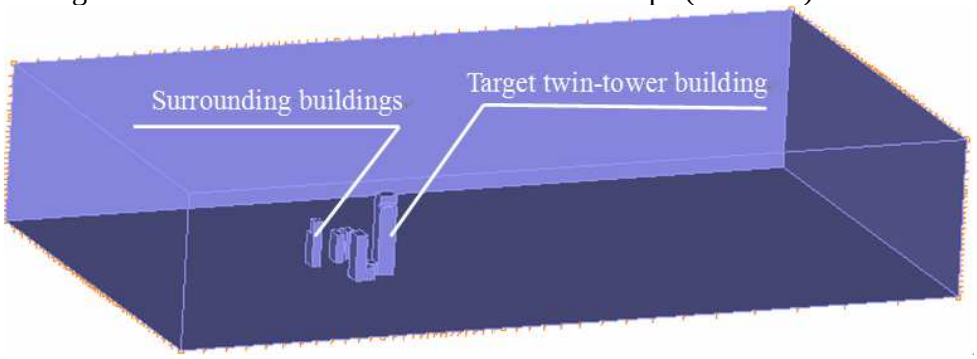
This paper aims to assess the wind pressure characteristics of a twin-tower high-rise structure under the interaction and obstruction effects of surrounding buildings. The study results will assist engineers and researchers having a better understanding of the risks involved, such as extreme pressure and unfavorable wind direction, when designing a similar twin-tower. To achieve this, the present paper contains CFD. The CFD simulations were performed using LES method. Studies on LES predictions were made in terms of the mean pressure coefficients for a number of pressure analysis around the outer and inner surfaces of the twin-tower building. Studies were also carried out for disturbance effect and spatial correlation of the fluctuating pressure and interaction and obstruction effect. In addition, the reliability of LES method in simulating flow around group of buildings was also revealed. So, the CFD analyses were investigated to assess the capability and accuracy of the LES method in simulating the wind flow in a group of building complex.

2 COMPUTATIONAL SIMULATION TECHNIQUE

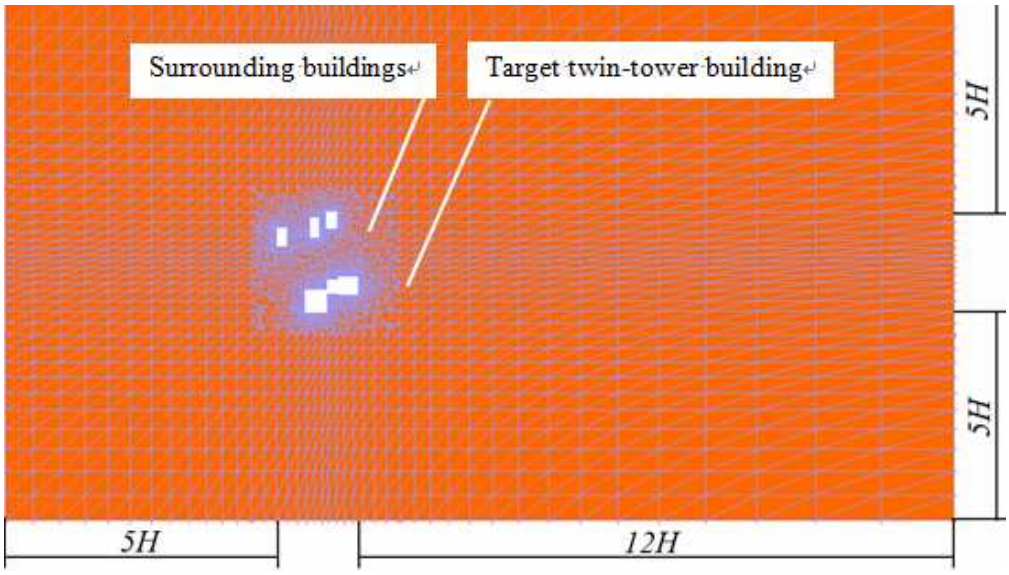
2.1 *Computational model*

In this study, a 1:300 scaled numerical model was designed. In order to eliminate flow obstacle effect on the inflow and outflow boundary conditions (Murakami, 1998), the length of inflow, outflow and side-flow of the computational domain are 5*H*, 12*H* and 5*H*, respectively, as shown in Fig.1 (*H* is the maximum height of the bluff bodies, *H*=0.75m). The total height of the computational domain is 3*H*. The reason for such a choice is to eliminate the flow obstacle effect on the inflow and outflow boundary conditions, and keep the blockage ratio less than 3% as discussed by Murakami (1998). The Reynolds number based on the width *L* and *U(z)* (Inflow velocity at $z=H$) is about 5.4×10^5. Both structured and unstructured grids were used for mesh generation, as shown in Fig. 1. For zones near the bluff body, an unstructured mesh was generated while for zones outside the unstructured mesh, the structured mesh was applied. One

important advantage of this arrangement is that it is convenient to generate a mesh fine enough in the neighborhood of the building surfaces while keeping the mesh in far field zones from the building surfaces unchanged or in a proper coarser mesh. ADINA (2005) platform was adopted in this study, which has the capacity of manage both structured and unstructured grids in its solver. The average distance of the first layer of nodes from the surface is about *L*/5000 in X direction and *B*/5000 (value of *L* and *B* can be found in Fig. 1(a)) in Y direction with same growth factor of 1.2, which are smaller than the values suggested by Murakami (1998) (i.e. *D*/1000) and Huang (2006) (i.e. *D*/4000), so as to ensure that the wall unit $y^+<5$ is satisfied. The maximum grid size used far away from the building is about *H*. Slip boundary conditions are imposed on the velocity near the solid boundaries. The Reichardt wall-law is then used to derive the shear stresses caused by the presence of the wall (Hinze, 1959; Camarri *et al*, 2002). Advantage of this wall law is that it can describe the velocity profile not only in the laminar sub-layer ($y^+<5$) but also in the logarithmic region of a turbulent boundary layer ($y^+ \geqq 40$) and in the intermediate region, which will guarantee correct asymptotic behaviour at the wall of the SGS terms in the Smagorinsky model. Totally, about 800,000 3D grid elements were generated in the present simulation. Computations are carried out on 16 Xeon E5580 3.2GHz CPUs and require about 16GB of Infineon memory and about 8 days of CPU time for the whole simulation. The numerical time step for the transient simulation is 5×10^{-4} sec and 8000 steps, which is equivalent to 4 seconds, are needed to collect data for computational stability purposes. The statistical average of flow field was taken for the last 4000 steps (i.e. 2 sec).



(a) Computational domain (Unit: m)



(b) Grid distribution

Figure 1. Computational domain and grid distribution

2.2 *Boundary conditions*

Reasonable boundary conditions will be helpful of saving computational time. For the inflow boundary condition, both the mean and fluctuating wind velocity were considered. The mean wind velocity can be achieved by matching a log-law profile (Obasaju, 1992):

$$\begin{cases} v(z) = 2.5v^* \log_e(40)\left(\dfrac{z}{40Z_0 + D}\right)^{0.25} & \left(\dfrac{z-D}{Z_0}\right) < 40 \\ v(z) = 2.5v^* \log_e\left(\dfrac{z-D}{Z_0}\right) & 40 \le \left(\dfrac{z-D}{Z_0}\right) \le 1000 \end{cases} \tag{1}$$

where, $v(z)$ is the horizontal wind speed at z, v^* is the surface friction velocity defined as $(\tau_\circ / \rho)^{0.5}$ ($\tau_\circ$ being the surface shear stress), D is the height of the zero plane above ground, Z_0 is the surface roughness length parameter. Height of the gradient wind is 450m.

Based on a procedure by Kraichnan (1970) for generation of an isotropic continuous flow field satisfying a spectrum of Dirac function, a new general inflow turbulence generation method for large eddy simulation, also called the discretizing and synthesizing random flow field generation (DSRFG) technique, is proposed by Huang *et al* (2010) and Li *et al* (2007). The isotropic fluctuating velocity in $\mathbf{x}$ space was synthesized by the following superposition of harmonic functions (Huang *et al*, 2010):

$$u_i(\mathbf{X}, t) = \sum_{n=1}^{N}\left[p_i^n \cos\left(k_j^n x_j + \omega_n t\right) + q_i^n \sin\left(k_j^n x_j + \omega_n t\right)\right] \tag{2}$$

$$p_i^n = \varepsilon_{ijm}\zeta_j^n k_m^n, \quad q_i^n = \varepsilon_{ijm}\xi_j^n k_m^n, \quad \zeta_j^n, \xi_j^n, \omega_n \in N(0,1), \quad k_j^n \in N(0, 1/2)$$

Where k and ε are the turbulence kinetic energy and the turbulence dissipation rate, respectively, ε_{ijm} is the permutation tensor used in vector product operation, k_j^n and ω_n, respectively, represent a sample of n wave-number vectors and frequencies of the modeled turbulence spectrum. Detailed calculation about the Eq. (2) can be found in Huang *et al* (2010). The first superiority of the DSRFG is that continuity condition, $div(\mathbf{u}) = 0$, can be ensured strictly. The second is that fluctuating velocity generated in inflow condition satisfies specified power spectrum density function. And the last one is that spatial correlation of inflow condition can be adjusted by scaling factor.

At the outflow, convective boundary condition is applied for velocity and pressure:

$$\partial/\partial t + c\left(\partial/\partial x\right) = 0 \tag{3}$$

where c is taken to be the bulk velocity so as to ensure global mass conservation. Slip condition was assumed for velocity on the two sides and top surfaces of the computation domain. With this kind of boundary condition, one has $\partial U/\partial y = \partial U/\partial w = V = W = 0$. And non-slip condition was used for velocity on the ground surface, that is u_n=0. Neumann condition for pressure was employed on surfaces of building and the computation domain as pressure gradient orthogonal to the surfaces equals to zero.

3 DATA PROCESSING

Pressure data obtained from computational simulation is processed using equations as shown in Table 1. External pressures were normalized with respect to the mean wind pressure at the reference height of *H*. Instantaneous pressure coefficients were determined at each pressure tap location and subsequently analyzed to determine maximum, minimum, mean, and standard deviation of pressure coefficients. Shape coefficient describes distribution status of static pressure on a building surface in wind action, which is influenced mainly by the shape and size of a building. Spatial correlation of fluctuating wind represents pressure dependency of two pressure taps, which is an important index of studying spatial flow status and corresponding transmission pattern.

Table 1 Data processing equations

Wind pressure coefficient	$C_{pi}(n)=\dfrac{p_i(n)}{\rho U_{ref}^2/2} \quad (n=1\cdots N)$
Mean wind pressure coefficient	$\bar{C}_{pi}=\sum_{n=1}^{N}\dfrac{C_{pi}(n)}{N}$
Fluctuating wind pressure coefficient	$C_{pi,rms}=\sqrt{\sum_{n=1}^{N}\dfrac{\left(C_{pi}(n)-\bar{C}_{pi}\right)^2}{N-1}}$
Shape coefficient	$\mu_s=\dfrac{\sum_i \bar{C}_{pi}A_i}{A}$
Correlation coefficient of fluctuating wind	$\rho_{ij}=\dfrac{E\left[\left(C_{pi}(n)-\bar{C}_{pi}\right)\left(C_{pj}(n)-\bar{C}_{pj}\right)\right]}{C_{pi,rms}C_{pj,rms}}$

As shown in Table 1, i is the number of pressure tap; N is the sample length of the wind pressure time series, N =4096; ρ is air density, ρ=1.2kg/m^3; V_{ref} is wind velocity of the reference height; z_i is the height of the i^{th} pressure taps; μ_{zr} is wind pressure coefficient of reference height; μ_{zi} is wind pressure coefficient of the i^{th} pressure taps; μ_{si} is the shape coefficient of the i^{th} pressure taps; A_i is the covered surface area of the i^{th} pressure taps; A is the total surface area.

4 RESULTS AND DISCUSSION

4.1 *Mean pressure coefficient*

The mean pressure coefficient contours obtained from numerical simulations results are shown in Fig. 2. It is well-known that the mean pressure coefficients on the windward face are largely positive for isolated building (Huang et al., 2006; Gomes et al., 2005). However, in this study the mean pressure coefficients were greatly affected by the interaction and obstruction effects between the main and sub-main towers and that of the upstream buildings. For example, the mean pressure coefficients of the main tower on the front face were negative on the lower level for 0^{O}wind incident direction, attributing to the influence of the sub-main tower. The mean pressure on the side and back faces were also greatly disturbed, which are discussed in detail in the next sections.

4.2 *Fluctuating pressure coefficient*

Fluctuating pressure coefficients of the different taps on front faces are largely of similar values, except those at the corner, as shown in Fig.3, which means that flow status on the front faces is relatively stable. At the corner, the fluctuating pressure coefficients increase as stronger vortex motion generates. On the side faces, larger fluctuating pressure coefficients relative to those on the front faces can be observed, especially for the region at the corner, due to the flow separation. The reason is that strong and orderly vortex motion appears on the side faces and greater vortex energy is then aroused, which causes the increase of the fluctuating pressure. On the back faces, the variation of the fluctuating pressure coefficients are complex relatively. The reason is that irregular and disorder vortex is generated in wake flow, which causes the pressure on back faces variable and no precise laws can be used to describe the pressure status.

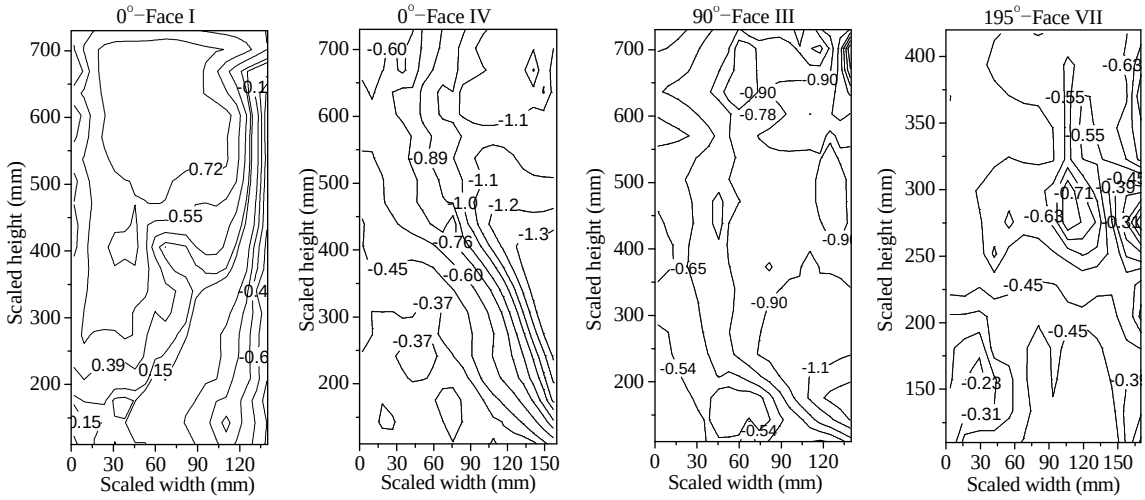


Figure 2. Mean pressure coefficient contours

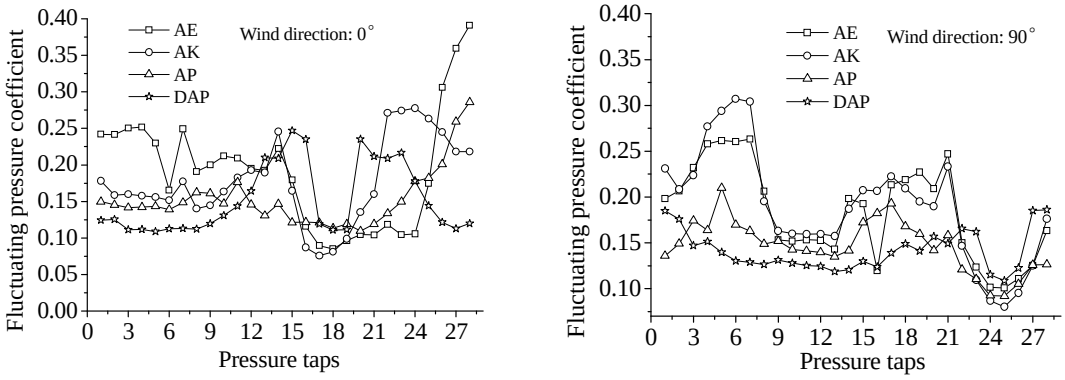
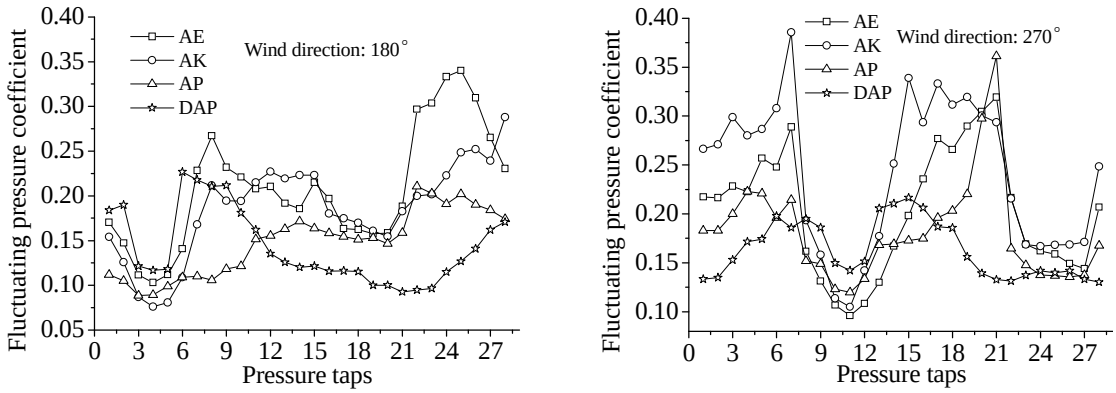


(a) 0° (b) 90°



(c) 180° (d) 270°

Figure 3. Fluctuating pressure coefficients in different wind direction

4.3 *Interaction and obstruction effect*

To research the interaction and obstruction effect of among buildings, interaction and obstruction factor γ is defined as:

$$\gamma=\mu_s/\mu_{sn} \tag{4}$$

Where: μ_s is shape coefficient with the interaction and obstruction effect, μ_{sn} is shape coefficient without the interaction and obstruction effect.

Variation of the interaction and obstruction factor along the height of both the main and sub-main towers in different wind directions is shown in Fig. 4. It can be easily found in Fig. 5 that the maximum shape coefficients of the front faces of the twin-tower building is 0.77, which is close to the value of 0.8 stipulated in the Chinese code (2002). However, greater discrepancy have been noticed for the shape coefficients of back and side faces when comparing to the Chinese wind code (2002). The maximum shape coefficients were -1.25 and -0.83 for the side and back faces respectively, which were higher than the values of the Chinese code (i.e. -0.7 and -0.5, respectively). So, it can be deduced that noticeable difference of pressure distribution on building faces exist relative to signal building (no interaction and obstruction effect exist in signal building).

(b) The sub-main tower

Figure 5. Shape coefficients

4.4 *Spatial correlation of fluctuating pressure*

Spatial correlation of fluctuating wind represents pressure dependency of two pressure taps, which is an important index of studying fluctuating pressure characteristic and also spatial flow status. The lateral correlation coefficient contours of fluctuating wind pressure are given in Fig.6. As revealed in these figures, the correlation coefficients decrease gradually as the distance of two pressure points increases. The correlation coefficient is influenced by vortex structure and its motion status of the surrounding flow field. Regular vortex structure (such as vortex shape and dimension) and similar motion status will contribute to enlarge the correlation coefficient in condition of the same distance of two points. E.g., two-point correlation in the middle region is relatively larger than that of the side region of the front faces in same distance.

5 CONCLUSIONS

The maximum mean pressure coefficients are found to be at the middle of windward surface with height of about 0.8*H*-0.9*H* in 24 wind directions, and the minimum pressure generates at the corner of flow separation. Flow with strong and orderly vortex motion yields large fluctuating pressure, such as the fluctuating pressure on side faces and especially at the corner of flow

separation. On the contrary, smaller fluctuating pressure yields if irregular and disorder vortex motion exist, such as the pressure on back faces.

Interaction obstruction effect of shape coefficients of the twin-tower building is mainly from the interference disturbance between the main and sub-main towers, and the disturbance effect of surrounding buildings. In this study, the disturbance effect of surrounding buildings on the fluctuating pressure of the twin-tower building is smaller than that of the interference disturbance between the main and sub-main towers.

The lateral spatial correlation of fluctuating pressure among pressure taps on the front and side faces are relatively larger than that of the back faces. As for the spatial correlation between two faces, larger correlation can only be found at the corner between the front and side faces. The vertical correlation decreases with increasing of distance between two pressure taps.

[a] *Eindhoven University of Technology, Department of the Built Environment, Eindhoven, the Netherlands*
[b] *TNO, Delft, the Netherlands*

ABSTRACT: Pressure measurements on the surfaces of a high-rise building model with height $h = 0.48$ m and width $b = 0.12$ m were performed in a boundary layer wind tunnel. Experiments were carried out for an isolated model and for three configurations with an interfering half-height building model. The effects of the interfering building to the minimum peak pressures on the reference model were determined. The influence of the separation distance and the shape of the interfering building (square and circular plan form) were investigated. For the smallest separation distance, $S = 0.5b$, the composition of the minimum peak pressures was studied in more detail by assessment of the mean and standard deviation pressure coefficient. This study shows that the magnitude of local minimum peak pressure increases with approximately 25-35% on two facades of the high-rise model. In the top corner of the façade on the side a reduction is observed of 20-40%, depending on the shape of the interfering model.

KEYWORDS: Wind interference, peak pressures, high-rise, mid-rise

1 INTRODUCTION

Wind loads on buildings can be influenced by the presence of nearby buildings. This influence can change the global loads on the interfering buildings, as well as the local loads on their building envelopes. Research on the influence of interference can be grouped in (1) studies on global loads and (2) studies on local loads. According to this categorization, Table 1 provides an overview of previously performed parametric wind tunnel studies on interference between high-rise buildings.

Studies on static global wind loads, performed by e.g. Taniike (1992) and Khanduri (1997), found that the influence of an interfering model with similar or larger height than the reference model can lead to an increase of 70-80%. Khanduri (1997) determined that the influence on the static wind load can be neglected if the interfering building is smaller than ¾ of the reference building height.

Even larger effects were found for dynamic global wind loads. Bailey and Kwok (1985) and Taniike and Inaoka (1988) found an increase in the dynamic base bending moment of respectively 440%, and 2000% for the case of a slender interfering model. Xie and Gu (2004, 2005 and 2007) performed an extensive wind tunnel study on two and three high-rise configurations. They derived a set of simplified guidelines and formulae to provide designers with tools to obtain an estimate for the influence of interference on the static and dynamic base-bending moment. According to these guidelines, an interfering building smaller than half the height of the reference building has no significant influence on the dynamic base-bending moment.

Table 1. Overview of previously performed parametric wind tunnel studies on wind load effects due to interference between high-rise buildings.

Few comprehensive studies were performed on the interference effects between tall buildings with a focus on local loads. Kim et al (2011) did perform such an extensive parametric wind tunnel study. One of the configurations they tested was a high-rise reference model under influence of a half-height model. Kim et al (2011) concluded that, in urban terrain conditions ($z_0 \approx 1.4$ m), an interfering model with half the height of the reference model has limited influence on the peak pressure coefficients. Bronkhorst et al (2011) performed an analysis on the mean and standard deviation pressure distribution for the same case in suburban terrain conditions ($z_0 \approx 0.8$ m). Three pressure effects resulting from interference were determined:

1. An increase on the faces in the passage for wind parallel to the passage.
2. An increase on the side faces of the reference model at roof height of the half-height interfering model for wind parallel to the configuration.
3. A reduction in the top corner of both side faces for wind parallel to the configuration.

This study investigates the magnitude of these effects when minimum peak pressures are considered. The goals of the study presented in this paper are:

- To determine local peak pressure effects resulting from interference between a high-rise building model and a half-height interfering model.
- To investigate the influence of the separation distance, the shape of the interfering model and the angle of incidence on the peak pressure effects.
- To gain understanding on the composition of these peak pressure effects by assessment of the mean and standard deviation pressure coefficient.

2 MATERIALS AND METHODS

Wind tunnel experiments were carried out in the open circuit atmospheric boundary layer (ABL) wind tunnel of TNO in the Netherlands. Measurements were performed on the isolated configuration and on three tandem configurations as illustrated in Figure 1(a). A detailed description of the experimental set-up can be found in Bronkhorst et al (2011). Both the influence of an interfering half-height model with square and with a half-height model with circular ground plan were investigated. Measurements were performed for twenty-four angles of incidence in 15° increments, for each configuration. The reference model pressure taps were distributed as illustrated in Figure 1(b), with 38 pressure taps on each face. Taps are designated by face F (which can be A, B or C), row (i) and column (j). For example, the pressure tap on face A, in the second row and the fifth column is specified as $A25$; the minimum peak pressure coefficient determined at this position is specified as $C_{p,min}(A25,\theta)$.

The fluctuating pressures acting at the pressure taps were measured with a sampling rate of 400 Hz for a period of approximately 20.5 seconds. The undisturbed static and dynamic pressure were measured with a pitot-static tube positioned at model roof height ($h = 0.48$ m), 2.6 m in front of the model and 0.7 m to the side. The mean velocity at this height (U_{ref}) for all tests was approximately 14.1 m/s, which corresponds with a width-based Reynolds number of $Re_b = U_{ref}b/\nu \approx 1.1 \times 10^5$. The instantaneous static reference pressure, $p_{ref}(t)$, was measured at a pressure tap in the left side wall at 1.2 m height, at the same longitudinal position as the instrumented reference model.

The measured pressure time series were converted to pressure coefficients with:

$$C_p(t) = \frac{p_s(t) - p_{ref}(t)}{q_{ref}} = \frac{p_s(t) - p_{ref}(t)}{\frac{1}{2}\rho U_{ref}^2} \qquad [1]$$

In which $p_s(t)$ is the instantaneous static pressure measured at the pressure taps, q_{ref} is the mean dynamic pressure measured at the pitot-static tube, and ρ is the air density.

The pressure coefficient time series were divided in thirty-two intervals of t = 0.64 s. For each interval, the mean, the standard deviation, and the minimum negative peak pressure coefficient were determined. The averages of each of these statistics over the thirty-two intervals are presented in the next paragraph.

Pressure coefficients have a magnitude and a sign. The magnitude (i.e. the absolute value) of the pressure coefficient is specified as large or small or showing an increase or decrease; the sign is negative or positive.

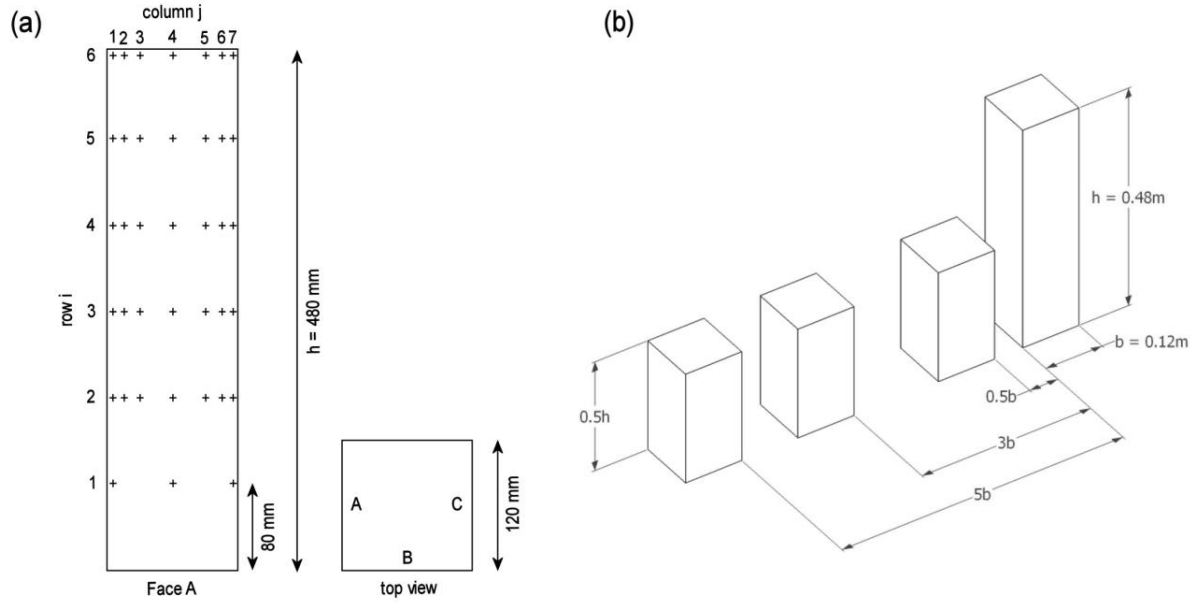

Figure 1. (a) Pressure tap distribution on the faces *A*, *B* and *C* of the instrumented building model, (b) the tandem configurations measured in the wind tunnel illustrated with the square half-height interfering model.

3 RESULTS AND DISCUSSION

This chapter gives results for the minimum peak pressure coefficient, and the mean and standard deviation pressure coefficient. First the overall effects are determined through investigation of the minimum peak pressure coefficients over all angles of incidence, the largest effects are investigated in more detail.

At each tap position, the minimum of the negative peak pressure coefficients over all angles of incidence $C_{p,min}(Fij,all)$ was determined. Figure 2 shows contour plots of the minimum peak pressure coefficient over all angles of incidence. The contour plots provide information on the location and the magnitude of the peak pressure effects which are a result of interference. The influence of the interfering half-height square cylinder is illustrated on the left-hand side; the influence of the circular cylinder is illustrated on the right. The pressure distributions on the model faces in the isolated case are plotted in the centre of the figure. The smallest minimum peak pressure coefficient for the isolated case, $C_{p,min}(F14,all) \approx$ -1.5, is found in the middle of the model face, near the ground. The largest minimum peak pressure coefficients $C_{p,min}(F61,all) \approx C_{p,min}(F67,all) \approx$ -2.4 are observed in the top corners.

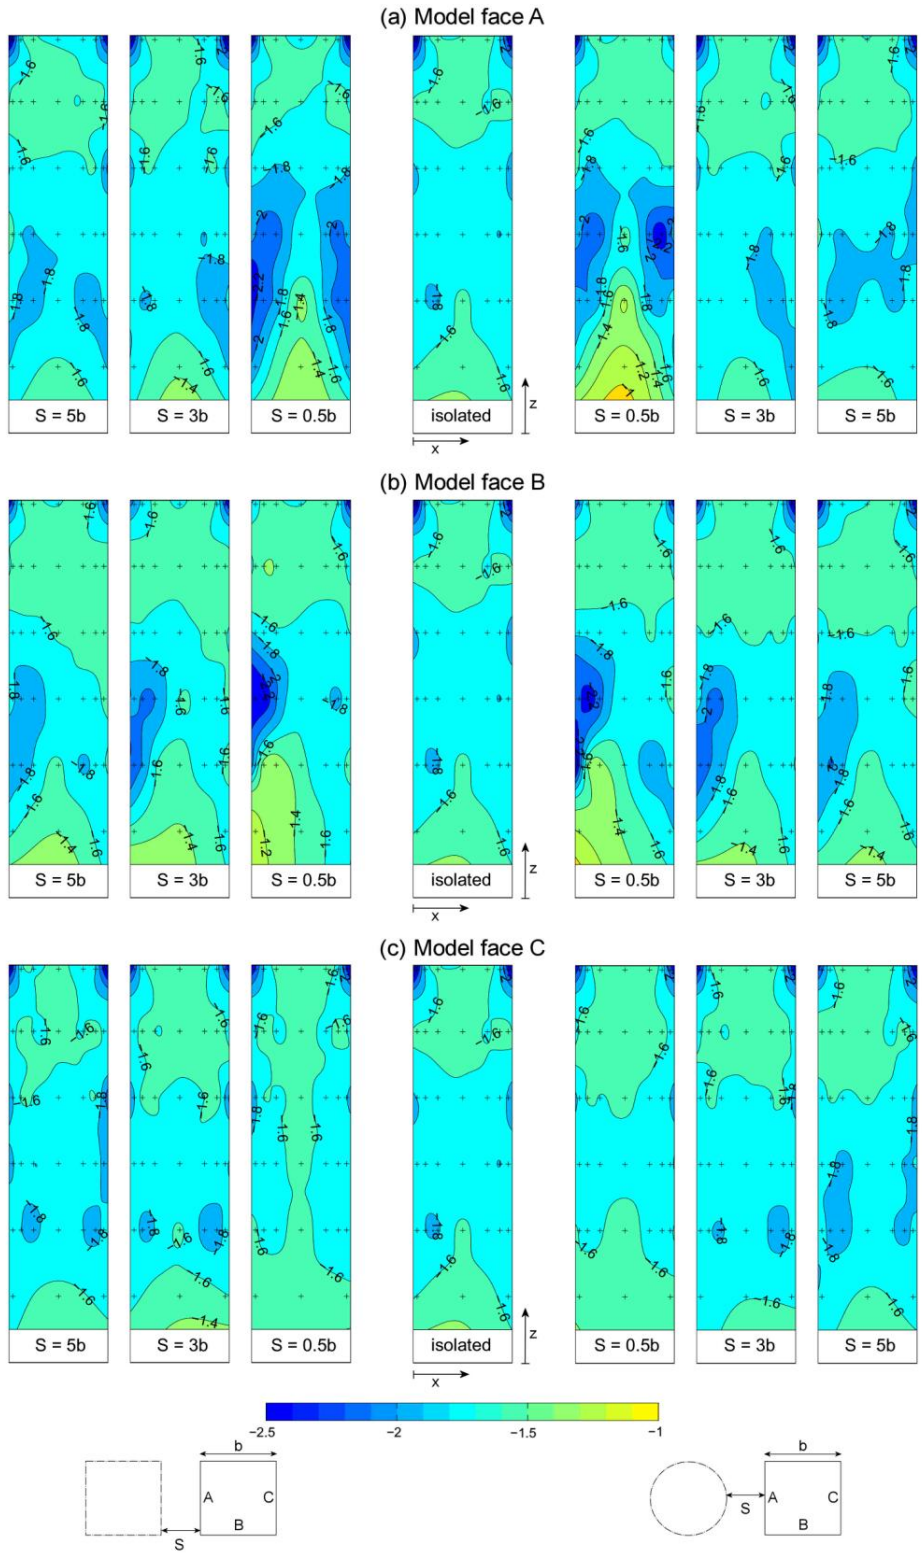

Figure 2. Contours of the minimum peak pressure coefficients over all angles of incidence, $C_{p,min}(Fij,all)$, on (a) face A, (b) face B and (c) face C of the reference model under influence of a square (left) and circular (right) mid-rise building. The contours of the isolated case are illustrated in the centre.

Table 2. Pressure coefficient values for the specified taps in Figure 2. For each position the minimum peak pressure coefficient over all wind directions are provided.

	isolated	***S = 0.5b***		***S = 3b***		***S = 5b***	
		square	***circle***	***square***	***circle***	***square***	***circle***
$C_{p,min}$*(A32,all)*	-1.7	-2.1	-2.1	-1.7	-1.8	-1.8	-1.8
$C_{p,min}$*(A21,all)*	-1.8	-2.2	-1.9	-1.7	-1.7	-1.8	-1.8
$C_{p,min}$*(B61,all)*	-2.4	-1.7	-2.0	-1.9	-2.1	-2.1	-2.2
$C_{p,min}$*(B32,all)*	-1.7	-2.3	-2.3	-2.0	-2.0	-1.9	-1.9

Figure 2(a) shows the influence of the half-height models on the minimum peak pressure distribution of face *A* with increasing separation distance (*S*). The largest interference effects on the minimum peak pressure are observed at taps *A32*, *A36*, *A21* and *A27*. At tap *A32* for a separation distance $S = 0.5b$, both square and circular interfering model increase the magnitude of the minimum peak pressure with approximately 25%. Table 2 shows that the square interfering model has a similar effect at tap *A21*. For $S = 3b$ and $5b$, these effects have disappeared, suggesting that the influence of the half-height interfering models on face *A* is only present for a separation distance smaller than at most three times the model width ($S < 3b$).

Figure 2(b) shows the influence of the interfering models on face B; the largest adverse effects are observed on the side of face B nearest to the interfering model (tap *B32*). At half the height of the reference model, the square and circular interfering models increase the minimum peak pressure coefficient with 25% and 35%. At a separation distance of $3b$ these effects have reduced to approximately 10%; at $S = 5b$ the influence has become negligible. Besides adverse pressure effects, the interfering models also have a positive effect on the local peak pressures. At the top corner near the front edge, tap *B61*, both square and circular interfering model increase the minimum peak pressure coefficient. The square interfering model increases the coefficient with 30%; the circular model results in a 15% increase.

The minimum peak pressure coefficient distributions on model face *C*, illustrated in figure 2(c), show little variation. Both square and circular interfering models have maximum effects which differ only 5% from the minimum peak pressures encountered in the isolated case. These effects are not nearly as large as the effects found on face *A* and *B*. Figure 2 and Table 2 show that the largest pressure effects are found at a separation distance $S = 0.5b$. Further discussion of the results focuses on the pressure effects observed on face *A* and *B* at $S = 0.5b$.

Figure 3 shows graphs of the mean (top graph), standard deviation (middle graph) and minimum peak pressure coefficient (bottom graph) versus angle of incidence for taps *A32*, *A21*, *B61* and *B32*. The graphs in Figure 3(a) show the influence of both a square and circular model ($S = 0.5b$) at pressure tap *A32*. For the isolated case, the largest value is -1.7, which is observed at $\theta = 75°$ and $\theta = 90°$. Both square and circular interfering models increase this minimum peak pressure coefficient to $C_{p,min}(A32,90°) = -2.1$. At this angle of incidence ($\theta = 90°$), the mean and standard deviation pressure coefficient show an increase of approximately 30% and 20%. Therefore, the amplification of the minimum peak pressure coefficient results from an increase in mean suction as well as an intensification of the fluctuations in the pressure signal. At pressure tap *A21*, illustrated in Figure 3(b), the square interfering model has a larger influence than the circular model over a large range of angle of incidence ($\theta = 45°$-$135°$). The largest effect caused by the square interfering model is observed at $\theta = 90°$ ($C_{p,min}(A21,90°) = -2.2$). The circular interfering model has no large influence on the minimum peak pressure coefficient at this location, which indicates the square interfering model has a larger area of influence than the circular model on face *A* of the reference model.

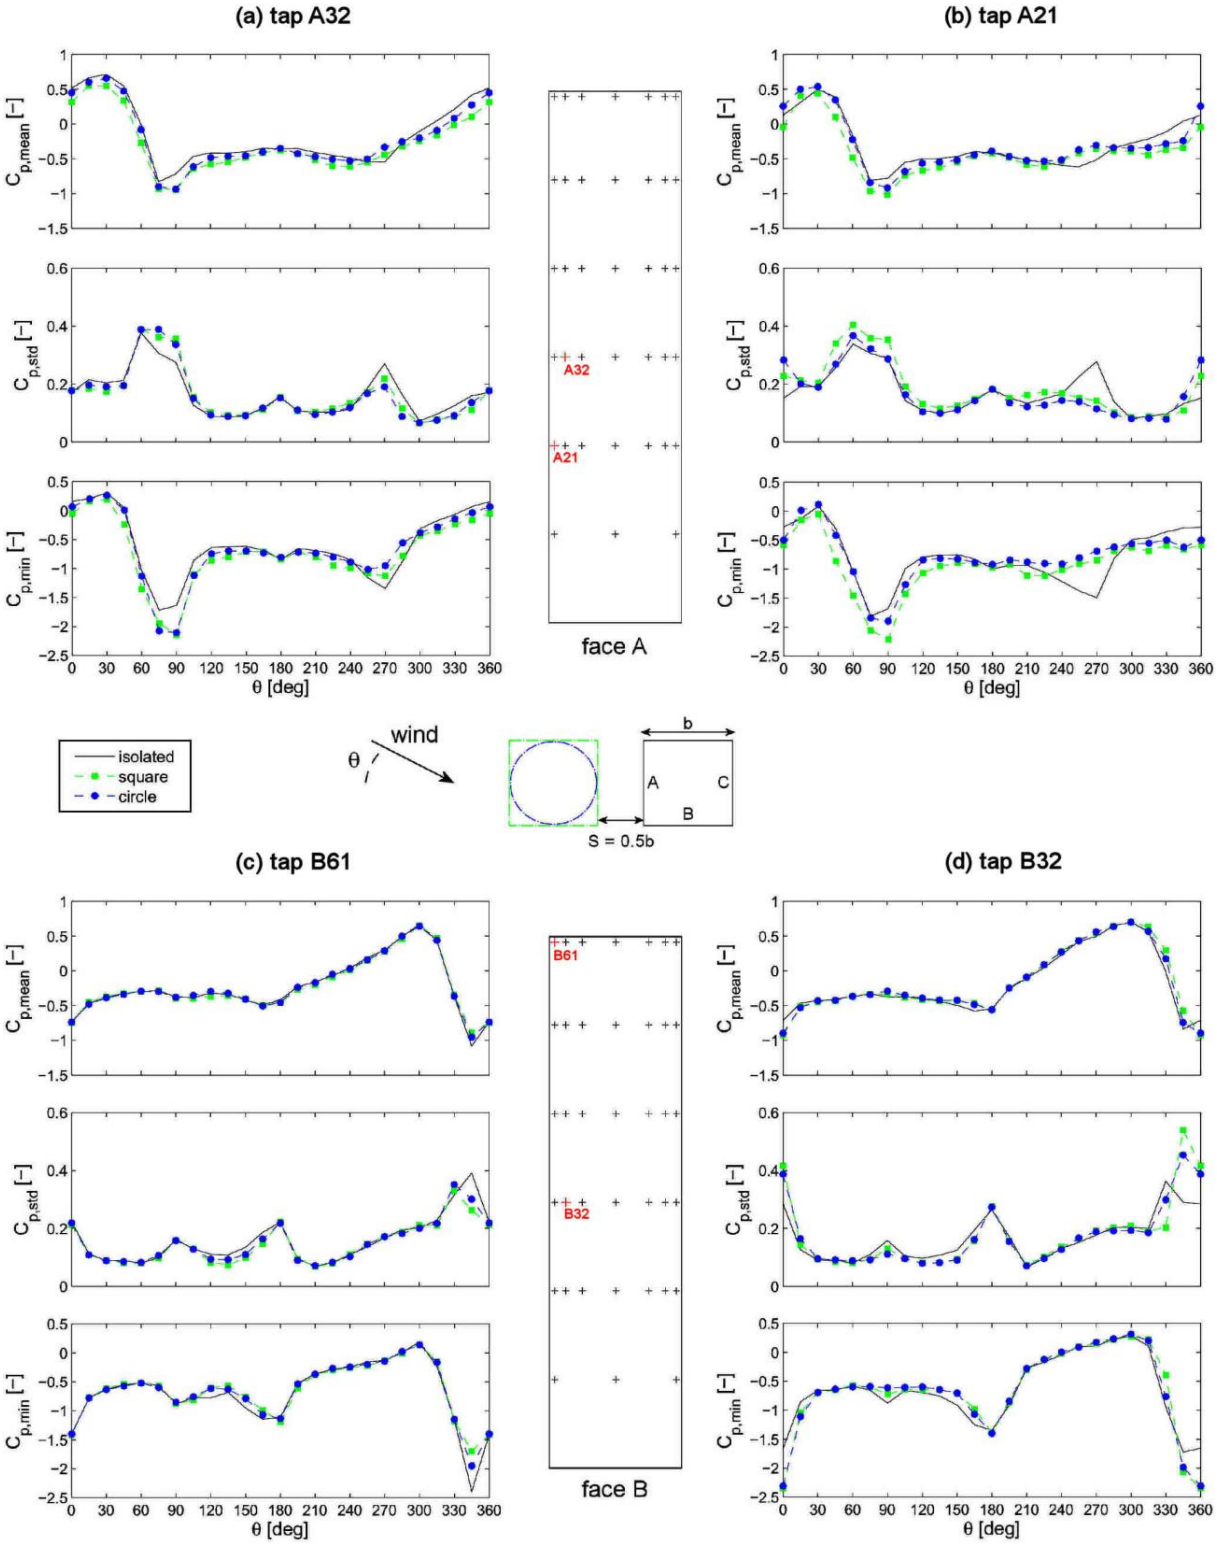

Figure 3. Variation of mean, standard deviation and minimum peak pressure coefficient with angle of incidence at the indicated taps on face A (a) tap *A32* and (b) tap *A21* and on face B (c) tap *B61* and (d) tap *B32*.

The variation of the pressure coefficient with angle of incidence on face *B* at tap *B61* and *B32* is illustrated in Figure 3(c) and (d). Figure 3(c) shows that the decrease in minimum peak pressure observed in Figure 2(b) at tap *B61* is found at $\theta = 345°$. In the isolated case, the peak pressure coefficient at this angle of incidence is $C_{p,min}(B61,345°) = -2.4$. The interfering models reduce this coefficient with 15% (circular cylinder) or 30% (square cylinder). This alleviation effect is mainly caused by a reduction in pressure fluctuations; the interfering model reduces the standard deviation pressure coefficient with 30%, whereas the drop in mean coefficient is 10%.

The results determined for tap *B32* are illustrated in Figure 3(d); they show an increase in minimum peak suction coefficient of 25% and 30% at an angle of incidence of 0° for the square and the circular interfering model. The largest intensities in pressure fluctuations are observed at an angle of incidence of 345°; the square interfering model causes an increase of 90% ($C_{p,std}(B32,345°) = 0.55$) and the circular model an increase of 60% ($C_{p,std}(B32,345°) = 0.47$). The reduction in mean pressure coefficient is responsible for the smaller minimum peak pressure coefficient at this angle in comparison with the coefficient observed at 0°.

Table 3 gives a summary of the largest minimum peak pressure effects encountered on face A and B, and specifies in which ranges of the investigated influence parameters (S and θ) these effects are most severe. The grey areas specified in the figures are indicative for the region of influence. The pressure effect on face A, illustrated in Table 3(a), was also described by Kim et al (2011) and Lam et al (2008). According to these studies, this pressure effect is the result of an increase in velocity through the passage, which is known as channeling. The adverse pressure effect on face B, illustrated in Table 3(b), is most likely caused by the shear layer separating from the roof of the interfering model. Although the largest peak value is observed at $\theta = 0°$, the largest intensity in pressure fluctuations is observed at $\theta = 345°$. At the same angle of incidence, a reduction is observed in the top corner of face B, illustrated in Table 3(c). The pressure effects illustrated in Table 3(b) and (c) appear to be related. Future spectral analysis of the pressure signals and analysis of the velocity field can provide more support for this observation.

Table 3. Summary of the investigated influence parameters and the pressure effects described on face A and face B.

	(a)	(b)	(c)
			Separation distance (S) [1]	$S < 3b$	$S < 5b$	$S < 5b$
Angle of incidence (θ) [2]	75°-90° and 270°-285° [*]	0°-15° and 345°-0° [*]	15° and 345° [*]
Location largest peak effect			
Square cylinder	$(x, z) = (0.04b; 0.3h)$	$(x, z) = (0.12b; 0.5h)$	$(x, z) = (0.04b; h)$
Circular cylinder	$(x, z) = (0.12b; 0.5h)$	$(x, z) = (0.12b; 0.5h)$	$(x, z) = (0.04b; h)$
Largest minimum peak pressure			
Square cylinder (isolated)	-2.2 (-1.8)	-2.3 (-1.7)	-1.7 (-2.4)
Circular cylinder (isolated)	-2.1 (-1.7)	-2.3 (-1.7)	-2.0 (-2.4)

[1] The specified range in separation distance indicates a region of influence on the reference building in which the influence of the interfering model on the minimum peak pressure is larger than 10% when all angles of incidence are considered.

[2] The specified value gives the angle of incidence at which the largest peak suction was determined.

[*] The region of influence at this angle of incidence is illustrated; the same effect occurs on the opposite side or face at the other specified angle.

4 CONCLUSION

Wind tunnel experiments were performed to determine the interference effects of a half high model on the pressure distribution of a nearby high-rise building model. Mean, standard deviation and peak pressure coefficients were analysed. The main findings are the following:

- For a half high interfering model, local increases in the magnitude of the minimum peak pressure were found on face *A* and face *B* (for definitions, see figure 3).
- Both square and circular interfering model cause a maximum increase of the minimum peak pressure $C_{p,min}(Fij,all)$ (i.e. the minimum over all angles of incidence) of 25% on face *A* and 35% on face *B*, for the investigated configurations.
- The pressure effects on face *A* and face *B* were most pronounced for a separation distance $S = 0.5b$. For $S = 3b$, the interfering model has no significant influence on the pressure distribution of face *A*; the effects on face *B*, although less severe, are still significant for $S = 5b$.
- The effects on face *A* occurred at an angle of incidence of 75° and 90°, i.e. for a wind approximately parallel to the building passage. The interference effects observed in the pressure distribution of face *B* were encountered at an angle of incidence of 345° and 0°.

This work has analyzed the influence of a half high model on the wind-induced local pressures on a high-rise model in terms of three main interference effects and it has established two model configurations in which large adverse pressure effects occur.

The study presented in this paper did not yet define cause-effect relationships between flow phenomena and pressure effects. The definition of such relationships requires more detailed analysis of the measured pressures (e.g. spectral analysis) and further investigation of the flow surrounding the models. Future research will entail more detailed analysis of the measured pressures in the critical configurations; additional experimental and numerical work will be carried out.

5 UNITS

b	Width of the reference model (m)

Research on interference effects of wind loads on tall buildings in staggered arrangement

Tang Yi[a] Jin Xinyang[a] Yang Liguo[a]

(a. China Academy of Building Research, Beijing100013, China)

ABSTRACT: To research the interference effects of wind loads on a real project with three similar-shaped staggered arranged tall buildings, wind tunnel tests about the three tall buildings and one isolated tower were conducted respectively. By comparison of the measured results, effects of wind directions and building positions on the design wind forces for main wind-force resisting system, i.e., along-wind, cross-wind and torsion wind loads, were discussed. Interference mechanisms were analyzed by integrating CFD simulated results and experiment measured data. It indicates that wind loads of the middle tower, named tower 2, are greatly increased compared to isolated cases and in the unfavorable wind direction of 110 degree, the static interference factor of torsion load, dynamic interference factor of wind load in Y and torsion directions are 1.53, 1.32 and 1.37 respectively.

Keywords：tall buildings, synchronization pressure wind tunnel test,staggered arrangement, static interference, dynamic interference

1 INTRODUCTION

Research shows that, wind loads of the tall buildings in the real environment and that of the isolated buildings are not same. In the early 1930s, people have realized the interference effects for a cluster of high-rise building [1]. In 1965, cooling tower collapse in the ferry bridge power plant aroused great research interest in wind interference [2], which marked the beginning of the wind-induced interference effects research. Hereafter, more and more wind tunnel tests were conducted in order to obtain general results[3-6]. In the late 1980s, some research results were applied to the wind load codes, such as the Australian standard. In China, interference research began at the end of 1980s [7]. Recently, interference effects of two and three tandem rectangular buildings models were tested in literature [8, 9] and [10] respectively. These research were mainly about tandem rectangular buildings and focused on the along and across wind results. But in realities, most unfavorable wind direction are not necessarily perpendicular to the facade, and under interfered conditions torsion wind loads are often not negligible [11,12]. In this paper, wind pressure of a real project including three staggered high-rise buildings was test in wind tunnel. A CFD numerical calculation was conducted to figure out the mechanism of interference. Comparison between three grouped buildings and one isolated building indicates the wind direction have great effects on the interfered wind loads.

2 WIND TUNNEL TEST

The project consists of three high-rise buildings, named tower 1, 2 and 3. These buildings are approximately 190m height and have consistent section size. To investigate the interference effect, wind pressure of additional isolated tower was measured after three tower group test. Both experiments were conducted in the 4m×3m test section of the China Academy of Building Research wind tunnel. Wind field of type A was simulated according to the Chinese load code. Rigid pres-

sure model scale ratio is 1:250. In each model, 162 ports are measured using Scanivalve electronic scanning pressure measurement system. Test wind speed is 14m / s at 1m height in wind tunnel. For each port, 4200 pressure signals were recorded in time domain with sampling frequency 312.5Hz.

3 RESULTS AND ANALYSIS

In this paper, maximum bending moments or torque are selected to evaluate the interference effects. Static interference factor can be calculated by

$$\overline{IF} = \frac{\mathrm{SIGN}\left(\overline{M}_s(\alpha_M)\right) \times \mathrm{MAX}\left(\left|\overline{M}_s(\alpha)\right|\right)}{\mathrm{SIGN}\left(\overline{M}_0(\alpha_M)\right) \times \mathrm{MAX}\left(\left|\overline{M}_0(\alpha)\right|\right)} \qquad (1)$$

where $\overline{\mathrm{M}}_s(\alpha)$ and $\overline{\mathrm{M}}_0(\alpha)$ is mean values of base moment or torque in α wind direction for interfered and isolated building respectively; '| |' denotes absolute value calculation; 'MAX' denotes maximum value calculation; 'SIGN' is to obtain number sign; α_M is wind angle where the maximum value occurs.

Dynamic interference factor can be evaluated as

$$IF = \frac{\mathrm{MAX}\left(\sigma_M^s(\alpha)\right)}{\mathrm{MAX}\left(\sigma_M^0(\alpha)\right)} \qquad (2)$$

Where $\sigma_M^s(\alpha)$ *and* $\sigma_M^0(\alpha)$ is RMS value of base moment or torque for interfered and isolated building respectively.

3.1 *Static interference effects*

Fig. 3 (a) ~ (c) show mean base moment and torque in different wind direction. Table 1 gives the static interference factor. It's notable that mean base torque of tower 2 reaches a maximum value in the direction of 110 degree, where the corresponding static interference factor is 1.53, which means that interfered by tower 1 and 3 the maximum static torsion of tower 2 increase by more than 50%. From the CFD simulation results shown in Fig.5, it can be seen that, unlike isolated buildings, wind pressure in the windward face of tower 2 is partially negative, which may result in large unsymmetrical torsional force.

3.2 *Dynamic interference effects*

Dynamic base moments are calculated by stochastic method. It can be seen from Figure 6 although the geometric and structural parameters are exactly the same, maximum responses of tower 2 are larger than that of tower 3.

Table 2 gives the dynamic interference factors. It can be seen from the table that all dynamic interference factors are greater than 1. It indicates that the interfered dynamic responses are to some extent amplified. Especially, in the wind direction of 110 degree, the dynamic interference factor of tower 2 in Y and torsion direction is 1.32 and 1.37 respectively. The pressure power spectra on each facade of tower 2 show obvious vortex peaks. Vortex excitation may result in larger dynamic interference factor as compared with tower 3.

Figure 7 shows the power spectrum of wind pressure in 110 degrees. It's evident that for the tower 2 wind pressure spectrum on each facade show distinguished spectral peak corresponding to votex shedding and for tower 3 and isolated building the votex shedding efftcs are weaken and spectrum peak are relatively not obvious.

4 CONCLUSION

Based on wind tunnel experiment, along-wind, across-wind and torsional load interference effects are discussed in this paper. CFD analysis method is used to figure out interference mechanism. The results show that wind direction and tower location are important factors that influence the interference effect. Tower 2, located in the middle of the staggered group, have much larger interference factor than that of tower 3. In the most unfavorable interference angle of 110 degree, the torsion static interference factor reached 1.53, the dynamic interference factor in weak lateral axis and torsional direction is 1.32 and 1.37 respectively.

ABSTRACT: In this paper, flow past around two circular cylinders which are tandem arranged at a Reynolds number of 200 is numerically investigated by spectral element method. To validate the numerical method for incompressible Navier–Stokes equations, the benchmark problem of flow over a single circular cylinder is employed, with the numerical results in a good agreement with the available literatures. Then, by changing the spacing ratios L/D from 1.2 to 10.0, the flow characteristics, including the flow patterns, force statistical parameters such as the drag and lift coefficients as well as wake oscillation frequencies (Strouhal numbers) are investigated. Numerical results show that there are around three wake flow patterns which are determined by the spacing ratio. In addition, the force parameters are highly affected by the flow patterns.

KEYWORDS: spectral element method; laminar flow; spacing ratio; Navier–Stokes equations; two tandem cylinders.

1 INTRODUCTION

The problem of flows past cylinders is very common in the fields of civil engineering, ocean engineering and hydraulic engineering, such as in high-rise buildings, long span cable-stayed or suspension bridges and chimneys experiencing wind loadings, as well as oil pipelines immersed in ocean current. Thus it has attracted, as an important aspect of computational fluid dynamics, much attention in scientific research. Among these problems, the flow past a circular cylinder plays an important part for its broad engineering applications and for being the foundation of flows past other bluff bodies. So far, wind tunnel experiments are still regarded as the most reliable means of studying this flow. In the last decades, however, the numerical simulation has been developed as the potential technique for its low cost, short time period, high efficiency and parameter adjustability.

Concerning the case of flow over two tandem circular cylinders, many important phenomna of fluid flow have been found through both experimental investigation and numerical simulation. For example, there is a critical spacing ratio, $L/D \approx 3.6$ (L is the center-to-center distance between the two cylinders, D is the cylinder diameter), at Reynolds number (Re) of 200, and the vortex shedding behind the upstream cylinder actually disappears when the spacing ratio is smaller than the critical one. Also, if the spacing ratio is over 3.6, the periodic vortex shedding will occur from both cylinders, which significantly changes the fluctuating lift force, drag force and Strouhal number (St).

More recently, some research studies have provided important insights into the numerical analysis of flow past two tandem circular cylinders. Using the Collocated Unstructured Computational Fluid Dynamic Code (CUCFDC), Sharman *et al.*[1] studied this problem when *Re*=100, and found that the critical spacing ratio is identified between 3.75 and 4.0, higher than the typical critical spacing ratio of 3.6, and that a unique reattachment point and a separation point appear at the downstream cylinder. Wu and Hu[2] investigated this problem at Reynolds numbers of 200 and 500 by employing the finite volume method and adaptive triangle meshing technology, and drew the conclusions that the lift and drag forces curves change at different space distance. Carmo and Meneghini[3] also studied this problem at the Reynolds numbers from 160 to 320. They found that, when the Reynolds number is greater than 190, three-dimensional effects occur, thus two-dimensional numerical simulations can not accurately satisfy the requirement of determining the critical spacing ratio.

Spectral element method (SEM) was first proposed by Patera[4], who applied this approach to Naver-Stokes equations under one- and two-dimensions. Spectral element is a high-order element combining the geometrical facility of the finite element method and the high accuracy of the spectral method, by increasing the order of the polynomial *p*. It can achieve a high convergence ability and computing efficiency even though the mesh is coarse. Blackburn and Karniadakis[5] studied the problem of vortex-induced vibration (VIV) of a single cylinder in two- and three-dimensions, and verified the efficiency of the SEM.

The current work pays attention to the problem of flow around two circular cylinders which are particularly arrayed as a tandem configuration at Reynolds number *Re*=200 using the SEM. But to start with, the problem of flows past one circular cylinder is simulated as a validation to examine the SEM computational code. Then using this method, the effects of gap spacing ratio of the two cylinders on the flow characteristics are investigated. In the current case, the numerical simulations are carried out associated with the center-to-center space ratios of *L/D* = 1.2, 1.5, 2.0, 3.6, 4.0, 6.0, 8.0 and 10.0. To show the flow pattern near the wake region, flow vorticity contours are clearly presented. The corresponding flow indexes such as the mean-averaged force coefficients and the frequencies of lift fluctuation are also obtained for all the cylinders.

The framework of this paper is organized as follow: In Section 2 we introduces the governing equations for incompressible viscous flow and provides the detailed processes of the SEM. The verifications of the computer code are achieved through the benchmark problem of flow over a single cylinder in Section 3. Section 4 presents and discusses the descriptions and results for the two tandem cylinders array with various spacing ratios. Main conclusions of the current work are finally summarized in Section 5.

2 GOVERNING EQUATIONS

In Cartesian coordinates, the non-dimensional tensorial forms of the Navier-Stokes governing equations for the incompressible viscous fluid flow in a domain Ω and a time interval [0, T] are written as:

$$\frac{\partial u_i}{\partial t} + u_j \frac{\partial u_i}{\partial x_j} = -\frac{\partial p}{\partial x_i} + \frac{1}{\mathrm{Re}} \frac{\partial^2 u_i}{\partial x_j \partial x_j} \tag{1}$$

$$\frac{\partial u_i}{\partial x_i} = 0 \tag{2}$$

The above equations are solved by employing the *Semtex* code. Released by Prof. H.M. Blackburn (Monash University, Australia), the *Semtex* is a quadrilateral spectral element DNS code that combines the standard nodal Gauss–Lobatto–Legendre (GLL) basis functions and Fourier expansions in a homogeneous direction[6]. More literatures related with *Semtex* include references[7-10]. In the current study, it should be noted that we choose 7 order GLL basis functions and incremental time step of 0.005 for all the computations.

Some definitions of the flow parameters required in the computations are given:

$$C_D = \frac{2F_D}{\rho U_\infty^2 D},\quad C_L = \frac{2F_L}{\rho U_\infty^2 d},\quad St = \frac{f_s D}{U_\infty},\quad C_p = \frac{2(p - p_\infty)}{\rho U_\infty^2}, \tag{3}$$

with the corresponding explanations as: C_D, drag coefficient; C_L, lift coefficient; St, Strouhal number; C_p, pressure coefficient; F_D, force in the stream-wise direction; F_L force in the transverse direction; f_s, vortex shedding frequency; ρ, the fluid density; U_∞, characteristic velocity, p_∞, characteristic pressure; and D, the characteristic length scale (Here it is treated as the cylinder diameter).

3 VALIDATION STUDIE

The problem of unsteady flow over a single cylinder is chosen as a workbench reference to validate the numerical code for further investigations. As shown in Figure 1, a computational domain $50D \times 40D$ is presented, where D is the diameter of the cylinder with the center position (0, 0). The inlet boundary is positioned 20D upstream from the cylinder center with the velocity boundary condition: u=1, v=0. And the boundary conditions of the outlet 30D downstream from the cylinder center point is prescribed as $\partial u/\partial x$=0, $\partial v/\partial x$=0, p=0. Concerning the upper and lower boundaries, they are both 20D away from the horizontal centerline, with a slip boundary condition as: $\partial u/\partial y$=0 and v=0. On the cylinder surface, no-slip conditions are applied as u=0, v=0.

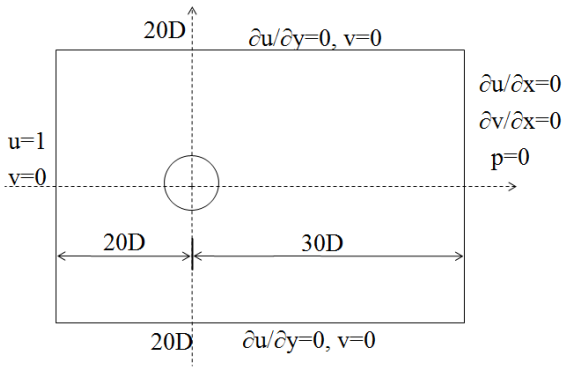

Figure 1.Schematic diagram of the computational domain and boundary conditions.

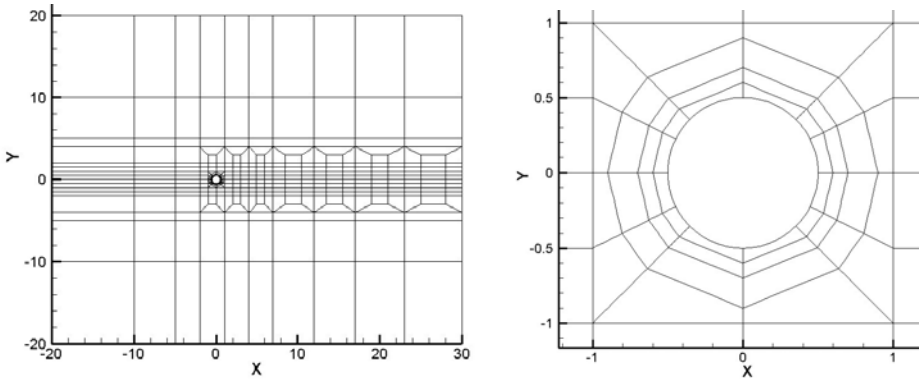
There are totally 354 spectral elements in the computational domain, as illustrated in Figure 2(a). In the region around the cylinder, the mesh grids are assigned as thin as 0.1D in order to obtain more accurate results (Figure 2(b)).



(a) (b)

Figure 2.(a) Spectral element meshes of the computational domain, 354 elements (b) zoomed-in view of the mesh around the cylinder.

We compare the computed mean drag coefficient C_D and Strouhal number St at Re=200 with the data from literatures[11-14] as shown in Table 1. The mean drag coefficient C_D is 1.346 while others range from 1.31 to 1.35. And the St=0.195 varies little to the exited results by Meneghini *et al*.[12] and Franke *et al*.[13]. Moreover, the current curve of St and Re, which is also chosen as a reference, is explored and plotted in Figure 3 with the corresponding data from references[15-17]. With the increase of Re ranging from 60 to 120, the obtained St is found to become larger. Meanwhile, our computed curve is quite close to the results provided by Young and Ni[17]. These evidences mentioned above can be good illustrations for the effectiveness of the *Semtex* computational code for the solutions of laminar flow.

Table 1.Comparisons of the mean drag coefficients C_D and Strouhal numbers St at Re=200

Parameters	C_D	St
Franke *et al*.[13]	1.31	0.194
Farrant *et al*.[14]	1.37	0.196
Meneghini *et al*.[12]	1.30	0.196
Braza *et al*.[11]	1.35	0.200
Present	1.346	0.195

4 FLOW AROUND TWO TANDEM CIRCULAR CYLINDERS

4.1 *Problem descriptions*

In this subsection, we present the problem of flow past two tandem cylinders (*Re*=200). Details of the computational models and one sample of the mesh grids are respectively shown in Figure 4(a) and (b). The width and length of the domain and boundary conditions are of the same as those in the above single cylinder case. Two cylinders are marked as "1" and "2" with the distance L between their circular centers. The inlet boundary is 20*D* upstream from the center of the cylinder "1" while the outlet is 30*D* downstream. In the following, different value is relatively set for the distance *L/D* as 1.2, 1.5, 2.0, 3.6, 4.0, 6.0, 8.0 and 10.0. In the example of *L*/*D*=2.5, there are totally 432 mesh grids while there are around 400~500 grids in the cases with other spacing ratios. Meanwhile, high resolutions of grid refinement are adopted around the cylinders and in the wake flow regions.

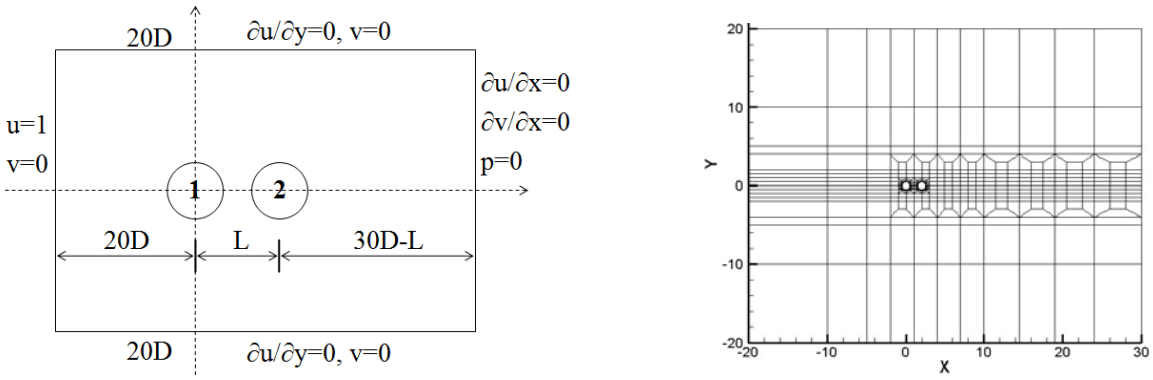

Figure 4.(a) Schematic of the computational model (b) the mesh grids of the spectral element for the case of flow past two tandem cylinders with *L/D*=2.

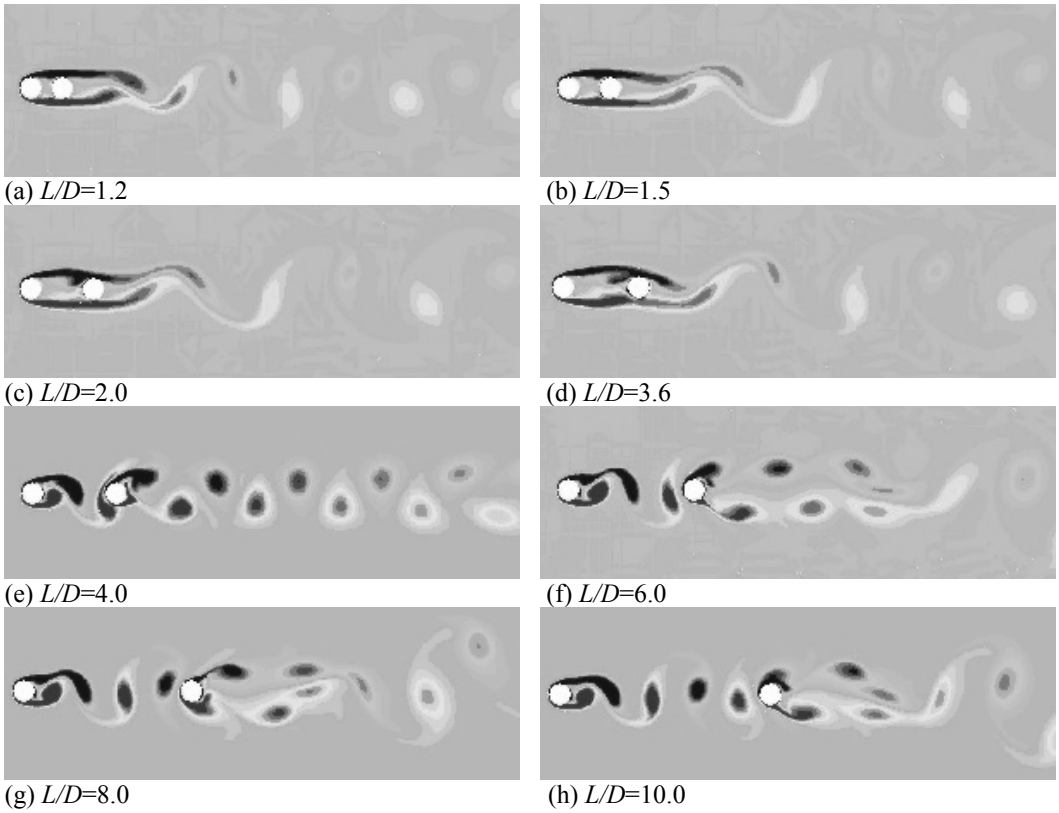
4.2 *Flow patterns*

The computational vorticity patterns at various spacing ratios are shown in Figure 5(a)-(h). It can be observed that there is a spacing ratio, smaller than which there is no vortex shedding from the upstream cylinder while larger than which periodical vortex shedding occurs. From there figures the critical spacing ratio is estimated at around *L/D*≈3.6. As *L/D*<3.6, the shear layers generated from the upside and downside of the front cylinder also attach on the upper and lower sides of the rear cylinder. In the far region behind the rear cylinder, an obvious Kármán vortex street can be observed. At the critical spacing ratio *L/D*＝3.6, the vortex begins to shed from the upstream cylinder. When the spacing ratio is higher, for example, *L/D*＝4, there is observed Kármán vortex in the gap region between the two cylinders. The vortex from the cylinder "1" periodically impinges on the front surface of the rear cylinder, affecting the flow pattern in the wake region. As the spacing ratio increases, the vortex from the front cylinder seems to have a higher influence on the wake flow. At *Re*=200 in which slight three-dimensional effect has occurred, the wake flow begins to show more complexity in the far region.



(a) L/D=1.2 (b) L/D=1.5

(c) L/D=2.0 (d) L/D=3.6

(e) L/D=4.0 (f) L/D=6.0

(g) L/D=8.0 (h) L/D=10.0

Figure 5.Vorticity contours with different spacing ratios: (a) L/D=1.2; (b) L/D=1.5; (c) L/D=2.0; (d) L/D=3.6; (e) L/D=4.0; (f) L/D=6.0; (g) L/D=8.0 and (h) L/D=10.0.

4.3 *Lift and drag coefficients*

Figure 6 shows the mean drag coefficients C_D for both cylinders as function of the spacing ratio between two cylinders in tandem. As can be seen, the mean drag coefficients C_D for both cylinders are smaller than that for the single one, while the one for the upstream cylinder is larger than that for the downstream one. The value of C_{D1} for the upstream cylinder decreases gradually with the increasing spacing ratio, and reaches its minimum value at L/D=3.6. At larger spacing ratio L/D=3.6~4.0, C_{D1} increases sharply, reaching the peak at L/D =4.0. Subsequently, it increases to a asymptotic value respectively, which should presumably be that of a single cylinder. For the downstream cylinder, the value of C_{D2} is much smaller than that of the upstream one. Also, at 3.6<L/D<4, the C_{D2} sharply increases like the behavior of C_{D1}. As discussed above, this is because of the transition of the flow patterns. In this spacing ratio region, obvious vortex shedding takes place on the first cylinder and strikes on the rear cylinder. These changes are believed as the main reason of the sharp changes in the drag coefficients. At higher spacing ratio as L/D>4, the vortex shedding modes become stable which is associated with the plat curves of C_{D1} and C_{D2}. Similar performances can also be seen from the relationships of RMS of drag and lift coefficients vs spacing ratios, as shown in Figure 7(a) and (b). There is an obvious changes in the region of 3.6<L/D<4, in which the flow patterns transform. These results are other evidences that vortices patterns determine the flow characteristic parameters.

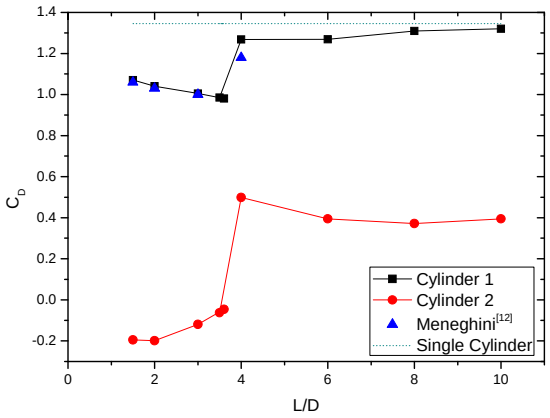


Figure 6.Variation of mean drag coefficients with different spacing ratios.

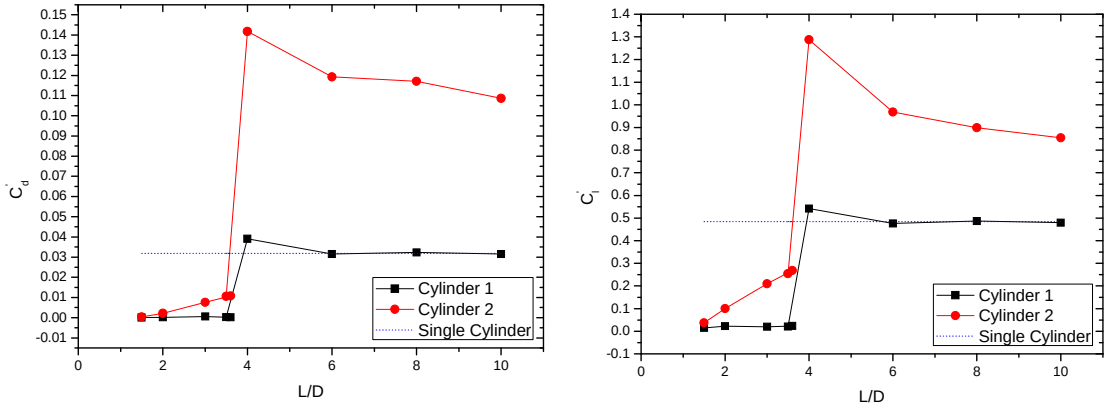

(a) (b)

Figure 7.Variation of (a) the RMS. drag coeffients (b) the RMS. lift coeffients with different spacing ratios

4.4 *Strouhal number*

Since all the parameters have been non-dimensionalized, the Strouhal number, *St*, is equal to the vortex shedding frequency which is obtained through the Fourier transform on the time dependent curve of lift coefficient.

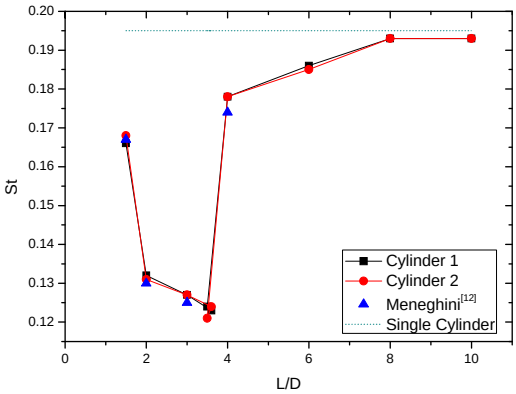

Figure 8. Variation of the Strouhal numbers, *St*, with different spacing ratios, *L*/*D*

The curves of *S*t and *L/D* for the two cylinders are demonstrated in Figure 8 and they are found to be much closed to the corresponding data from Meneghini *et al*.[12]. The Strouhal number shows a decreasing trend as $L/D < 3.6$, and it begins to rapidly increase with higher *L/D* value, especially at $3.6<L/D<4.0$. It is believed that this strong change is mainly caused by the transformation of flow patterns. When $L/D>8$, the Strouhal number becomes an almost constant value around 0.195, approaching the one of the single cylinder case.

5 CONCLUSIONS

In this current study, spectral element method is employed to investigate the flow around two tandem circular cylinders at a Reynolds number of 200. The spacing ratios are found to have a great impact on the flow characteristics and flow patterns. A critical spacing ratio of around 3.6 is observed. At smaller spacing ratio as $L/D<3.6$, no obvious vortex shedding is observed around the upstream cylinder and it only occurs on the downstream cylinder. As $L/D>4.0$, vortices are generated around both the front and rear cylinders. Meanwhile, the vortex from the front cylinder strikes on the surface of the rear cylinder, giving rise to higher drag coefficients and larger vortex shedding frequencies. Good agreements are found between the current study and data from existed literatures. The SEM is tested as an effective and reliable approach to cope with the fluid flow problems at low Reynolds numbers.

ABSTRACT: Properties of wake excitation of circular cylinders in the tandem arrangement of central distance of three diameters were experimentally investigated. In order to investigate the influence of Reynolds number on the wake excitation, the effects of surface roughness of circular cylinders on it were examined. For circular cylinders with smooth surface, two types of stable limit cycles in transverse responses were measured. Effects of surface roughness on the wake excitation were quite large and the complicated interaction between the separated shear flow from the windward cylinder and the leeward cylinder were observed by flow visualization tests.

KEYWORDS: Wake excitation, Surface roughness of circular cylinder, Tandem arrangement, Vibration of leeward circular cylinder.

1 INTRODUCTION

Properties of wake excitation for tandem and staggered circular cylinders have been studied by lots of researchers, for example, Cooper & Wardlaw [1], Simpson [2], and so on. It is well known that the wake excitation vibrations of circular cylinders are deeply depended on the arrangement of the circular cylinders and Reynolds number, *Re*. Furthermore, for the wake excitation of tandem and staggered circular cylinders, the interaction between the leeward circular cylinder and the wake flow of the windward circular cylinder plays an important role.

Authors also investigated the instability of closely spaced triple circular cylinders [3], where the effect of Reynolds number, *Re*, was found in the onset velocity of wake galloping. In order to reduce the effects of the *Re*, the wake excitation of a circular cylinder in the wake of several shapes of rectangular cylinders was also tested and some interesting results were reported [4, 5].

In the paper, the effects of surface roughness of the circular cylinder on the wake excitation were experimentally investigated and a part of the results achieved here has already been reported in References [6, 7].

2 EXPERIMENTAL SETTING

A wind tunnel with a semi-closed circuit was used and its working section was 1m wide, 1.5m high and 4m long. Two stainless steel circular cylinders were used. Their diameter, *D*, was 42mm and their length was 900mm, respectively. The central distance between both circular cylinders in tandem arrangement was three times of their diameter, 3*D*, where the windward cylinder was fixed to side walls. The responses of the leeward circular cylinder were measured under longitudinal and transverse freedoms (2DOF). The Scruton number, $Sc=2m\delta/\rho D^2$, in which m is the mass, δ is the logarithmic damping and ρ is the air density, was changed from 6.8 to 35.1. Natural frequencies for longitudinal direction, f_x and transverse direction, f_y of the leeward cylinder were almost the same and also changed from 1.7 Hz to 2.7Hz. However, the results obtained un-

der the conditions of Sc=16.4 and f=2.2Hz were only focused on the paper for the lack of space. Properties of the wake of the windward circular cylinder were investigated by I-type hot wire anemometer. Flow visualizing tests were carried out by using the high speed camcorder, where five hundred flames were recorder in a second. The experimental conditions examined here were summarized in Table 1.

The surface roughness of the cylinders was changed by rough plastic meshes, parallel and helical wires whose diameter, d, was 2mm. The interval of helical wires set $2\pi/3$ (three wires were installed), $\pi/3$ (six wires) and $\pi/6$ (twelve wires), respectively. For twelve wires, the inclination from cylinder axis, θ, was changed from 0 to 30 degrees at ten-degree intervals. Moreover, the roughness lengths of surface roughness materials were also measured by I-type hot wire anemometer and summarized in Table 2.

Table 1 Experimental conditions

Diameter, D (mm)	42
Mass, m (kg/m)	2.58
Scruton numbers, $Sc=2m\delta/\rho D^2$	6.8, 16.4, 35.1
Degrees of freedom	Two(Longitudinal and Transverse directions)
Natural Frequency, f (Hz)	1.7, 2.2, 2.7
Surface roughness of cylinders	Plain (smooth), Rough plastic meshes (Mesh A; width, b=1mm, thickness, t=1mm, central distance, B=4mm, Mesh B; b=2mm, t=1.85mm, B=10mm), Parallel wires (diameter, d=2mm, interval of wires, $\pi/6$) Helical wires (inclination from cylinder axis, $\theta=\pi/18$, $\pi/9$, $\pi/6$, d=2mm, interval of wires, $2\pi/3$, $\pi/3$, $\pi/6$)

3 RESULTS AND DISCUSSION

3.1 *Responses of Smooth Surface Cylinders*

Figures 1(a) and (b) show the typical longitudinal and transverse responses and the static displacements, l/D, of leeward circular cylinder in tandem arrangement, Sc=16.4 and f=2.2Hz, in 2DOF. From Figure 1(a), two different transverse responses were measured; the first stable limit cycle (1-SLC) had almost the same amplitude, $2Y/D\approx1.2$, which closely related to the formation of wake of the windward circular cylinder. On the contrary, the second one (2-SLC) vibrated beyond the separated shear flow of windward cylinder and also developed from $2Y/D$=2.25 to 3.0 with the increase of wind speed. Furthermore, two unstable limit cycles were also measured. Longitudinal responses were quite small.

From Figure 1(b), under the same wind speed, the static displacements, l/D, of 2-SLC were much larger than those of 1-SLC and at rest. However, somewhat large l/D of the rest condition for the higher V/fD, larger than 75, was introduced by the longitudinal vibration. Furthermore, the longitudinal vibration in the wake of a square cylinder was not generated at all [4]. Therefore, properties of the wake of the square cylinder and those of the circular cylinder were much different each other.

Effects of damping and natural frequencies on the responses of the wake excitation were reported in References [6, 7]

3.2 *Wind speeds distribution behind a smooth cylinder*

The distribution of the mean wind speed and the turbulence intensity of the wake at the distance of 3D from the center of the windward circular cylinder were given in Figures 2 (a) and (b), re-

spectively. The amplitudes of second stable limit cycle (2-SLC) correspond to the just outside of separated shear flow where wind speeds return to the approaching mean wind speed, V_0. On the contrary, around the amplitude of the first one (1-SLC), the largest turbulence intensity induced by Kármán Vortex was measured, where the mean wind speeds recovered to 80% of the approaching wind speed. Therefore, 1-SLC and 2-SLC occurred inside and outside of the wake of the windward circular cylinder, respectively.

Table 2 Roughness length and appearance of surface materials

Surface material	Roughness length (mm)	Solidity ratio (%)	Appearance
Plain (smooth)	0.0025		Rough plastic mesh A (Mesh A)	0.20	43.8	Rough plastic mesh B (Mesh B)	0.52	36	
Twelve parallel wires	0.51	18.1	Twelve helical wires $\theta=\pi/18$	0.43	18.5	
Twelve helical wires $\theta=\pi/12$	0.40	19.3	
Twelve helical wires $\theta=\pi/6$	0.25	20.9	Six helical wires $\theta=\pi/6$	0.19	9.2	Three helical wires $\theta=\pi/6$	0.06	4.6

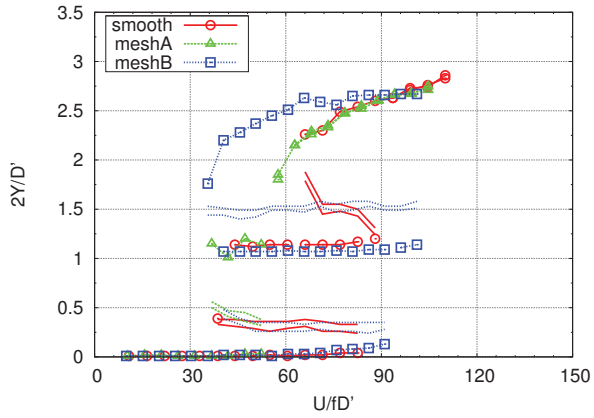
3.3 *Responses with Surface Roughness*

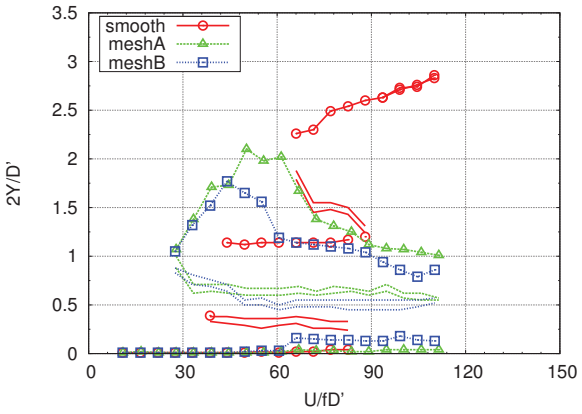
3.3.1 *Rough plastic mesh*

Figure 3 shows the effects of the installation of meshes to circular cylinders on the wake excitation, where amplitudes and wind speeds were normalized by the relative diameter of circular cylinder taking into account of the thickness, *t*, of meshes, *D'=D+2t.* Effects of meshes only installed on the windward circular cylinder were summarized in Figure (a), inversely, Figure (b) showed responses with meshes only attached to the leeward circular cylinder; furthermore, Figure (c) gave the results with meshes on both circular cylinders. From Figure (a), due to the installation of meshes on the windward cylinder, the larger transverse responses, 2-SLC, developed in the lower wind speeds in comparison with those of the smooth surface circular cylinder, where the installation of rougher mesh started the vibration in the lower wind speed. From Figure (b), due to the installation of meshes only on the leeward cylinder, the larger transverse responses of 2-SLC were only measured in the lower wind speeds, on the contrary, in the higher wind speeds, more than 60 for Mesh B, more than 70 for Mesh A, the smaller amplitudes of the 1-SLC were only measured and the larger responses of the 2-SLC were disappeared. For the installation of

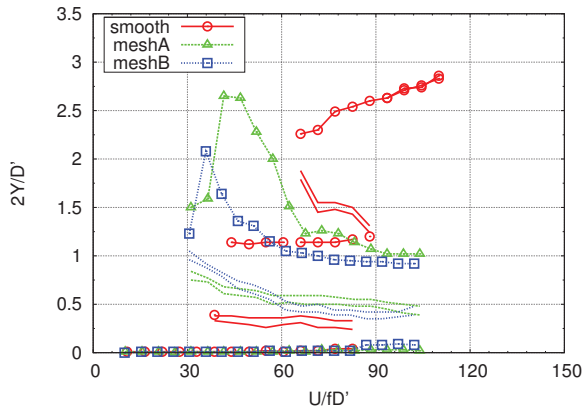
meshes on the both circular cylinders as shown in Figure (c), the responses closed to those of the installation of meshes only on the leeward cylinder.



(a) Meshes attached to only the windward cylinder



(b) Meshes attached to only the leeward cylinder



(c) Responses with meshes attached to both cylinders

Figure 3 Effects of the installation of meshes on the wake excitations.

3.3.2 *Helical wires*

Figure 4 shows transverse responses of the leeward circular cylinder with zero, three, six and twelve helical wires, whose diameter, d, was $0.048D$, and the inclination from cylinder axis, θ, was $\pi/6$, in the condition of Sc=16.4, f=2.2Hz, 2DOF, where the helical wires were installed on both cylinders. Due to the installation of three helical wires, the large amplitudes of 2-SLC were completely disappeared. For the installation of six helical wires, 1-SLC was moved toward the higher wind speed and unstable limit cycle was also enlarged in comparison with the results of the installation of three helical wires. In the case of twelve helical wires, the wake excitation was completely disappeared. Therefore, even though the roughness length of twelve helical wires was shorter than that of the rough plastic mesh, Mesh B, the increase of helical wires attached to the cylinders improved the wake excitation efficiently. The efficiency of helical wire on the wake galloping was also reported by Fujino et al. [8] by using the full-size models for parallel cables.

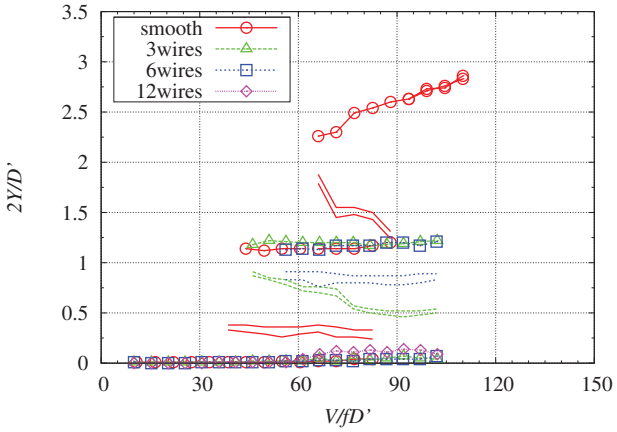


Figure 4 Transverse responses of the leeward cylinder with and without the helical wires, *Sc*=16.4, *f*=2.2Hz.

The effects of the inclination of wires, θ, on transverse responses of the leeward cylinder in the condition of *Sc*=16.4, *f*=2.2Hz, 2DOF were summarized in Figure 5, where twelve wires were installed on both cylinders. For the installation of parallel wires to the cylinder axis, θ=0, the larger amplitudes of 2-SLC were observed in the lower wind speeds, around *V/fD*'= 30, as same as the responses with meshes installed on both cylinders. Due to the installation of helical wires, the large amplitudes of 2-SLC were completely disappeared even if the small inclination of wires such as θ=10 degrees. Furthermore, for the case of the smallest inclination of wires, θ=10 degrees, 1-SLC was moved toward the higher wind speed. The larger inclination of the helical wires removed the wake excitation completely. Therefore it is clear that the increase of the inclination of wires reduced the transverse responses of the leeward cylinder.

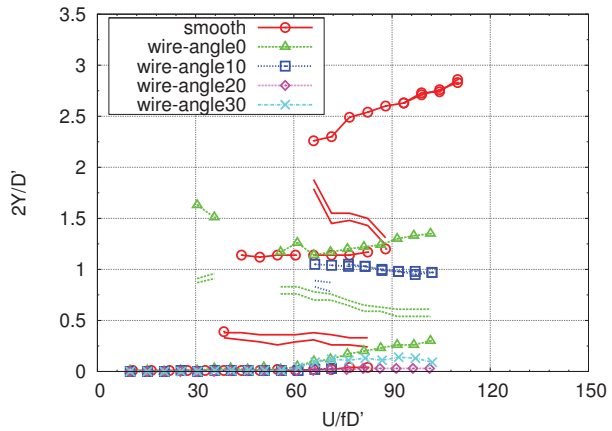

Figure 5 Effects of the inclination of wires from cylinder axis, θ, on the transverse responses, *Sc*=16.4, *f*=2.2Hz.

Figure 6 shows the transverse responses with twelve helical wires attached to the windward cylinder or the leeward cylinder or both cylinders, in the condition of *Sc*=16.4, *f*=2.2Hz, 2DOF. For the installation of twelve wires on only the leeward cylinder, the amplitudes of 1-SLC were

decreased. However, the occurrence of 1-SLC moved toward the lower wind speed and 1-SLC developed from the rest condition without 1-USLC. On the other hand, the amplitudes of 1-USLC were increased by the installation of wires on only the windward cylinder; furthermore, the amplitudes of 1-USLC due to the installation of the windward cylinder were almost the same as that of the 1-SLC of the installation of them on only the leeward cylinder. For the installation of wires on both cylinders, the stabilizing effects for the windward cylinder and the leeward cylinder should act together.

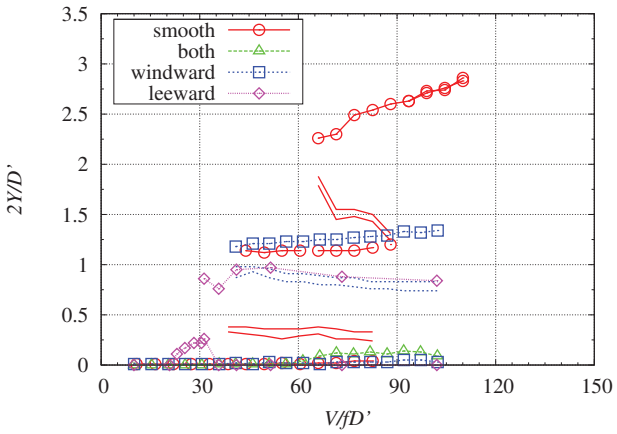

Figure 6 Responses of the leeward circular cylinder with and without the twelve helical wires, *Sc*=16.4, *f*=2.2Hz

3.4 *Flow visualization*

Figures 7 and 8 show the results of flow visualization tests for smooth surface circular cylinders during free vibrations in 1-SLC and 2-SLC under the same reduced wind speed, *V/fD*=65, respectively, where phase angles of the sinusoidal vibration of leeward circular cylinder were changed from the neutral position of 0 (Figure (a)) to 11π/6 (Figure (l)) with the interval of π/6. In the figures, representative streak lines were also shown by solid arrows. As shown in Figure 7, the smaller amplitude of vibration of 1-SLC was restricted by the separated shear flow formed by the windward circular cylinder, where the leeward cylinder was completely included in it. As shown in Figures 6 (d), (e), (j), (k), the wake excitation of 1-SLC was induced by the gap flow into the wake region as detected in previous papaers [8, 9]. On the contrary, under the larger amplitude of 2-SLC, Karman vortices were developed behind the windward circular cylinder during all vibration phases as shown in Figure 8. As given in Figure 2 (a), the amplitudes of second stable limit cycle (2-SLC) almost correspond to the separated shear flow formed behind the single circular cylinder, on the other hand, the amplitudes of first stable limit cycle (1-SLC) restricted by the separated shear flow formed behind the windward cylinder in tandem arrangement of circular cylinders. Therefore, taking into an account of the time integrated mean flow situation, the larger amplitude of 2-SLC could be excited by the similar flow properties for the smaller amplitude of 1-SLC.

As shown in Figures 3 (b) and (c), due to the installation of meshes only on the leeward cylinder or both cylinders, the larger transverse responses of 2-SLC were measured in the restricted lower wind speeds, where flow patterns around cylinders were also similar to those under the larger amplitude of 2-SLC for smooth surface circular cylinders as given in Figure 8. Furthermore, during smaller responses for the installation of meshes or helical wires to the cylinder, flow pat-

terns around cylinders were almost the same to those for smooth surface circular cylinders under the smaller amplitude of 1-SLC as given in Figure 7.

4 CONCLUSIONS

From the experimental investigation of the tandem circular cylinders of central distance of three diameters with several kinds of surface roughness, following results were obtained:

In the range of tested Scruton number, *Sc*, two types of stable limit cycles were occurred in transverse responses. The amplitude of larger responses (2-SLC) almost correspond to the separated shear flow formed behind the single circular cylinder, on the other hand, the smaller amplitudes of first stable limit cycle (1-SLC) restricted by the separated shear flow formed behind the windward cylinder in tandem arrangement of circular cylinders.

Effects of Reynolds number on the wake galloping were quite large. The surface roughness installed on the leeward circular cylinder played a more important role in the wake galloping in comparison with that installed on the windward circular cylinder, however, the stabilizing effects of the installation of helical wires on both cylinders have been accomplished by the mutual effect achieved with the windward cylinder and the leeward cylinder.

The interaction of wake properties and the responses of the leeward circular cylinder should be investigated in detail.

Investigation on wind tunnel blockage effect of super high-rise building

WANG Lei LIANG Shu-guo TANG huai-qiang SONG Wei-wei

School of Civil & Building Eng., Wuhan University, Wuhan,China

ABSTRACT: As the significant difference in wind tunnel data between two scaled models of a practical engineering, the cause of this difference ,which was regarded as blockage effect，was analyzed in this paper. Research shows that, for wind tunnel test with more surrounding buildings, blockage effect may result in serious data distortion, especially for lateral wind pressure，and existing correction method does not possess universality. Moreover, blockage ratio, as a global concept, is not appropriate to evaluate blockage effect of wind tunnel pressure data at different parts of building models. This study has reference value for blockage effect of wind tunnel pressure date in practical engineering.

KEYWORDS: blockage effect rectangular high-rise building wind pressure coefficient wind tunnel test

1 INTRODUCTION

Wind field of models in wind tunnel has wall boundary, while the wind field of actual structure in the atmosphere is unbounded. Simulation of unbounded atmospheric flow field in the bounded wind tunnel will bring the wall interference. Lateral constraint of flow field around the model by the wind tunnel boundary is known as the body obstruction, and the lateral constraint of the wake flow field is known as the wake blocking, namely, which are blocking effect.

Blocking effect seriously affected the accuracy of test data in some cases. Taking an example that blocking ratio is 15% in the wing - body combination model wind tunnel test, when the attack angle is 90^{o}, the correction value of the drag coefficient reaches 88% of the measured values [1]. Saathoff and Melbourne found through the study on rectangular building blocking effect that when the blocking ratio is 5%, the mean lateral wind pressure near the corner increased by 15%, the root variance of wind pressure increased by 20% [2], which shows the blocking effect of test data cannot be ignored. However, building wind tunnel tests, even when the obstruction is relatively large, its effects are often ignored [3].

The blocking effects correction of aviation and automotive wind tunnel tests have been effectively developed. The correction methods used commonly are mirror method, the vortex lattice method, the wall pressure of Information Act [4] and the Mercker semi-empirical method[5]. However, due to the differences between the shape of the rectangular buildings and aircraft, as well as cars, the above methods cannot be applied to wind tunnel blocking effect correction of rectangular building models.

Wind engineering researchers have investigated on wind tunnel blocking effects of rectangular building models for several decades. As early as 1978, Awbi proposed blocking effect correction method for two-dimensional rectangular section [6] on the basis of the Maskell theory, he believed that the difference of the aspect ratio of rectangular cross section should be taken into account for the blocking effect correction, the blocking effect of the long side windward without reattachment, is more obvious than the shorter side windward [7]. Cherry, Melbourne, et al also pointed out that the

average length of the bluff body surface reattachment will decrease with blockage ratio increasing. Cherry's test results showed that 5% of the blockage ratio makes reattachment length reduce by 20% [8]. According to these theory results, blocking will not only affect the size of the surface pressure, but also affect the pressure distribution. Therefore, the blocking effect mechanism and correction formula based on the Maskell assumption, that the blocking effect affects only the size of wind speed and doesn't affect the pressure distribution, has not been widely accepted. After that, Saathoff [2], Hunt [9], Noda, [10], Atsushi Okajima [11] et researchers also researched on the blocking effect with special wind tunnel tests or numerical simulation. While a large number of scholars are concerned about and studied on the blocking effect of the rectangular cylinder, but so far there is still no generally accepted blocking effect theory and correction method of wind tunnel test for practical rectangular tall building models.

The research objects of above-mentioned studies are single rectangular buildings, the results of these studies can be summarized as follows: 1、blocking effect of the along wind pressure on a rectangular cylinder is very small, makes the lateral pressure increase, change the lateral pressure distribution as the result. 2、most of the blocking effect correction methods focus on the correction of dynamic pressure, however these methods did not jump out of the stereotype of Maskell assumptions. This study found that the above conclusion cannot be applied to the wind tunnel test of an actual building project with group effects.

2. WIND TUNNEL TEST

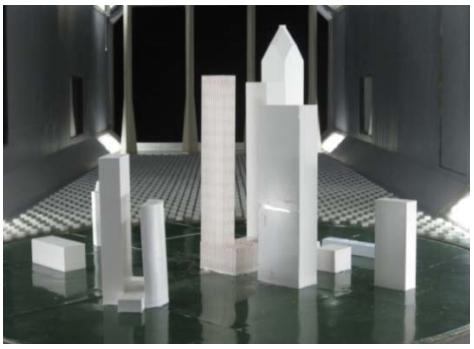

Fig. 1 1/300 model

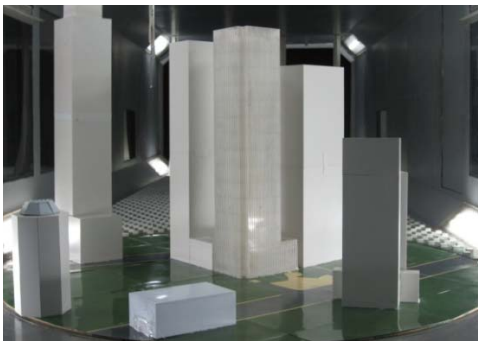

Fig. 2 1/200 model

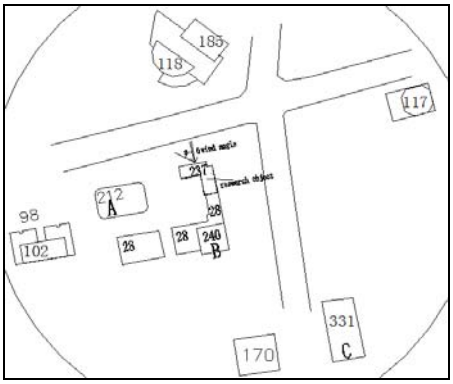

Fig. 3 layout of surrounings

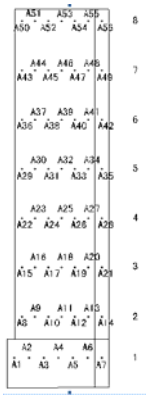

Fig. 3 layout of test points

The layout of manometrical model and surrounding buildings with 1/300 geometrical scale in wind tunnel is shown in Figure 1, the layout of those with 1/200 geometrical scale in wind tunnel is in Figure 2, and two sets of models are same except the geometry sizes. The general layout of the

building surrounding is shown in Figure 3. Among the models, the manometrical model is simulating a 237m-highrise building with rectangular cross section. In actual wind field, there are 9 surrounding buildings whose heights are above one hundred meters, where Building A is 212m, Building B is 240m, and Building C is 331m. The wind tunnel test was carried out in low-speed test section (3m x 2m) of the CGB-1 wind tunnel in Guangdong Provincial Academy of Building Research, and the test wind field is the C category, according to China's code. Under the wind azimuths of 0°, the blocking ratio , the ratio of effective frontal area S to wind tunnel cross-sectional area , reaches the maximum，which were 8.9% for the 1/200 models and 4.1% for 1/300 models, respectively.

3. ANALYSIS OF EXPERIMENTAL DATA

3.1 mean wind pressure coefficients

The mean wind pressure coefficients of the test points on the along wind side, leeward side and the lateral side are illustrated in Figure 5, 6 and 7 respectively, where the abscissa is the point number. The pressure coefficients of 1/300 model are relatively close to those of National Building Codes, To facilitate the analysis here, the difference between the pressure coefficient of 1/200 and 1/300 models is called the absolute difference, the ratio of absolute difference to the pressure coefficient 1/300 model is called the relative difference (seen in Equ. 1 to 4). Figure 8 illustrate the pressure coefficient relative difference on the along wind side, leeward side and the lateral side.

Mean pressure of test points:

$$\overline{w} = (\sum_{i=1}^{N} w_i) / N \qquad (1)$$

Mean wind pressure coefficient:

$$\mu_s = \frac{\overline{w}}{\overline{w}_{h_{ref}}} (\frac{h_{ref}}{h})^{2\alpha} \qquad (2)$$

Absolute difference between the mean wind pressure coefficients:

$$\Delta_1 = \left|\mu_{s200} - \mu_{s300}\right| \qquad (3)$$

Relative difference between the mean wind pressure coefficients:

$$\Delta_2 = \left|\mu_{s200} - \mu_{s300}\right| / \left|\mu_{s300}\right| \qquad (4)$$

Where the mean wind pressure $\overline{w}$ of 1/200 model is corresponding to the pressure coefficient μ_{s200} of 1/200 model and the mean wind pressure $\overline{w}$ of 1/300 model is corresponding to the pressure coefficient μ_{s300} of 1/300 model. h_{ref} is the height of the reference point, and $\overline{w}_{h_{ref}}$ is the wind pressure of the reference point. N is the number of the wind pressure time history sample data, and w_i is the wind pressure at ith time.

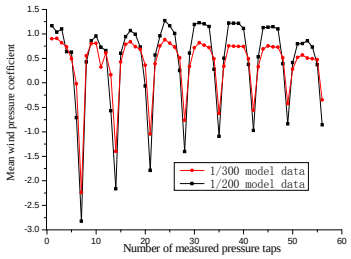

Fig. 5 mean along wind pressure coefficient

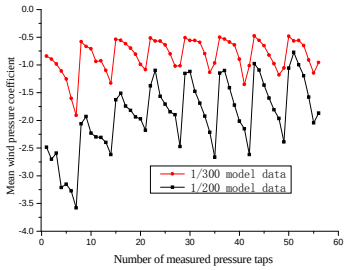

Fig. 6 mean lateral wind pressure coefficient

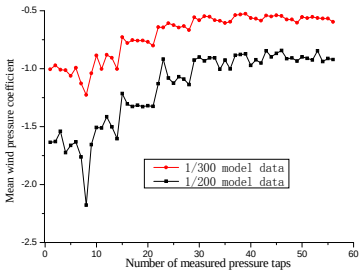

Fig. 7 mean leeward wind pressure coefficient

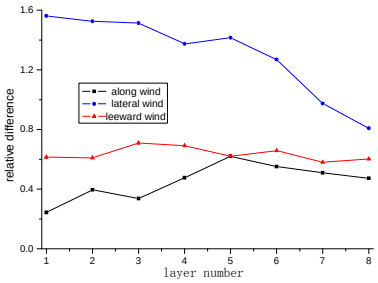

Fig. 8 relative difference of mean wind pressure coefficient

It can be seen from the figures:

a. The absolute value of mean wind pressure coefficients of 1/200 model is much larger than those of 1/300 of load cell model. b. In Figure 5, the mean wind pressure coefficient curves of two model change consistent, along wind pressure distribution doesn't change much with different blocking ratios. In Figure 6, the trend of the two curves is very different, and the peak position is not the same. c. As the height increases, the difference between the two curves is decreasing. It should be noted that the along wind pressure of some points is negative, due to the edges of the building and the surroundings. In fact, the blocking ratio of 1/300 model is still 6.7%, blocking effect exists, thus, the difference between the test data of 1/200 model test data and the correct values should be greater.

It can be seen in Figure 8, the relative difference on the lateral side is more significant than those on the along wind side and leeward side; furthermore, the relative difference of lateral side decreases along the height and the along wind relative differences increase at the beginning, and then decrease along the height. The reason can be explained as follow: the lateral wind pressure is influenced by the blocking effects caused by the manometrical model itself and the surrounding model, and the accelerated air would inevitably lead to the increased pressure coefficient. On the along wind side, in a certain height range from the bottom the blocking effect is the most serious, according to the basic characteristics of the boundary layer of fluid motion, the bottom blockage which has a most serious blockage ratio， will not significantly cause flow velocity changes, but it will only affect on the stream lines high away badly. In the middle of the pressure measurement model, the wind velocity changes most serious; the relative difference near the tor of the mean wind pressure coefficients is small because this effect there is weak, together with the blocking effect of the height decreasing. It is made that the along wind relative differences increase at the beginning, and then decrease along the height. Ultimately that makes the relative difference on the along wind side trend with height first increases and then decreases. Generally, the blocking ratio is definite as an overall concept, but in fact, the degree of blockage along the high greatly affects the quantitative analysis of the blocking effect in wind tunnel tests with surrounding buildings, which is one reason why correction method is not applied to the actual engineering of wind tunnel test.

3.2 RMS wind pressure coefficients

RMS pressure coefficients and differences can be obtained as follow:
RMS wind pressure of test points:

$$w_\sigma = \left(\frac{\sum_{i=1}^{N} w_i^{\,2} - N\overline{w}_i^{\,2}}{N}\right)^{0.5} \quad (5)$$

RMS pressure coefficients:

$$\mu_\sigma = \frac{w_\sigma}{w_{h_{ref}}}\left(\frac{h_{ref}}{h}\right)^{2\alpha} \quad (6)$$

Absolute difference between the RMS wind pressure coefficients:

$$\Delta_{\sigma 1} = \left|\mu_{s\sigma 200} - \mu_{s\sigma 300}\right| \quad (7)$$

Relative difference between the mean wind pressure coefficients:

$$\Delta_{\sigma 2} = \left|\mu_{s\sigma 200} - \mu_{s\sigma 300}\right| \Big/ \left|\mu_{s\sigma 300}\right| \quad (8)$$

Where the RMS wind pressure w_σ of 1/200 model is corresponding to the pressure coefficient $\mu_{s\sigma 200}$ of 1/200 model and the RMS wind pressure w_σ of 1/300 model is corresponding to the pressure coefficient $\mu_{s\sigma 300}$ of 1/300 model.

The comparison charts of the RMS coefficients of the points on the along wind side, leeward side are illustrated respectively in Figure 9, 10 and 11, and in Figure 12 is for the pressure coefficient relative difference on the along wind side, leeward side. It can be seen: the lateral and the along wind and leeward relative differences are small, the lateral relative difference is significant. The RMS wind pressure of 1/200 has been severely distorted, thus, extreme pressure cannot be for engineering wind assessment. It can also be seen from Figure 12, the relative difference of the RMS coefficients on three sides significantly changes along the height, the curve trends are consistent with those of the mean pressure coefficients.

3.3 data results with correction of reference pressure

There are many blocking effect correction methods, but the pressure data are corrected on the overall proportion according to them. Literature 14 considered that the model blockage makes the wind through the model at wind speed slightly higher than the calibration of no-load wind tunnel, when the air flows through the model, the dynamic pressure at the place in the calculation of the pressure coefficient correction method: $q = q_0(1+1.25\varepsilon)$ .where, when the air flows through the empty wind tunnel model, q_0 is dynamic pressure, ε is blockage ratio. In fact, this correction method is actually that the pressure coefficient is multiplied by the adjustment factor which is less than 1. This correction method extends to be applied to the wind tunnel tests of the building structures. In fact, it is equivalent to the correction of wind speed of the reference point. In this paper, the experimental data were corrected by the correction method in the literature 14.

Figure 13 and Figure 14 shows after the correction of the pressure at the reference point the relative differences of the mean wind pressure coefficient and RMS wind pressure coefficient difference. It can be seen that the relative difference has increased after the correction, but the reduction is only about 10%. And correction of the reference point wind speed is just changing the whole pressure measurement data on the scale, regardless of the differences and other factors among the three sides. This means that the pressure errors of the reference point affect of on the data distortion only a little, or the impact of the blocking effect cannot be eliminated fundamentally, solely by the amendment of the reference point pressure.

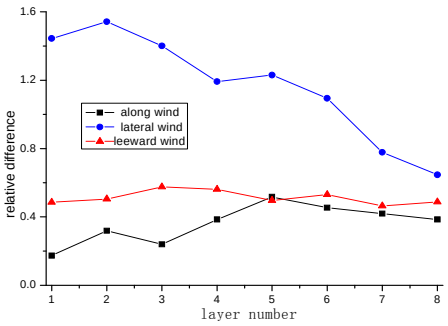

Fig.13 relative difference of the mean wind pressure correcting reference pressure

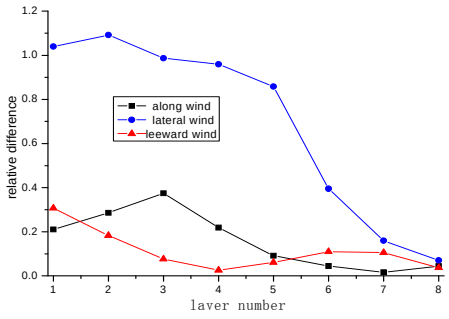

Fig.14 relative difference of the RMS wind pressure coefficient with coefficient with correcting reference pressure

4. CONCLUSIONS

In this paper, the blocking effect on rectangular high-rise buildings with surroundings is studied; the conclusion can be summarized as follows:

(1) Blocking effect on the pressure data cannot be ignored. When the blocking ratio is big, the change of pressure coefficient caused by obstruction is even more than double of the due pressure value without interference

(2) Blocking effect influences the lateral wind pressure greatly, and also changes the lateral wind pressure distribution to some extent; the change on pressure data of windward and leeward caused by blocking effect is relatively small.

(3) For wind tunnel data of high-rise building model with many low surrounding buildings, the influences of blocking effect on its pressure coefficient change along the height significant. In the amendment to blocking effects, blocking effect influenced by the degree of obstruction at different heights should be considered.

(4) For wind tunnel data of rectangular building model with surroundings, blocking mechanism is very complex, so far, there is no universal theory and proper correction method to solve this problem, thus reasonable proportion of the model to control the blocking effect is particularly important.

ABSTRACT: This paper presents results obtained for vertically placed cylinders of circular cross-sections during wind tunnel tests. All models are considered as aeroelastic ones and can represent real chimneys. Accelerations in two perpendicular directions in horizontal plane (along and across wind tunnel) were measured at the tops of 27 cylinders. An attempt to research along-wind as well as across-wind responses with respect to different approaching flows was taken up.

KEYWORDS: circular cylinder, wind tunnel, aspect ratio, wind structure, along-wind response, across-wind response, vortex excitation.

1 INTRODUCTION

Cylinders of circular cross-sections were investigated in wind tunnels by many researches, who carried out experiments in order to obtain pressure distributions on the surface, the lift force and the drag force coefficients, Strouhal number, the correlation coefficient of the load, etc. In general research tasks can be gathered in specific groups: the study on motionless cylinders (measurement of forces and pressures), aeroelastic models (study of dynamic behaviour), vibrating cylinders (f.e.: lock-in). Experiments were performed mainly on stationary cylinders.

Pantazopoulos (1994) collected and characterized the majority of wind and water tunnel studies carried until 1992, which were focused on measurements on fixed cylinders in connection with: rms of lateral force coefficient, the dependence of Strouhal number (St) on Reynolds number (Re), load correlation length coefficient. Changes of St values with Re were presented by Schewe (1983) (smooth cylinder, H/D = 10, H = height, D = diameter), who also studied the change of lateral force based on direct measurements of forces and by Leung et al. (1997) (smooth and rough cylinders). Ribeiro (1991, 1992), for steady and unsteady flow, suggested an empirical relationship for estimating the standard deviation of the local fluctuating lateral force caused by vortices, and based on the knowledge of the distribution of the pressure fluctuations and the correlation coefficient of fluctuating lateral force.

Recently circular cylinders were investigated by: Sumner and Heseltine (2004) and Sumner et al. (2004) who investigated the vortices forming near the free-end of the cylinder (H/D = 3, 5, 7, 9), at Re = $6 \cdot 10^4$. Velocity fields were measured in the excitation area and averaged in time, and then strength of vortices in every measuring point was estimated. General conclusion was that the vortex excitation for the model with the free-end occurs only in certain areas along the height of the model. In the next paper by Sumner and Heseltine (2008) detailed information about the tip vortex structures and their streamwise development were provided. The turbulent wake of cylinders was investigated at Re = $6 \cdot 10^4$ by Adaramola et al. (2006) and was similar for cylinders of aspect ratios of 5, 7, 9 whereas distinctly different was for the cylinder of aspect ratio of 3. More details about the flow around the model of aspect ratio of 9 are presented in the paper by Adaramola et al. (2010). Cao et al. (2007) studied experimentally and Cao and Tamura (2008) studied experimentally and numerically the flow around cylinders (H/D =2.22, 4, 8) in linear

shear flows, at Re = $1.7 \cdot 10^4$-$3.6 \cdot 10^4$. Vortex shedding was investigated by examination of Strouhal number and base pressure variations with respect to shear parameter. Also the mean pressure distributions around cylinder as well as drag and lift forces were studied. The 3D effect of the flow passing over the free-end on vortex shedding in the case of cylinder of small aspect ratio of 3, at Re = $6 \cdot 10^4$-$11 \cdot 10^4$ was investigated by Iungo et al. (2012). Pressures, forces and velocities measurements were conducted during tests. Pressure measurements on the surface of the cylinder at Re = $4.0 \cdot 10^4$-$1.64 \cdot 10^5$ were conducted by Lee et al. (2011) in order to investigate the difference of aerodynamic characteristics between non-accelerated and accelerated flow. Pressure and hot-wire measurements for two cylinders of aspect ratios of 8 and 8.6 and different surface roughness at Re = $1.73 \cdot 10^5$-$5.86 \cdot 10^5$ were conducted by Miau et al. (2011). Particular attention was paid to the flow behavior in the near wake region.

Many papers are devoted to the vibrating cylinders. The results of studies on the relation between St and Re numbers at various intensities of turbulence of the approaching flow in the case elastically mounted model were described by Cheung and Melbourne (1983). The standard deviation of local lift caused by vortex excitation, obtained in studies in turbulent flow in dependence on Re number and turbulence intensity were also examined in that research. Novak and Tanaka (1975) found that the correlation length of the load increases rapidly with the amplitude of vibrations, and the increase is higher for steady flow than for turbulent flow. Howell and Novak (1980) studied the global force acting on cantilever, rigid cylinder, mounted elastically. The authors measured correlation coefficient of pressures as the function of the distance between the reference point and the location of the second point moving along the height. The experiment was performed in steady and turbulent flows, with the model oscillating transversely, at Re number $7.5 \cdot 10^4$. The study showed an increase in lateral force coefficient with increase of the vibration amplitude to 0.1D.

More recent researches on vibrating cylinders were made by Gupta and Arun (2003) who performed measurements of the wind velocity fields around cylinders of different cross-sections, in which oscillations caused by vortices were observed. The dependence of Strouhal number on Reynolds number was formulated. Pastò (2008) analysed the behavior of freely vibrating model in laminar and turbulent flows. Studies were focused on the influence of mass-damping parameter of circular models and Reynolds number on lock-in phenomenon, on the response amplitude and on wake correlation. Measurements of unsteady pressure distributions on the surface of oscillating cylinder were presented by Zasso et al. (2008). Studies were focused on vortex shedding and on integral forces on the cylinder and their correlations with motion. The effect of free-stream turbulence on vortex-induced vibrations of an elastic cylinder (H/D =20) in a cross-flow and the associated fluid forces were investigated experimentally at Re number $5 \cdot 10^3$-$4.1 \cdot 10^4$ by So et al. (2008). Belloli et al. (2012) investigated vortex induced vibrations of the cylinder (H/D = 10) of low structural damping and high mass ratio at Re = $5.4 \cdot 10^4$. Tests showed the clear correlation between wake and force changes during cylinder vibrations.

2 RESEARCH DESCRIPTION

2.1 *Models*

The experiments were carried out in the boundary layer wind tunnel in Wind Engineering Laboratory in Cracow, Poland. Circular cylinders were placed vertically in the working section of the wind tunnel (Fig. 1). The basic geometrical characteristics of the 27 models are collected in Table 1 together with measured frequencies. All models were made of carbon fiber in order to assure particular stiffness, which was necessary to fulfil similarity criteria. The applied material has got the following characteristics: elastic modulus E = 105 GPa, density: ρ = 1455 kg/m^3.

The following parameters are settled in Table 1: geometrical characteristics of the models (D – diameter, H – height, λ – aspect ratio), f = natural frequencies of vibrations calculated from power spectral density functions of top accelerations. There are distribution of natural frequencies with respect to case number and aspect ratio in Figure 2.

2.2 *Wind conditions*

The influence of wind characteristics – wind mean speed profiles, turbulence intensity profiles and PSD functions – on the mean pressure coefficient distributions were examined. Over 40 configurations of barriers, spires and blocks generating boundary layer were taken into account Three (six in case of pipes of the diameter D =16 mm) flows were chosen for further measurements. The mean wind speed profile (power-law formula), intensity of turbulence, and PSD function (similar to Davenport's function) were described by respective equations:

$$v(z) = k \cdot z^{\alpha} \quad \text{for } z > z_{min} \qquad I_v(z) = \frac{\sigma(z)}{\bar{v}(z)} \qquad G(f) = \frac{bf^2}{\left(1 + cf^2\right)^d} \tag{1}$$

where: z = height [cm], z_{min} = minimum height [cm] for which all profiles have the same value at 70 cm, k and α = values selected by the least squares method, $\bar{v}(z)$ = mean wind speed, $\sigma(z)$ = standard deviation of wind speed, b, c, d = coefficients selected by the least squares method. Respective plots are collected in Figure 3.

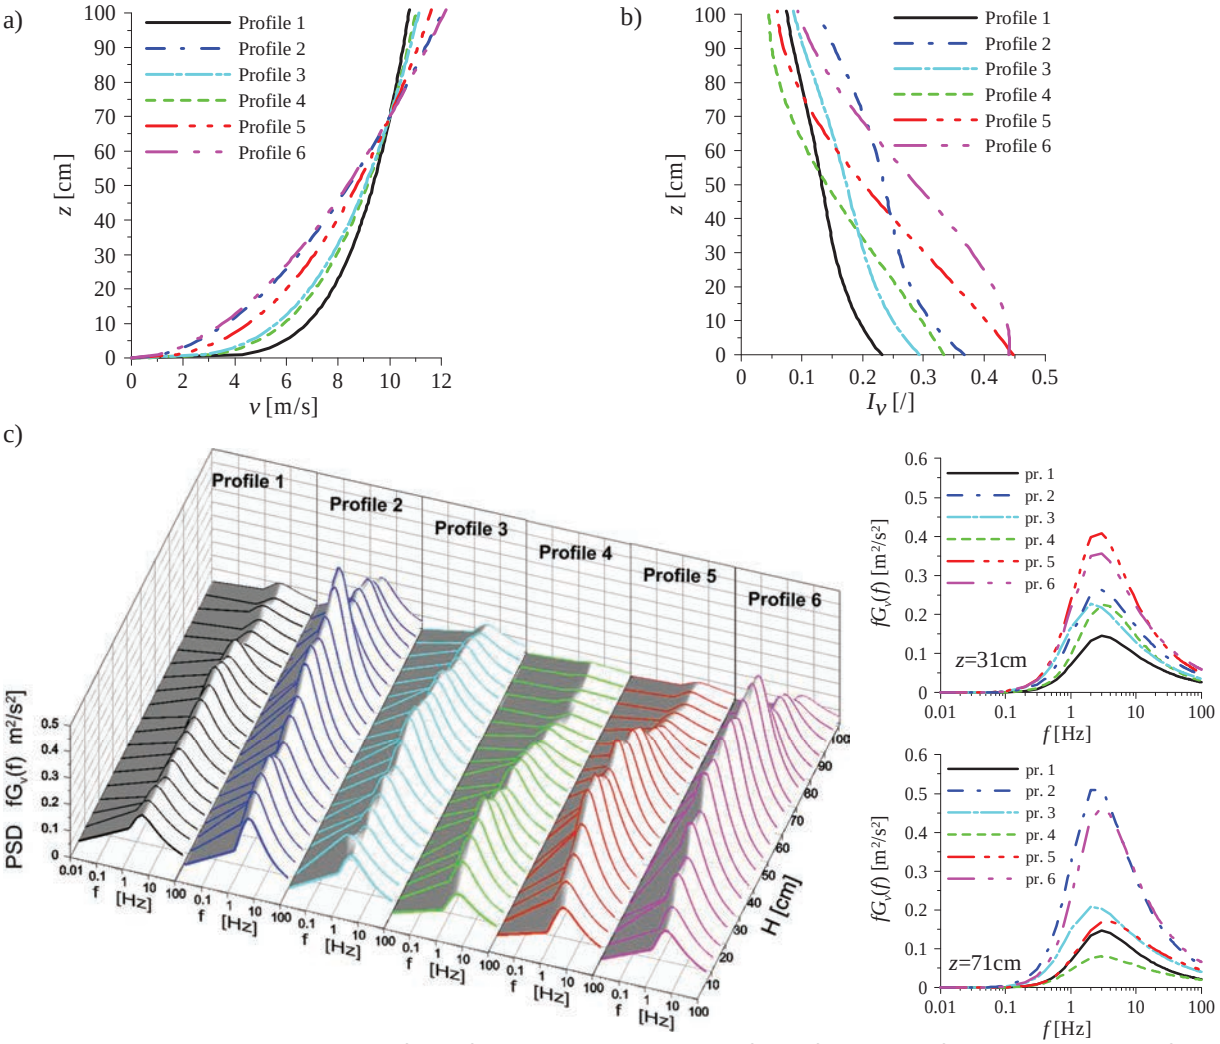

Figure 3. Wind characteristics: a) profiles of mean wind speed, b) profiles of intensity of turbulence, c) PSD functions: spatial distributions and examples at two levels.

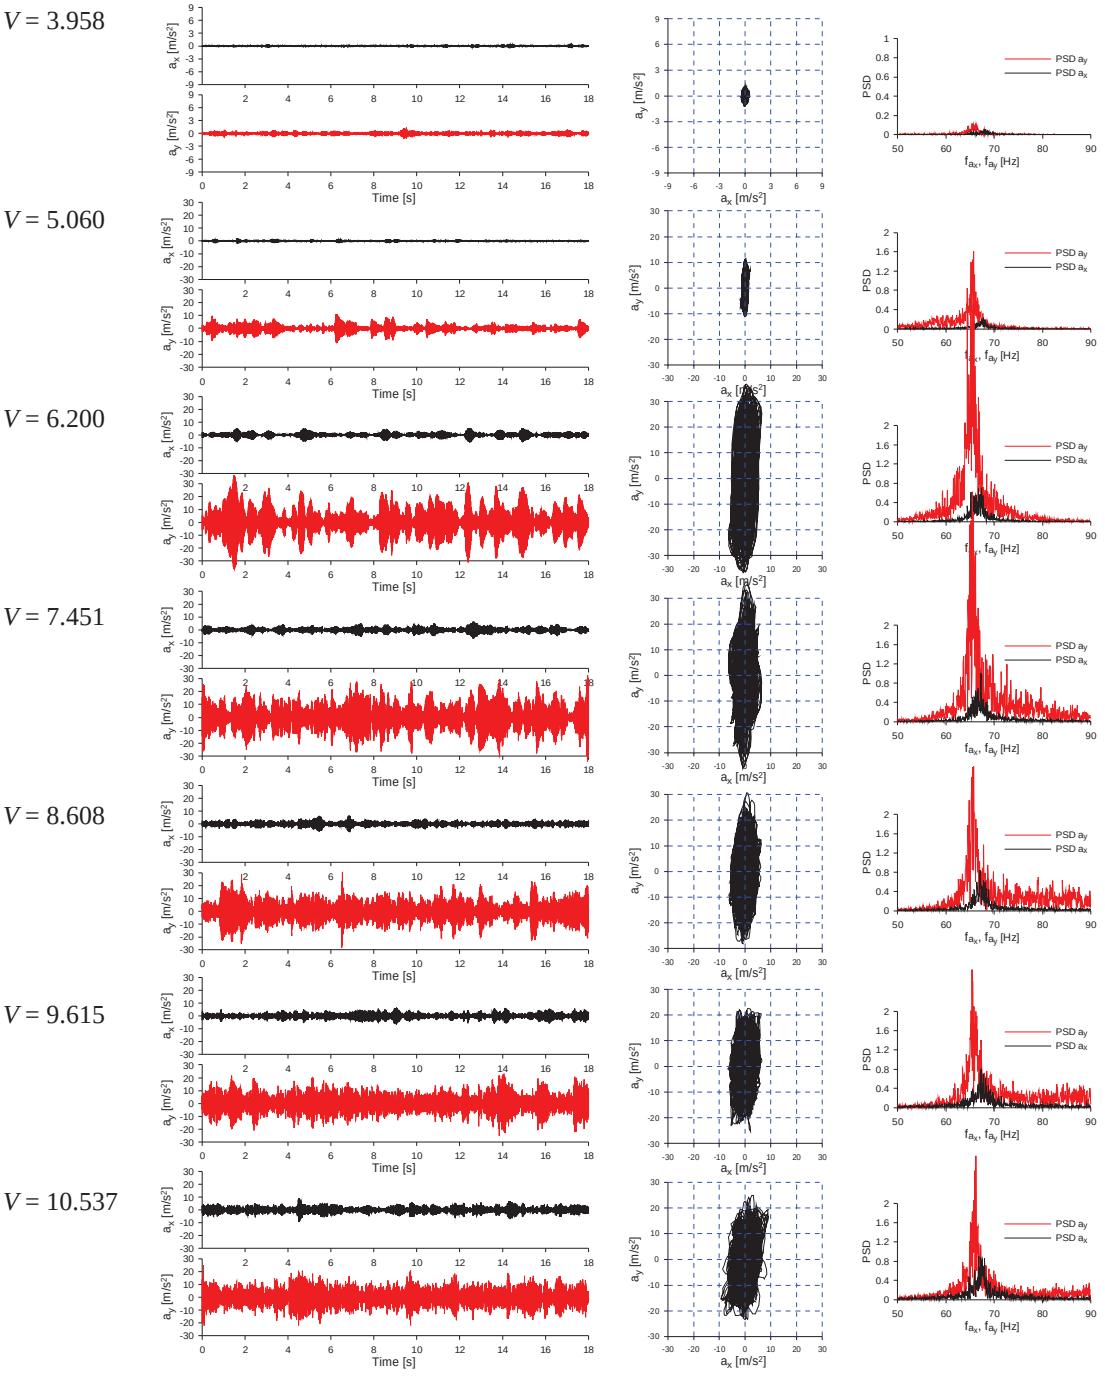
2.3 *Experiment*

Two Brüel&Kjær accelerometers were installed at the top of each model. The data was gathered with PULSE system. Time series of accelerations in two perpendicular direction: along and across wind tunnel were measured. The view of a model with installed accelerometers in wind tunnel is presented in Figure 1. The wind speed was changing from 0 m/sec to about 20 m/sec during measurements.

3 RESULTS AND ANALYSIS

Statistical data handling has allowed to define wind speeds at which vortex excitation could take place. Top accelerations in two perpendicular directions and PSD functions of time series with respect to increasing wind speed are presented in Figure 4 in the case of the model No. 8 (D = 20 mm, H = 40 cm) and profile 1. Amplitudes of top accelerations for wind speeds at which vortex shedding occur in cases of the same pipe and profiles 3 and 6 are presented in Figure 5 in order to compare results. The same analysis was carried out for all cases of models and wind structures.



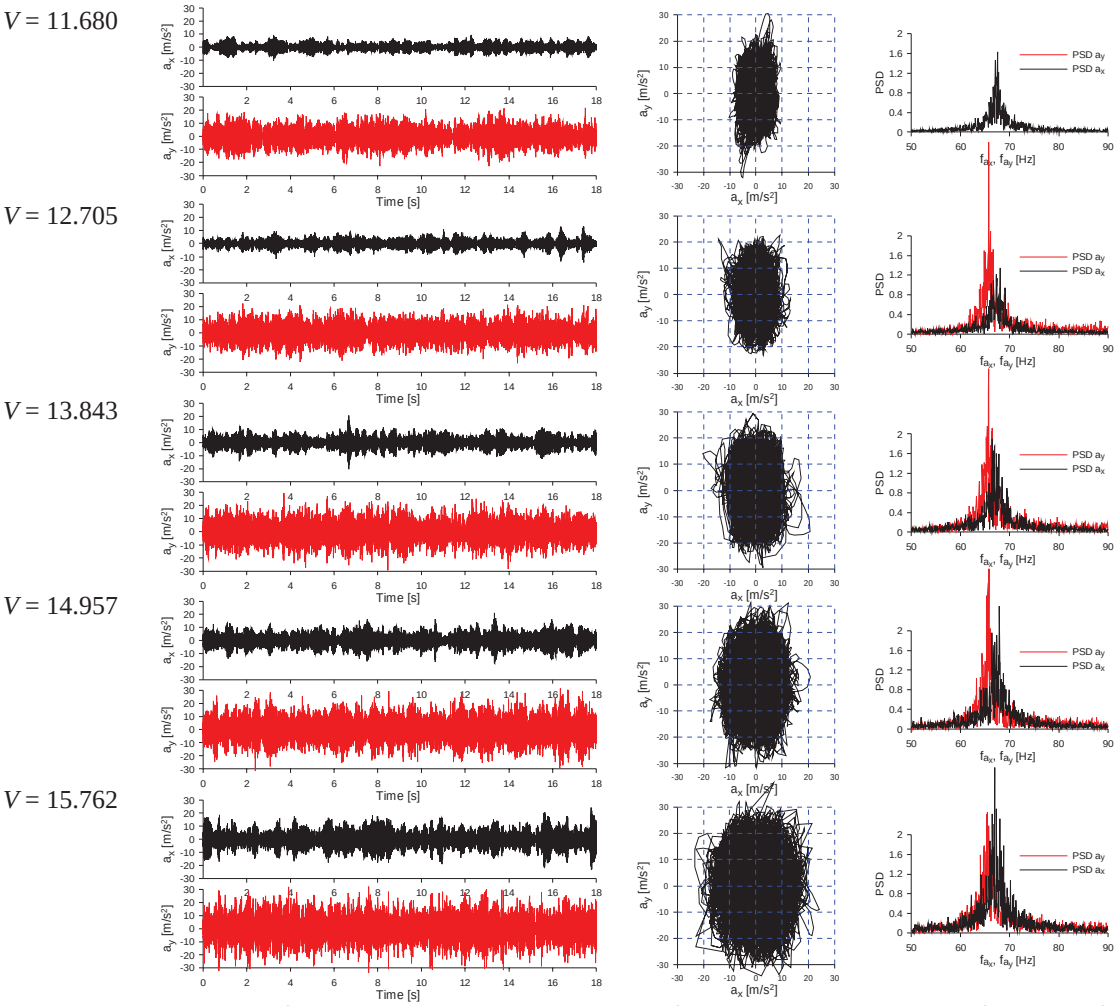


Figure 4. Time histories of accelerations (a_x, a_y), trajectories of top accelerations and PSD functions of along and across- wind components for consecutive wind speeds, for wind profile no. 1, for pipe no 8.

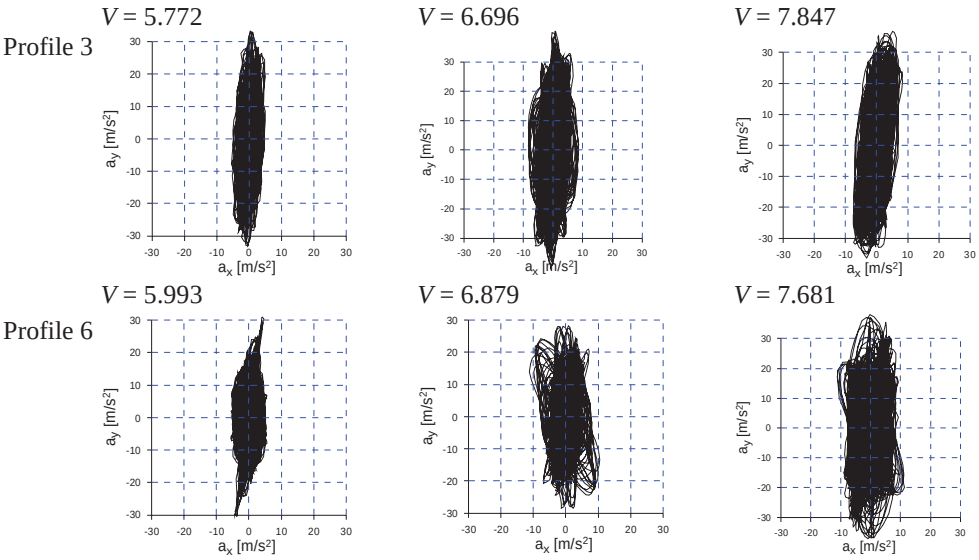

Figure 5. Top trajectories of accelerations at the range of wind speeds at which vortex shedding occur.

Vortex excitation is clearly visible on time histories of accelerations (higher amplitude of the acceleration in direction perpendicular to the flow) as well as on power spectral density functions (higher peak value). Increasing amplitude of the accelerations in both directions are caused by the increasing wind speed.

The reduced standard deviations of top accelerations respectively along and across mean wind speed (σ_{ax}, σ_{ay}) were assumed as results, which allow to compare two components of the cylinder response to the wind action. Examples of normalized standard deviations (σ_{ax}/V^2, σ_{ax}/V^2) and their ratio (σ_{ax}/σ_{ay}) are presented in Figures 6 and 7. As it can be seen in these figures – the range of wind speeds in which vortex excitation appears could be recognized with a good approximation. Some more cases of the ratio σ_{ax}/σ_{ay} are enclosed in Figure 8 and 9 for pipes of the smallest and the largest diameter equal respectively to 16 mm and 50 mm.

Critical wind speed values obtained in the research were evaluated from maxima at plots of standard deviations or their ratio as shown in Figures 6-9. It should be emphasized that values obtained in the studies are approximated and only shows the range of wind speeds close to which vortex excitation can appear. The way of attaching accelerometers at the top of the model pipe causes flow disturbances and then differences in values of measured and calculated critical wind speeds. Vortex exciatation appears in the range of wind speeds different in particular cases of flow. There was no excitation for pipes 18, 22, 26, 27 in considered wind speed range. From the other hand an exact critical wind speed could not be estimated (there are no maxima on plots) but only the beginning of vortex excitation was determined in some cases of pipes. Evaluated and calculated critical wind speeds are collected in Table 2 with respect to case of wind structure. Theoretical value was calculated from $V_{cr} = fD/St$, where St = 0.18

4 CONCLUSIONS

Based on the analysis of results it can be stated that the response of aeroelastic models of circular cross-sections depends strongly on the structure of the approaching flow. The response of such models is highly influenced by buffeting load resulting from the turbulence (fluctuations of wind speed and direction) as well as by the vortex excitation load.

It seems that the wind structure have the higher influence on critical speed for models with larger aspect ratios. Perhaps this is related to a combination of wind gusts and vortex excitation. On the other hand, the wind strucutre has less effect on the critical speeds for smaller aspect ratios (lower differences between calculated and measured values – Table 2).

The standard deviations obtained for the profile 6 are in most cases lower than those obtained for other cases. For most of models, the largest standard deviations and their ratios were obtained in case of profile 1 (the lowest turbulence of the flow), the smallest in case 6 (the largest turbulence of the flow).

The studies provided a range of critical wind speeds (different for various cases of flow), which in general is close to the theoretical values obtained for St = 0.18. Differences are caused by the way of accelerometers attachment on the top (disturbance of the flow around). Also the approximated estimation of maxima values on plots in Figures 6-9 causes the difference between

calculated and theoretical values. But it can be clearly noticed that vortex excitation appears in the range of wind speeds almost for each case of the pipe.

It seems that further analyses are necessary to better understand the influence of wind structure on the response of pipes. Numerical simulations of dynamic response taking into account buffeting load as well as vortex excitation is also planned

ABSTRACT: In order to clarify the characteristics of large amplitude wind-induced response of cables in cable-stayed bridges, a series of wind tunnel tests was conducted in smooth and grid-generated turbulent flow. Tests were conducted at up to around 50 m/s, using circular cylinder models with inclined angle of 30°, 40° and 45°. *Sc* of the models was somewhat smaller than the prototype. Large responses with amplitude more than 2*D* were observed. The response in more turbulent flow had less intense negative aerodynamic damping, but large nondimensional response, σ/D, around 1.3 was still observed with structural damping in logarithmic decrement δ = 0.027-0.034 for β = 30° and I_u = 4.6% case. For β = 30° case, the order of onset wind speeds in different turbulence intensities seemed to correspond to that of the critical *Re* numbers. However, for the other two cases, the order was opposite. Therefore, the cause of the intense response still needs to be studied for clear understanding. In limited cases, effects of model mass or natural frequency were also studied.

KEYWORDS: Inclined cable, Dry cable galloping, Wind-induced vibration, Wind tunnel test

1 INTRODUCTION

Wind-induced vibrations of stay cables of long-span cable-stayed bridges need to be considered in the design, because they are very flexible with low damping (Tanaka & Yagi[1]). Phenomena such as the rain-wind induced vibration have been drawing attention for decades and their characteristics as well as countermeasures have been clarified so that their harmful effects can be reduced to some extent.

On the other hand, the possibility of dry inclined cable galloping was pointed out relatively recently. There are some theoretical (Macdonald & Larose[2,3]) and computational (Yeo & Jones[4]) studies as well as experimental (Cheng *et al.*[5,6], Matsumoto *et al.*[7]) and field measurement (Zuo and Jones[8]) ones on the dry inclined cable galloping, but its characteristics and mechanism are still not clear. One reason seems to come from that the vibration is difficult to be reproduced even among laboratory experiments.

The authors conducted a series of aeroelastic wind tunnel tests of inclined circular models in smooth flow (Kimura *et al.*[9]). By adjusting the inclination of a fairing plate installed at the windward of the model top end, reasonably good reproducibility was obtained among the test results. This study is to extend the test cases also in grid generated turbulence with heavier models, in order to clarify the response characteristics with conditions more close to the prototype cables.

2 EXPERIMENTAL SETUP

A circular cylinder model with an inclined angle was elastically supported in a closed section of a wind tunnel and its responses were measured.

2.1 *Wind tunnel and flow condition*

The wind tunnel at Sumitomo Heavy Industries Ltd. was used (Fig. 1). The closed test section has the width of 2.0 m, height of 3.0 m, and length of 15 m. The wind speed can be varied between 0.3 and 60 m/s.

Tests were conducted in smooth flow with turbulence intensity less than 0.5 %, and grid-generated turbulent flow. The turbulence generating grid had mesh size of 800 mm and bar size of 100 mm and it was located at 9.05 or 3.66 m upstream of the model. The turbulence intensities of *u*-component (mean wind direction), I_u at the model location were 4.6 % and 10.4 %, respectively. I_v (lateral wind direction component) were 4.8 % and 10.5 %, and I_w (vertical wind direction component) were 5.1 % and 11.9 %.

2.2 *Circular cylinder models and model supporting system*

The circular cylinder models had a diameter D = 114 mm and were made of a standardized polyvinyl chloride pipe. Three types of inclined angles β were tested using different models, i.e., β = 30°, 40°,and 45° (Fig. 2). The circular cylinder model was supported in the vertical plane that includes the wind direction. Only inclined angle β was given without any yaw angle. The height between top and bottom of the models was 1.18 m.

In order to avoid the complicated effects caused by the leakage flow through the gap between the hole of the wind tunnel wall and the circular cylinder model, whole model supporting system was installed in the wind tunnel (Figs. 1 and 2). Model supporting systems as shown in Figure 3 supported the top and bottom of the model which allowed along-wind and across-wind motion of the model. For each supporting system, four bars with air bearings were used, and two sets and one set of coil springs for along-wind and across-wind motion, respectively, were installed to provide the restoring force. The air bearings were used for the small structural damping. The supporting system was designed by taking reference to the study by Sarkar *et al.*[10], but

	I_u=4.6%	0.892	0.0035	
	I_u=10.4%	0.892	0.0030	
	Smooth	1.012	0.0031	12.66

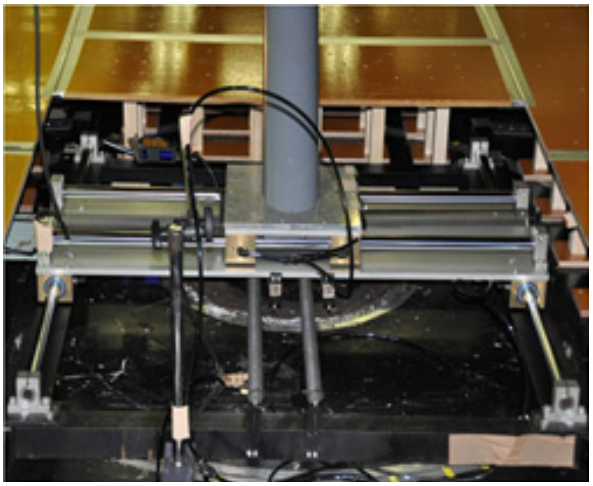

Figure 3. Model supporting system (at the bottom of the model, viewed from leeward)

the system in this study support the model's upper and lower sides instead of its right and left sides in their study. It allowed the response as large as 2D with simple restoring force provided by the coil springs without any secondary stiffness. Although the supporting system allowed 2DOF motion, there were considerable difference between the masses corresponding to the along-wind and across-wind motion; the mass in the along-wind motion was larger by about 40 kg in total than the across-wind motion. Therefore, the along-wind response was used simply to calculate the mean wind force, and only the across-wind motion is considered to be significant and its characteristics are discussed in this study.

The test cases and dynamic characteristics of the model are shown in Table 1. Their Scrouton numbers of the models, Sc, defined as $Sc = 2\ m\delta / (\rho\ D^2)$, were 9.6-11.6 for most of them, which is about half of the prototype stay cables. The logarithmic decrement was close to the prototype value but the model mass could not be increased due to the supporting system's limitation. In the definition of Sc, ρ is the air density. The cases with larger damping for $\beta = 30°$ or lighter mass for $\beta = 45°$ were also conducted to clarify the effects of them.

2.3 *Response measurement*

The along-wind and across-wind motions were measured by laser displacement sensors. The output of the sensors was low pass filtered at 30 Hz, and sampled with 500Hz for 60 sec. Because some of the responses were non-stationary, the standard deviation of the across-wind displacement data for 60sec, σ, was normalized by D, and it was plotted as the response amplitude in the wind speed-amplitude figures. In some cases, time histories of developing response from at rest condition or decaying response from larger initial displacement were measured to obtain the aerodynamic damping data.

(b) β=40°

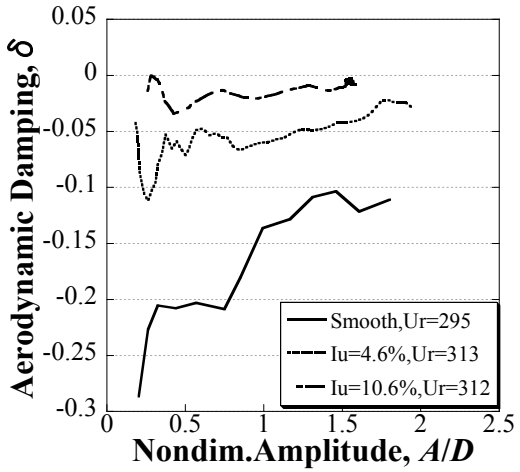
(c) β=45°

Figure 4. Model responses and drag coefficients

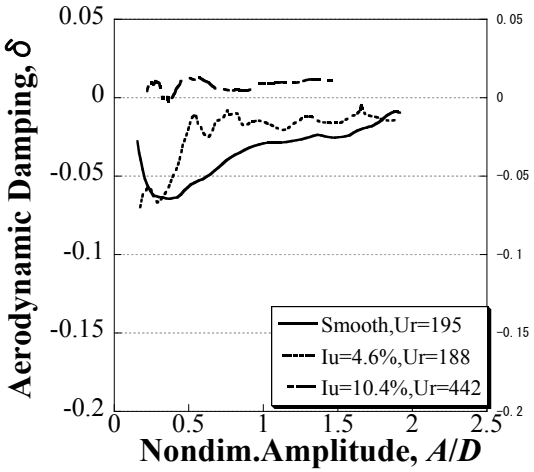
3 EXPERIMENTAL RESULTS

3.1 *Model responses and drag coefficients*

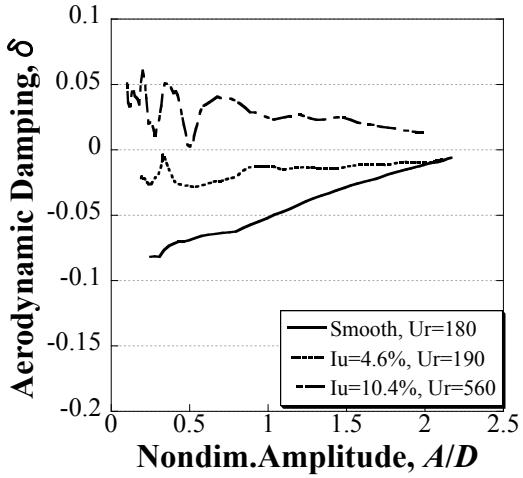
The nondimensional standard deviation across-wind response amplitudes of the models are shown in Figures 4. The horizontal axis is the reduced wind speed $U_r = U / (f_0 D)$ and *Re*. In the figures, drag force coefficients are also plotted that were simply estimated from mean along-wind displacement of the model. The C_D data at particularly lower wind speed seem to change alternately. This is because a half of the data were taken by increasing the wind speed and the rest were taken by decreasing the wind speed between the measurements, so that the wind speed of each measurement was arranged alternately. It should be judged that this simple C_D measurement was not very accurate including the error as much as the amplitude of the alternate change. Nevertheless, a clear tendency can be seen that the critical *Re* decreases with increased turbulence.



(a) β=30°



(b) β=40°



(c) β=45°

Figure 5. Aerodynamic damping in log decrement

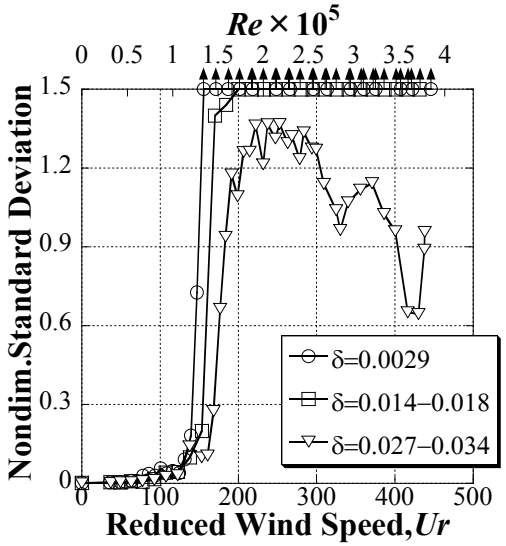


Figure 6. Response with various damping (β=30°, I_u=4.6%)

Large responses with amplitude more than 2*D* were observed in less turbulent flow for all β cases. The response became less intense in more turbulent flow. For $\beta = 30°$ case, the order and value of onset wind speeds in different turbulence intensities seem to correspond to those of the critical *Re*. However, for the $\beta = 40°$ and 45° cases, the order was opposite, and the onset wind speed and critical *Re* do not correspond to each other. Therefore, it is still difficult to identify the possible cause of the intense response.

3.2 *Aerodynamic damping*

Some of the measured aerodynamic damping are shown in Figures 5. The horizontal axis of the figure is A/D, where, A is the model response amplitude in across-wind direction. The exciting force of the large response vibration was strong and the absolute value of negative aerodynamic damping exceeded $|\delta| = 0.2$ for $\beta = 30°$ case in smooth flow at the amplitude less than $A/D = 0.8$. The exciting force was less intense for the response in stronger turbulence. In order to confirm the intense negative aerodynamic damping of the response, a few cases were conducted with added structural damping by attaching adhesive tape to the model supporting springs. It can be seen that large nondimensional standard deviation response around 1.3 was still observed with much larger damping ($\delta = 0.027$-0.034) for $\beta = 30°$ and $I_u = 4.6\%$ case (Fig. 6).

3.3 *Effects of the masses and natural frequencies*

In this study, heavier models were used than the previous study (Kimura *et al.*[9]) as stated in the introduction. The effects of the mass were studied in one set of cases and the responses are shown in Figure 7. It should be noted that the natural frequencies of the models were also different by 13%. The responses were somewhat different, and the effects of the model mass seem to be complex.

The effects of the natural frequency were also studied in one set of cases (Fig. 8). When the horizontal axis is taken as reduced wind speed as in the figure, the onset wind speeds seem to coincide. On the other hand, in the previous study (Kimura *et al.*[9]) where the similar comparison was made with $\beta = 45°$ model, the onset wind speeds were more closely matched when the wind speeds were expressed in terms of *Re*. These different characteristics with respect to the natural

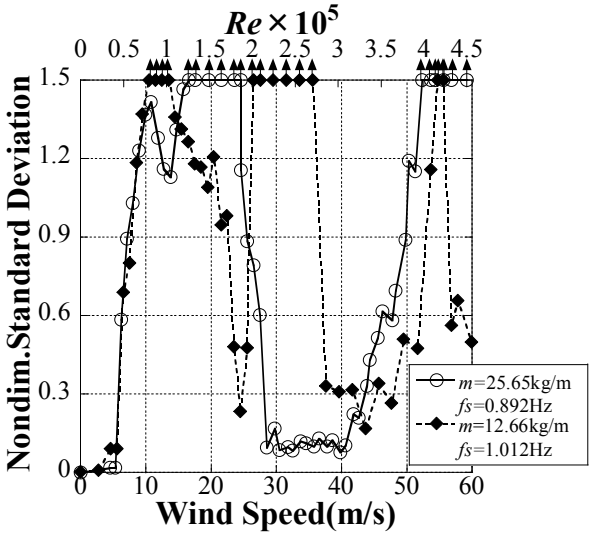

Figure 7. Effects of different masses
($\beta = 45°$, smooth flow)

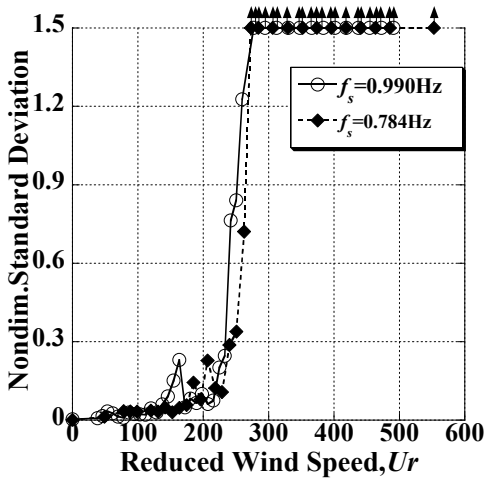

Figure 8. Effects of different natural frequency
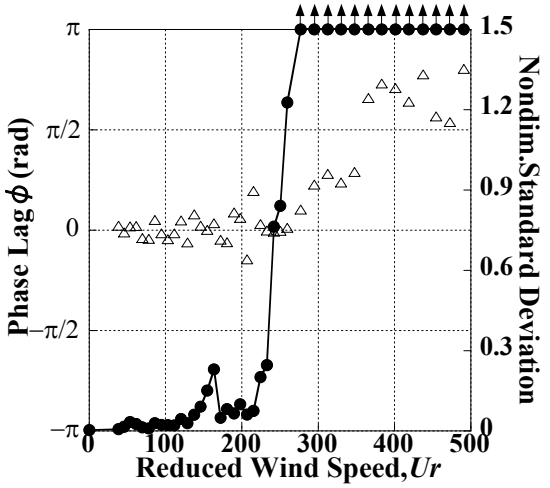
(β=30°, smooth flow)

frequency may be due to different β of the models. However, still further studies seem to be necessary for clear understanding.

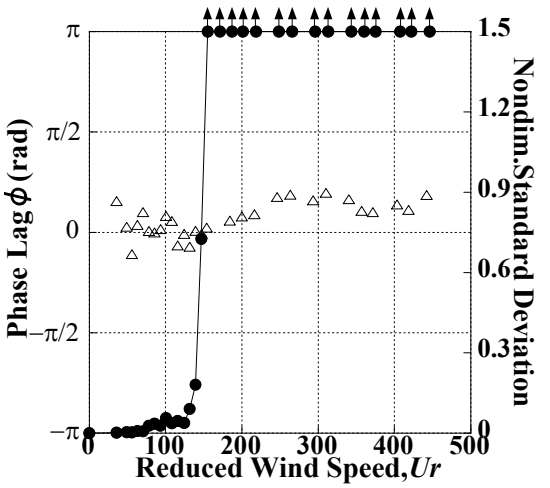
4 EXCITING FORCE CHARACTERISTICS

In order to understand the response characteristics in more detail, the excitation forces were tried to be computed by numerically integrating the equation of motion. Some examples of the phase difference of the force from the response is plotted with open triangle symbols in Figures 9. The response is also shown in the figures for reference. This way of the force estimation may result in some error, but from the figures, the computed phase lag seems to be more or less consistent.

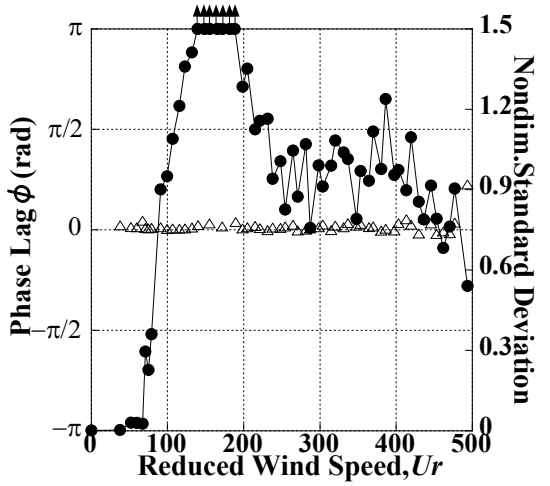
For $\beta = 30°$ case, positive phase lag up to more than $\pi/2$ was observed during large response in smooth flow (Fig. 9(a)). The phase lag became much smaller in turbulent flow (Fig. 9(b)). The phase lag for $\beta = 40°$ and $45°$ cases were even smaller and nearly zero in turbulent flow with $I_u = 4.6\%$.



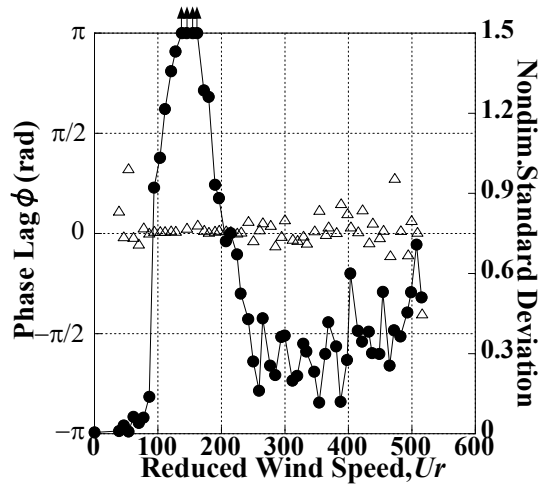
(a) β=30°, smooth flow



(b) β=30°, I_u = 4.6%



(c) β=40°, I_u = 4.6%



(d) β=45°, I_u = 4.6%

Figure 9. Phase lag of the exciting force from the response

5 CONCLUDING REMARKS

Wind tunnel tests were conducted to clarify the characteristics of large amplitude response of stay cables. The response generally became less intense with increase of turbulence, but large response of $\sigma/D = 1.3$ was still observed with $\delta = 0.027$-0.034 for $\beta = 30°$ and $I_u = 4.6\%$. It is necessary to confirm that the flow condition around the model in this study actually corresponds to the stay-cables with very large aspect ratio. However if it is the case, the large amplitude response in high wind speed may have been reproduced in this study. The characteristics and cause of the response still needs to be studied for clearer understanding.

6 ACKNOWLEDGEMENTS

The authors would like to thank Dr. Masao Miyazaki at Sumitomo Heavy Industries Ltd. and Mr. Kazuhiro Asai at Sumitomo Heavy Industries Engineering & Services Co., Ltd. for their kind arrangements to make the wind tunnel tests possible. Also the help by Mr. Yoshihiro Ohhashi at COA Co., Ltd. and Mr. Yusuke Ogawa and Rokhamsay Chinda at Graduate School of Engineering, Kyushu Institute of Technology are acknowledged with the authors' sincere thanks.

Two degrees of freedom flow-induced vibrations on a cylinder

Dai ZHOU [a], Jiahuang TU [a], Yan BAO [a]

[a] *School of Naval Architecture, Ocean and Civil Engineering, Shanghai Jiaotong University, Shanghai,China.*

ABSTRACT: A numerical study is performed on the flow-induced vibrations of isolated cylinder that is elastically mounted in two degrees of freedom with varying in-line to transverse natural frequency ratios, f_{nx}/f_{ny}. A characteristic-based-split finite element method is utilized for obtaining the solution of the incompressible flow equations in primitive variables. The Reynolds number based on upstream flow velocity and cylinder diameter, D, is fixed at Re=150. The computation is carried out for lower reduced mass of M_r=2.0 and for reduced velocities in the range of U_r=3.0-12.0, with increment of one; the structural damping ratio is set to zero to maximize the vortex-induced response of the bodies. We mainly focused on the effect of natural frequency ratios on the characteristics of vortex-induced vibration (VIV) responses, including wake frequencies, orbital trajectories, response amplitudes, aerodynamic forces and wake mode patterns.

KEYWORDS: isolated cylinder; two degrees of freedom (2-dof); vortex-induced vibration(VIV); natural frequency ratio; Arbitrary Lagrangian-Eulerian (ALE) formulation; finite element method.

1 INTRODUCTION

Vortex-induced-vibration (VIV) of cylindrical structures is of practical interest to many engineering fields (such as long span cable-stayed building structures, suspension bridges, heat exchangers *etc.*), and has led to extensive fundamental studies in the past decades.

For flexibly mounted circular cylinders immersed in uniform cross-flows, large amplitude transverse motions are excited, when the vortex shedding frequency of the stationary cylinder is sufficiently close to the natural frequency of cylinder vibration. This well-known condition is called ‘lock-in’ or ‘frequency synchronization’, at which the vortex shedding frequency shifts on the natural frequency of vibration. Dynamic interaction between vortex shedding and cylinder body can also lead to significant oscillation in in-line direction at a double-frequencies of the vortex shedding, due to oscillating drag component exerted on the cylinder. In-line amplitude is typically one-order smaller compared to the values of transverse counterpart, and hence, the in-line response has surprisingly little effect on the transverse response in a regime where the mass ratios are greater than 6. However, Jauvtis and Williamson [1] showed that, as the mass ratios are reduced to below 6, stream-wise response makes dramatic changes in the fluid-structure interaction, yielding massive vibration with three times diameters of peak-to-peak amplitudes. The response branch characterized by this massive oscillation was called by Jauvtis and Williamson [1]as a ‘super-upper’ branch, and the associated periodic vortex mode, in which a triplet of vortices are formed in each half cycle, was defined as a ‘2T’ mode. More recently, a number of research studies have provided important insights into the 2-dof responses [2, 3].

The previous studies of 2-dof VIV response of cylinder with varying natural frequency ratios have been limited to relatively larger Reynolds numbers [4-6]. In the laminar flow regime, the combined in-line and transverse VIV may show quite different response characteristics; this

expectation is derived from the numerical work by Lucor and Triantafyllou [7], since they showed that the two distinct response peaks, which originally appeared in the experiment as the frequency ratio close to 2.0, do not appear in the 2-D numerical simulations, although they explained that the coarse resolution in the frequency ratios does not allow to verify the presence of this double peak. It is, therefore, more desirable to explore the response characteristics of VIV for varying natural frequency ratios in the laminar flow regime.

In this work, we present computational results for VIV response of single cylinder, which is free to vibrate in 2-dof with varying in-line to transverse natural frequencies, corresponding ratio values varies between 1.0 and 2.0. The Reynolds number, based on the diameter of cylinder, is fixed to be 150; therefore, laminar 2-D flow assumption is expected to be valid in this investigation. The main objective of the present work is to systematically study the effects of natural frequencies on 2-dof VIV responses of single cylinder at laminar flow regime. The VIV response is characterized in terms of vortex shedding frequencies, motion trajectories, amplitudes and aerodynamic forces exerting on cylinder. Vortex shedding modes are also scrutinized to reveal the effects of natural frequencies on the unsteady wake patterns behind the cylinder.

2 GOVERNING EQUATIONS AND NUMERICAL METHODS

2.1 *Governing equations*

The fluid flow is governed by the two-dimensional, incompressible, Navier-Stokes equations, which is expressed in terms of the primary variables in Cartesian coordinate system as follows:

$$\frac{\partial u_i}{\partial t} + u_j \frac{\partial u_i}{\partial x_j} = -\frac{\partial p}{\partial x_i} + \frac{1}{\mathrm{Re}} \frac{\partial^2 u_i}{\partial x_j \partial x_j} \tag{1}$$

$$\frac{\partial u_i}{\partial x_i} = 0 \tag{2}$$

where u_i (or u_j) is the velocity component in the x_i (or x_j) coordinate direction and p is the pressure divided by the fluid density, ρ. The dimensionless parameter of Reynolds number, Re, is based on the cylinder diameter, D, the free-stream velocity, U_∞, and the kinematic viscosity of the fluid, υ; i.e., $Re=U_\infty D/\upsilon$.

As the flexible body is under the action of flow-induced forces, it may exhibit oscillatory motions in both in-line and cross-flow directions. The motion of the body can be modeled via a mass-spring system, and is governed by the motion equations, respectively, in in-line and transverse directions as follows:

$$\ddot{X} + 4\pi\xi_x f_{nx} \dot{X} + 4\pi^2 f_{nx}^2 X = \frac{C_D}{2M_{rx}} \tag{3}$$

$$\ddot{Y} + 4\pi\xi_y f_{ny} \dot{Y} + 4\pi^2 f_{ny}^2 Y = \frac{C_L}{2M_{ry}} \tag{4}$$

Here, $\ddot{X}$, $\dot{X}$ and X denote the in-line acceleration, velocity and displacement of the cylinder, respectively; while $\ddot{Y}$, $\dot{Y}$ and Y represent the same quantities corresponding to the transverse motion. f_{nx} and f_{ny} represent the natural frequencies of the cylinder respectively along

in-line and cross-flow directions; $\xi_x=\xi_y=\xi$ are the structural damping ratios; $M_{rx}=M_{ry}=M_r=m/\rho D^2$ are the reduced masses of the body, where m is the mass of the cylinder per unit length. C_D and C_L are the instantaneous drag and lift coefficients, respectively, and calculated as $C_D=2F_D/\rho U_\infty{}^2 D$, $C_L=2F_L/\rho U_\infty{}^2 D$, where F_D, F_L are the forces acting upon the cylinder in the in-line and cross-flow directions. The fluid forces are computed by performing an integration, involving both the pressure and viscous stresses, around the surface of the cylinder. The reduced velocity of the cylinder is based on the natural frequency in transverse direction; i.e., $U_r=U_\infty/f_{ny}D$.

2.2 *Numerical formulations*

To account for the cylinder motions, an Arbitrary Lagrangian-Eulerian (ALE) formulation of the incompressible Navier-Stokes equations is employed for the solution of fluid flows with moving boundaries [8, 9]. The ALE formulation is easily implemented by modifying convective velocity in equation (1) into $c_i=u_i-w_i$, where w_i is the ith component of the grid velocity vector.

A stabilized second-order characteristic-based-split method, as explained in Bao et al. [10], is employed for the discretization of governing equations in ALE form.

Dynamic equations of cylinder motions are solved using an explicit time integration method that was presented in Placzek et al. [11]. They reported that the numerical damping in this algorithm was dramatically reduced by combining a centered upwind and downwind scheme for the prediction of the displacement. The integration step is described as follows:

(i) The cylinder acceleration is explicitly predicted from the previous time step,

$$\ddot{X}^{n+1}=\frac{C_D^n}{2M_{rx}}-4\pi\xi_x f_{nx}\dot{X}^n-4\pi^2 f_{nx}^2 X^n \tag{5}$$

$$\ddot{Y}^{n+1}=\frac{C_L^n}{2M_{ry}}-4\pi\xi_y f_{ny}\dot{Y}^n-4\pi^2 f_{ny}^2 Y^n \tag{6}$$

(ii) The cylinder velocities and displacements at n+1 time step are evaluated using linear approximation:

$$\dot{X}^{n+1}=\dot{X}^n+\Delta t\ddot{X}^{n+1} \tag{7}$$

$$X^{n+1}=X^n+\Delta t[(1-\theta)\dot{X}^n+\theta\dot{X}^{n+1}] \tag{8}$$

$$\dot{Y}^{n+1}=\dot{Y}^n+\Delta t\ddot{Y}^{n+1} \tag{9}$$

$$Y^{n+1}=Y^n+\Delta t[(1-\theta)\dot{Y}^n+\theta\dot{Y}^{n+1}] \tag{10}$$

where, θ is the blending factor, Placzek et al. [11] suggested that θ=0.5 can produce the smallest numerical damping; hence, in the present simulation, we also take the same value.

3 DESCRIPTION OF THE PROBLEM

3.1 *Simulation parameters*

In the present study of 2-dof vortex-induced vibration are conducted. The cylinder has equal diameter of D, and immersed in steady cross-flow of velocity U_∞, yielding the Reynolds number to Re=150. The cylinder is free to vibrate both in the streamline and transverse directions, and take very low value: M_r=2.0. To encourage high amplitude oscillations, the structural damping coefficients in both directions are set to zero; i.e., ξ=0.0. The reduced velocity, U_r (based on the natural frequency in transverse direction), is systematically increased within the range U_r=3.0-12.0 in increments of one. For each reduced velocity, five frequency ratios are considered; i.e., f_{nx}/f_{ny}=1.0, 1.25, 1.5, 1.75 and 2.0.

3.2 *Flow domains and boundary conditions*

The flow configuration and boundary conditions for a single cylinder case are shown in Figure 1. The entire computational domain was defined as Ω = [-25D, 50D] × [-30D, 30D]. A no-slip condition was applied on the surface of the cylinders: $u_x=\dot{X}$, $u_y=\dot{Y}$; a Dirichlet boundary condition was used on the inlet boundary as $u_x=U_\infty$=1. 0 and u_y=0, while at the outlet of the computational domain, it was $\partial u_x/\partial x$=0, $\partial u_y/\partial x$=0. A slip boundary condition was imposed upon the lateral boundaries: $\partial u_x/\partial y$=0 and u_y=0. For each set of numerical simulations, the solution of the stationary counterpart configurations was used as the initial conditions.

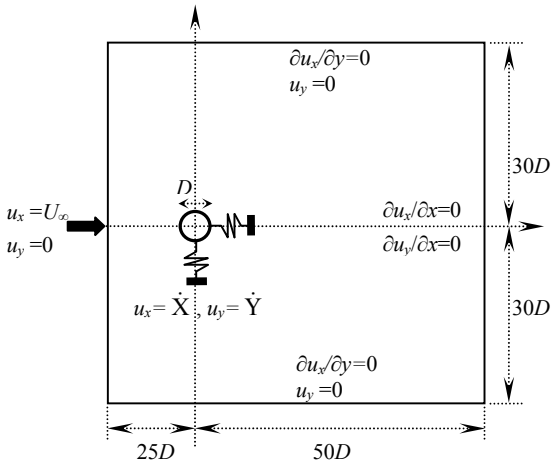

Figure 1. Schematic of the computational domain and boundary conditions for vortex-induced vibration of two-degree-of-freedom single cylinder system.

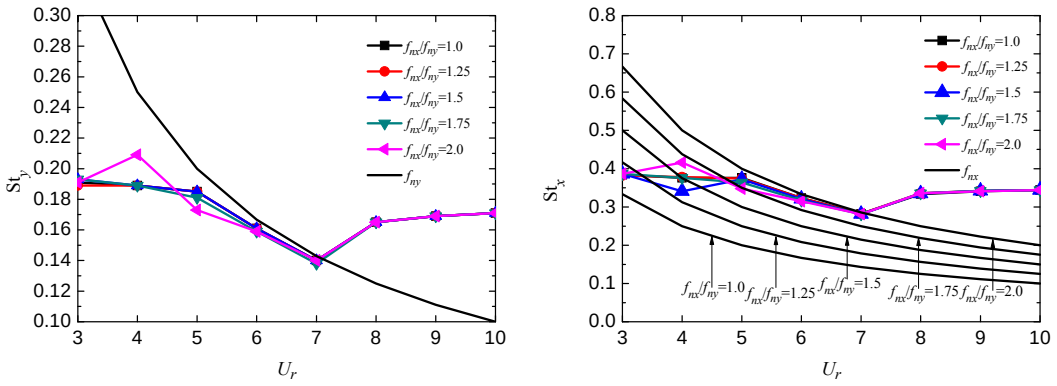
4 RESULTS AND DISCUSSION

4.1 *Vortex shedding frequency*

In Figure 2, we show the variations of Strouhal frequencies as a function of reduced velocity, corresponding to the motions in the transverse and inline directions. It is noted that, in Figure 2, we only plot the fundamental frequency components of lift and drag signals, and hence only a single value corresponds with a given reduced velocity. The variation curves of the natural fre-

quencies (f_{nx}, f_{ny}) with the reduced velocity are also shown in this figure. In the f_{nx}/f_{ny} range 1.0-1.75, the St_y curves coincide with each other, indicating that the in-line motions have insignificant effect on the frequency synchronization features (U_r=3.0-7.0). At f_{nx}/f_{ny}=2.0, the U_r range associated with the resonant response is equal to that for the lower f_{nx}/f_{ny}, however at U_r=4.0, the corresponding value of St_y is closer to the f_{ny} curve of the cylinder. A similar curve trend in the St_x is observed in Figure 2(b); the St_x curves for the range f_{nx}/f_{ny}=1.0-1.75 also nearly collapse into a single variation curve, whereas a slight difference for f_{nx}/f_{ny}=2.0 is noticed at the lower reduced velocity range. An important frequency feature associated to the dual resonant response can be identified in Figure 2, that is, at f_{nx}/f_{ny}=1.0, the St_x curve is located upper side of the f_{nx}, indicative of the non-occurrence of dual resonant response. At f_{nx}/f_{ny}=1.25-1.75, an intersection of the St_x curve and corresponding f_{nx} curve is evidenced in the plot, showing that frequency synchronization never occurs at this range. A striking frequency behavior is observed at f_{nx}/f_{ny}=2.0, where the St_x goes up along the f_{nx} curve in the U_r range from 4.0-7.0, giving a powerful evidence for the occurrence of frequency synchronization in the in-line direction. From the above observation, it may be inferred that, in contrast to the higher Reynolds number flow, the condition for the occurrence of dual resonant response in the laminar flow regime is strictly restricted, and the associated f_{nx}/f_{ny} is about the value of 2 in a very narrow range.



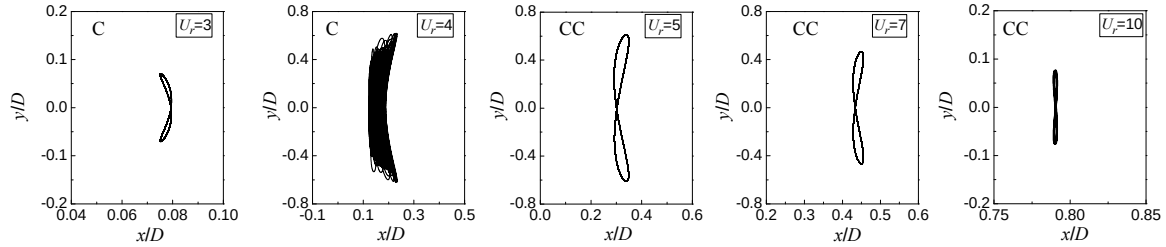
(a) vertical direction (b) in-line direction

Figure 2. Variation of Strouhal numbers of two-degree-of-freedom as a function of reduced velocity at different natural frequency ratios

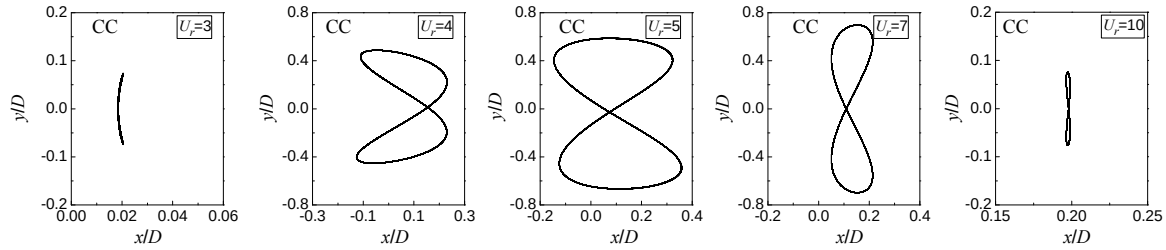
4.2 *Cylinder orbital trajectories*

In general, the combined in-line and cross-flow vibrations of a single cylinder typically show a Figure-eight motion, due to the fact that the dominant frequency in the drag oscillation is twice that for the lift. The same response in terms of cylinder orbit is also noticed in the current simulations. We select the two cases of f_{nx}/f_{ny}=1.0, 2.0 to display the cylinder orbital trajectories versus the reduced velocity in Figure 3, in which (a) represents the result associated to the 'single-resonant' only in the transverse direction, while (b) corresponds to the dual-resonant response in two degrees of freedom. It can be observed that, except the case of U_r=4.0 at f_{nx}/f_{ny}=1.0, which shows a fairly messy unrepeatable orbit, most of the cylinder motion appears to be a regular periodic Figure-eight trajectories. However, it is not the case in higher Reynolds number flows. Dahl et al. [6] reported that, as the nominal natural-frequency ratio is near 1, many of the orbital shapes appear irregular, due to the fact that in-line motion does not settle into a regular trajectory. In Figure 3, the path direction in the orbital motion is also marked by a letter 'C' or 'CC', which represent the direction of the cylinder motion at the top position of the figure-eight path;

i.e., ‘C’ means clockwise , while ‘CC’ denotes counterclockwise direction. It is found that at f_{nx}/f_{ny}=1.0, the path direction appears to be either clockwise or counterclockwise trajectories; however, at f_{nx}/f_{ny}=2.0, where dual-resonant response could occur, only counterclockwise trajectory accompanies the cylinder motion. This observation is similar with that reported in Dahl et al. [5]. They also argued that the path direction and the orbital shape are important indicators of the appearance of higher harmonic forcing, and show that the counterclockwise path direction is highly repeatable.



(a) f_{nx}/f_{ny}=1.0



(b) f_{nx}/f_{ny}=2.0

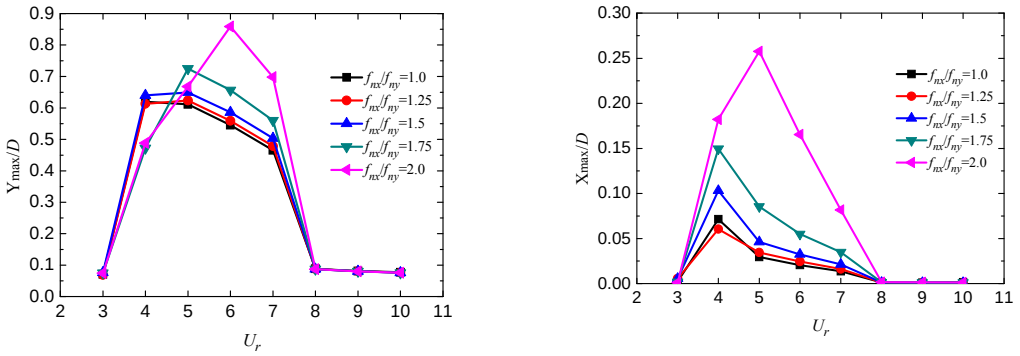
Figure 3. Comparison of Lissajous figures of the trajectory for a single cylinder at different natural frequency ratios; CC (Counterclockwise): trajectory moves upstream at the top of the figure-eight; C (Clockwise): trajectory moves downstream at the top of the figure-eight.

4.3 *Cylinder response amplitudes*

When the mass ratios are less than 6.0, a dramatic change occurs in the fluid-structure interactions and hence, the freedom to oscillate in line greatly affects the transverse vibrations [1]. In this subsection, the effects of the combined 2-dof vibrations on the amplitudes of the cylinder motions are studied at different natural frequency ratios. Figure 4 shows the variation of the non-dimensional maximum vibration amplitudes with U_r for both transverse and inline directions; i.e., Y_{max}/D, X_{max}/D. As observed in Figure 4(a), in the f_{nx}/f_{ny} range from 1.0 to 1.5, the resonant response curves collapse together and exhibit similar variation trend against the reduced velocity. The maximum amplitudes reach a peak value at a reduced velocity, to which the resonant response begins, with the values around Y_{max}/D=0.615. At f_{nx}/f_{ny}=1.75, the response curve shifts slightly, with an increased peak value of Y_{max}/D=0.722. A dramatic change is observed as the frequency ratio increases up to 2.0, where the peak amplitude shifts to occur at a larger reduced velocity of U_r=6.0, with the value rapidly increased to as large as Y_{max}/D=0.86. It is worth noting that, in contrast to the earlier experiments, two distinct response peaks could appear when the frequency ratio is near the value of 2.0 [4,12], however, in the present simulations, we does not observed the presence of the double-peak response. The same numerical results are also reported

recently by Lucor and Triantafyllou [7]; they also ascribed this to the lower level of the resolution of the simulation parameters.

Corresponding to the response curve of the transverse amplitude, a distinct response in the in-line amplitude of the cylinder motion is excited at f_{nx}/f_{ny}=2.0, on which the cylinder undergoes dual-resonant vibrations. The peak value of the non-dimensional amplitude, X_{max}/D, shifts to a larger reduced velocity as that in the transverse direction, and it reaches a value as high as X_{max}/D=0.256; this value is at the same level as reported in the experiment of Dahl et al. [6].

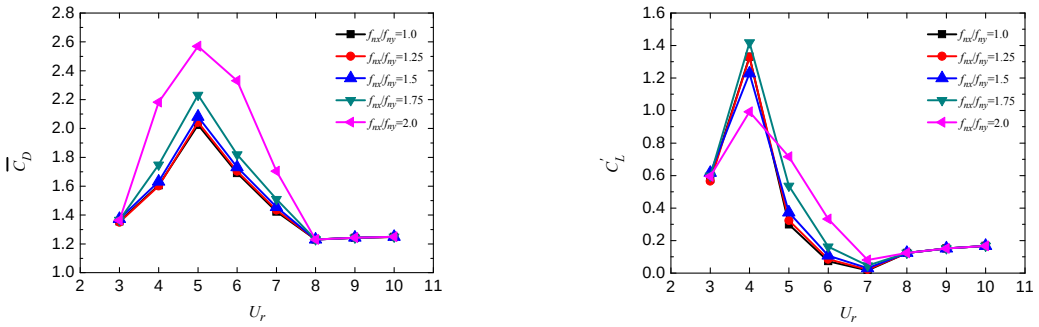


(a) vertical direction (b) in-line direction

Figure 4. The non-dimensionalized maximum vibration amplitudes in two-degree-of-freedom as a function of reduced velocity at different natural frequency ratios.

4.4 *Aerodynamic forces*

In the following, we further investigate the statistical characteristics of the forces exerted on the cylinder. Figure 5 shows the variation of the drag and lift coefficients against the reduced velocity, including mean drag coefficient ($\overline{C}_D$) and lift (C'_L) coefficients. As seen in Figure 5(a), the force curves of mean drag are nearly coincided in the range of f_{nx}/f_{ny}=1.0-1.75, while a marked increase is evidenced as the natural frequency increases to f_{nx}/f_{ny}=2.0. The lift oscillation appears to be less sensitive to the variation of f_{nx}/f_{ny}; the peak response is reduced from C'_L=1.419 to 0.992 at the same reduced velocity as the f_{nx}/f_{ny} increases to 2.0, in Figure 5(b).

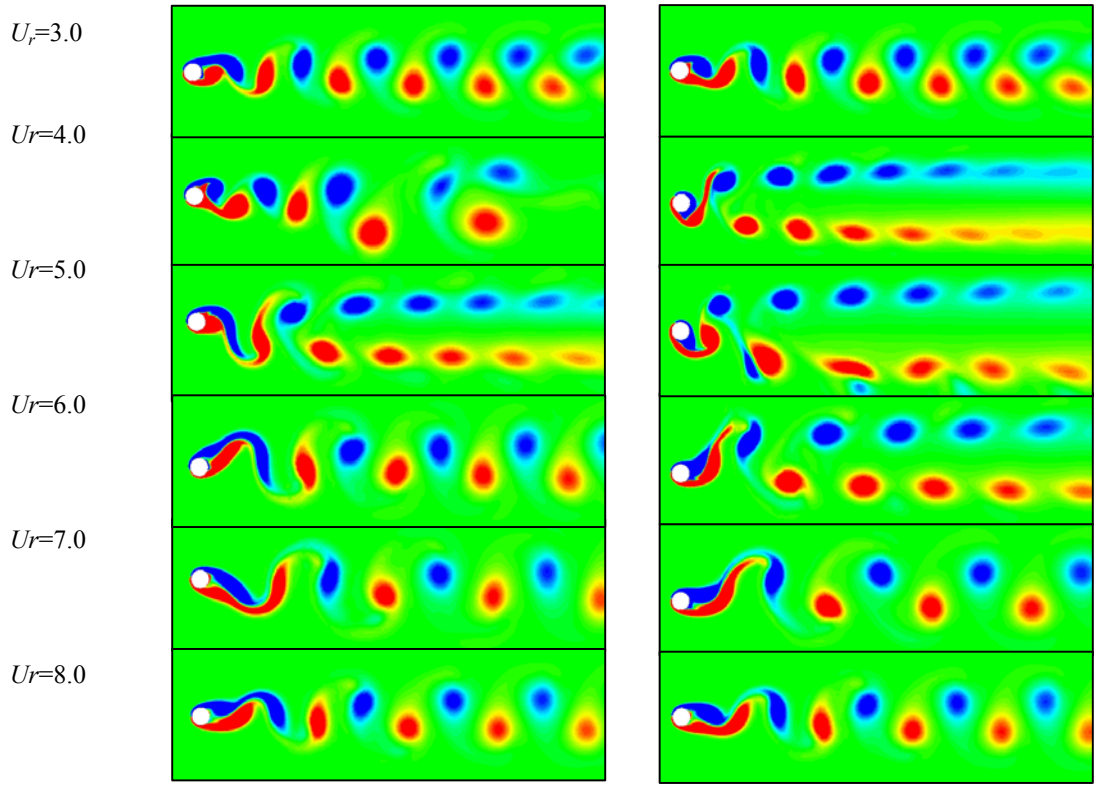


(a) mean drag coefficient (b) r.m.s. of lift coefficient

Figure 5. Variations of drag and lift force coefficients with the reduced velocities at different natural frequency ratios.

4.5 *Vortex shedding modes*

Figure 6 provides the instantaneous wake structure in terms of fully developed vorticity fields for selected natural frequency ratios of f_{nx}/f_{ny}=1.0 and 2.0. As seen in Figure 6(a), a classical 2S mode (two single vortices of opposite sign are shed per cycle) becomes the predominant vortex shedding pattern for the f_{nx}/f_{ny}=1.0. Even so, there exist some differences in the wake structures associated with the different reduced velocities. For example, an irregular unstable vortex street is observed at U_r=4.0, which is consistent with the unrepeatable cylinder motions as shown in Figure 3(a). In addition, the vertical or horizontal spacing between the successive vortices may be different for the different reduced velocities. For example, at U_r=5.0, a two-row vortex structure is formed in the wake, in which the vertical spacing is relatively large. When compared to the results from the case of transverse-only motions [13], the wake pattern for the 2-dof VIV at f_{nx}/f_{ny}=1.0 is basically consistent with the former situations. It is not surprising, because under this condition, the limited oscillation in the in-line direction has only very restricted impact on the wake.



(a) f_{nx}/f_{ny}=1.0 (b) f_{nx}/f_{ny}=2.0

Figure 6. Variation of instantaneous vorticity fields for the fully developed, unsteady flow past a freely vibrating cylinder as a function of reduced velocity at different natural frequency ratios.

A dramatic change in the wake structure is found at f_{nx}/f_{ny}=2.0, as in Figure 6(b). From the in-line amplitude curve in Figure 4(b), we have observed that the X_{max}/D increases with increases in reduced velocity, and reaches its peak at U_r=5.0, after then, it drops down with the further increase of the reduced velocity. Correspondingly, the wake pattern varies with the variation in the amplitude of the cylinder motions. As the reduced velocity changes from 3.0 to 4.0, the wake re-

tains the 2S mode; however, it becomes significantly wider and leads a two-row configuration behind the cylinder. As the reduced velocity further increases to reach U_r=5.0, the in-line amplitude reaches its peak value; correspondingly, the wake pattern transforms from 2S mode to P+S mode (a single vortex and a pair of opposite signed vortices are released per cycle of shedding). After the in-line motion reaches the peak, with the decrease in the X_{max}/D, the wake is appeared as two-row vortex streets firstly, and then it changes into a classical 2S mode in a single vortex street.

5 CONCLUSION

In the present study of 2-dof vortex-induced vibration: the cylinder is immersed in steady cross-flow of velocity U_∞ and is free to vibrate both in the streamline and transverse directions, and the associated reduced masses of the structures are equal to each other and take very low value: M_r=2.0. To encourage high amplitude oscillations, the structural damping coefficients in both directions are set to zero; i.e., ξ=0.0. The reduced velocity, U_r (based on the natural frequency in transverse direction), is systematically increased within the range U_r=3.0-12.0 in increments of one. For each reduced velocity, five frequency ratios are considered; i.e., f_{nx}/f_{ny}=1.0, 1.25, 1.5, 1.75 and 2.0.

Based on the comprehensive analysis of the results, we could draw following findings:

It is found that interaction of the 2-dof dominant force frequencies is significant in the dual-resonant response regime, where the peak frequencies of the drag and lift signals can appear at the same value. In the laminar flow regime, the condition for the occurrence of dual-resonant response is strictly limited around f_{nx}/f_{ny}=2.0.

The cylinder orbital trajectory shows that at f_{nx}/f_{ny}=1.0, the path direction can appear to be either clockwise or counterclockwise; however, at f_{nx}/f_{ny}=1.0, where dual-resonant response could occur, the cylinder orbit is only in counterclockwise patterns. The combined 2-dof vibrations significantly amplify the transverse response of the cylinder, and the peak response delays to appear at a higher reduced velocity. Double-peak response, which occurs at higher Reynolds number flow, is not observed in the present simulation; this difference may be ascribed to the Reynolds number effect. The oscillating drag component is most sensitive to the variation of the natural frequency ratios, and maximized within the dual-resonant regime.

A 2S wake pattern is accompanied to the VIV of single cylinder in the transverse-only resonant response state, however, the vortex distance in both in-line and transverse directions varies with the reduced velocity. As the cylinder experiences dual-resonant response, the wake may convert from 2S to P+S pattern, which would associate to the state where the in-line response reaches its maximum amplitude.

Vortex-induced vibrations of a flexible circular cylinder based on the CIBC method

Tao HE[a], Dai ZHOU[b]

ABSTRACT: The loosely-coupled partitioned algorithm is intrinsically exposed to the notorious time lag effect whose remedy promotes the combined interface boundary condition (CIBC) method. CIBC correction terms for velocity and traction are introduced at two sequential time steps with a coupling parameter ω. The structural traction ratio that appears explicitly in the traction correction is estimated based on the solution of the structural subsystem. This handling asks for the structural traction before it is corrected by the CIBC method. In this paper, a new formulation for the CIBC method is developed to repair the aforementioned inconvenience. After simple manipulation, the structural traction ratio is removed in constructing the traction correction. Therefore the structural traction is no more needed in CIBC correction terms. A flexible cylinder ar Re = 200 is tested to validate the proposed methodology and some famous features of flow phenomena have been detected successfully.

KEYWORDS: Arbitrary Lagrangian-Eulerian; Finite element method; CBS; Combined interface boundary condition.

1 INTRODUCTION

The vortex-induced vibrations (VIV) of bluff body under wind flow or other fluid flows are of great practical interest and crucial importance in many areas of civil engineering. In the cable-stayed building structures, for instance, the cable is always subjected to the vibration caused by coming wind. The design of the structures experienced VIVs is depended heavily on accurate prediction of structural aerodynamic responses and fluid flow dynamics, where the generation mechanism must also be recognized scientifically.

2 GOVERNING EQUATIONS

2.1 *Incompressible fluid flows*

The incompressible Navier-Stokes equations in the arbitrary Lagrangian-Eulerian (ALE) description read as:

$$\frac{\partial \mathbf{u}}{\partial t} + \mathbf{c} \cdot \nabla \mathbf{u} + \nabla p - \frac{1}{Re} \nabla^2 \mathbf{u} - \mathbf{f} = \mathbf{0} \tag{1}$$

$$\nabla \cdot \mathbf{u} = 0 \tag{2}$$

where **u** represents the fluid velocity, **c** = **u** – **w** the convective velocity, **w** the mesh velocity, ∇ the gradient operator, **f** the body force, p the pressure, Re = $\rho U_\infty D/\mu$ the Reynolds number, U_∞ the free stream velocity, μ the dynamic viscosity. The problem is complete with the proper boundary conditions together with the initial condition.

2.2 *Characteristic-based split (CBS) scheme*

The CBS scheme, which was originally introduced by the trilogy of Zienkiewicz and his co-workers [1-3] since 1995, is employed to solve Eqs. (1) and (2). The procedure of the semi-implicit CBS scheme can be actualized by the following steps:

Step 1: Calculate the intermediate velocity field

$$\tilde{\mathbf{u}} - \mathbf{u}^n = \Delta t\left(-\mathbf{c}\cdot\nabla\mathbf{u} + \frac{1}{Re}\nabla^2\mathbf{u} \right)^n + \frac{(\Delta t)^2}{2}\left(\mathbf{c}\cdot\nabla\left(\mathbf{c}\cdot\nabla\mathbf{u}\right)\right) \tag{3}$$

Step 2: Update the pressure field

$$\nabla^2 p^{n+1} = \frac{1}{\Delta t}\nabla\cdot\tilde{\mathbf{u}} \tag{4}$$

Step 3: Correct the velocity field

$$\mathbf{u}^{n+1} - \tilde{\mathbf{u}} = -\Delta t\nabla p^{n+1} + \frac{(\Delta t)^2}{2}\left(\mathbf{c}\cdot\nabla\left(\nabla p\right)\right)^n \tag{5}$$

In the above algorithm, the body force **f** and third-order term are neglected. The stabilization parameter $(\Delta t)^2/2$ is independent on a local element size, thus leads to some computational savings. The finite element method (FEM) is used for the spatial discretization. A T3 element is considered as it is very convenient to use a low- and equal-order interpolation for velocity and pressure in the CBS scheme. For a compromise between accuracy and efficiency, the lumped mass matrix is used. Imposing boundary conditions follows the suggestion of Ref. [4].

2.3 *Equation of the structual motion*

A rigid structure immersed in a fluid undergoes unsteady forces and its motion is governed by the following equation:

$$\ddot{\mathbf{x}} + 4\pi f_{\mathrm{r}}\zeta\dot{\mathbf{x}} + \left(2\pi f_{\mathrm{r}}\right)^2\mathbf{x} = \frac{\mathbf{C}_{\mathrm{f}}}{2m^*} \tag{6}$$

where m, c and k represent the mass, damping and stiffness of the structure, **x** the structural displacement, $\mathbf{C}_{\mathrm{f}} = [C_{\mathrm{D}}, C_{\mathrm{L}}]^{\mathrm{T}}$ the force coefficient vector, $F_{\mathrm{r}} = f_{\mathrm{n}}D/U_\infty$ the reduced natural frequency, $\zeta = 0.5c/(mk)^{0.5}$ the damping ratio, $m^* = \mathrm{m}/(\rho \mathrm{D}^2)$ the mass ratio, $f_{\mathrm{n}} = (km)^{0.5}/(2\pi\mathrm{m})$ the natural frequency of the oscillator. Eq. (6) is solved by way of Newmark-β method with $\alpha = 0.25$ and $\beta = 0.5$.

3 MESH MOTION

Moving submesh approach (MSA) [5] is employed for re-arranging the deformable fluid mesh in this paper. The main steps of MSA are summarized as follows:

Step 1: Extract the information of the fluid and MSA meshes;
Step 2: Find out which zone a point belongs to;
Step 3: Calculate the interpolation formulae of each point;
Step 4: Gain the motion of the zones adhering to the moving boundaries;
Step 5: Update the fluid mesh using the associated interpolation formulae.

A submesh without interior nodes permits a direct application of MSA. When interior nodes arise, MSA works in conjunction with the ortho-semi-torsional spring analogy method [6] that is solved by a successive over relaxation technique [7].

In this research, a mass source term (MST) [8] is adopted for obeying geometric conservation law. As a result, Eq. (4) can be recast as:

$$\nabla^2 p^{n+1} = \frac{1}{\Delta t}\nabla\cdot\tilde{\mathbf{u}} + S_{\mathrm{MST}} \tag{7}$$

where MST $S_{\mathrm{MST}} = \dfrac{1}{2A_e}\begin{vmatrix} w_1^2 - w_1^1 & w_2^2 - w_2^1 \\ w_1^3 - w_1^1 & w_2^3 - w_2^1 \end{vmatrix}$, A_e is the area of element e, superscript i (i = 1, 2 and 3) means point i of element e and subscript j component j (j = 1 and 2) of coordinates.

4 COMBINE INTERFACE BOUNDARY CONDITION (CIBC) METHOD

As derivated in [9], the new CIBC formulation is expressed as:

$$\delta\mathbf{u}_*^n = \frac{\Delta t}{\rho_{\mathrm{f}}}\left(\frac{\partial\boldsymbol{\sigma}_{\mathrm{f}}^n}{\partial n_{\mathrm{f}}} + \omega\frac{\partial\left(\delta\boldsymbol{\sigma}_*^n\right)}{\partial t}\right) \tag{8}$$

$$\delta\boldsymbol{\sigma}_*^{n+1} = \frac{\Delta t}{2\omega}\left(\rho_{\mathrm{f}}\frac{\partial\mathbf{u}_{\mathrm{s}}^{n+1}}{\partial t} - \frac{\partial\boldsymbol{\sigma}_{\mathrm{f}}^{n+1}}{\partial n_{\mathrm{f}}}\right) \tag{9}$$

with a positive constant ω which should be small enough to make sure the interfacial energy is always stable [10]. Then the velocity and traction along Γ_{fs} are severally corrected by

$$\mathbf{u}_{\mathrm{f}}^{n+1} = \mathbf{u}_{\mathrm{s}}^{n+1} + \delta\mathbf{u}_*^n \tag{10}$$

$$\boldsymbol{\sigma}_{\mathrm{s}}^{n+1} = \boldsymbol{\sigma}_{\mathrm{f}}^{n+1} + \delta\boldsymbol{\sigma}_*^{n+1} \tag{11}$$

Because of our measure for updating the fluid mesh, the interfacial displacement continuity due to Eq. (10) must be corrected as follow:

$$\mathrm{d}\mathbf{x}_{\mathrm{f}}^{n+1} = \mathrm{d}\mathbf{x}_{\mathrm{s}}^{n+1} + \Delta\mathbf{x}_{\mathrm{c}} = \mathrm{d}\mathbf{x}_{\mathrm{s}}^{n+1} + \left(\delta\mathbf{u}_{\mathrm{f}}^n - \delta\mathbf{u}_{\mathrm{f}}^{n-1}\right)\Delta t \tag{12}$$

The loosely-couple partitioned procedure equipped with the CIBC method is summarized as follow:

Step 1: Fluid and structural variables at time n are given;

Step 2: Loop over an FSI cycle in each time interval $t = t_{n+1} - t_n$:

(a) The structural equation (6) is calculated for the new structural variables;

(b) The velocity increment along the interface is obtained by solving Eq. (8) and the fluid velocity is corrected according to Eq. (10);

(c) The coordinates of the fluid-structure interface are updated due to Eq. (12);

(d) MSA is employed to renew the dynamic mesh based on (c);

(e) Eqs. (3), (7) and (5) are solved for the fluid velocity and pressure at time $n + 1$;

(f) The traction increment along the interface is obtained by solving Eq. (9) and the structural traction is corrected according to Eq. (11);

Step 3: Return Step 2 until the computational time is over.

The schematic diagram of the loosely-coupled partitioned procedure is sketched in Figure 1 where S stands for a structural variable while F a fluid variable.

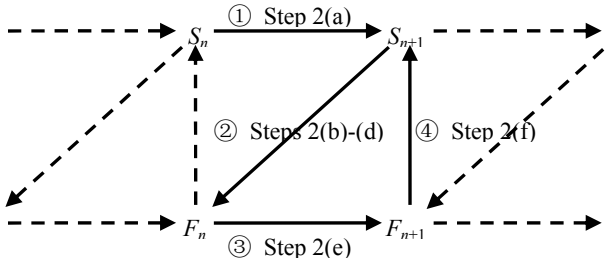

Figure 1. Loosely-coupled partitioned algorithm

5 NUMERICAL EXAMPLE

A free oscillating circular cylinder is simulated numerically to reproduce the numerical analysis of Zhou et al. [11] in this section. The definition of this problem is plotted in Figure 2 while its MSA mesh is viewed in Figure 3.

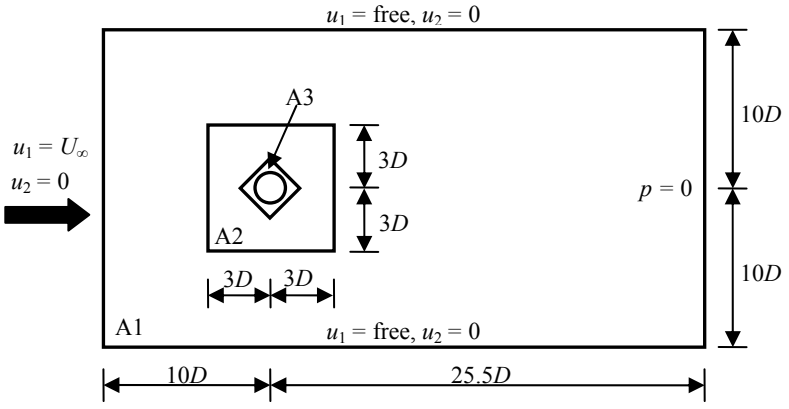

Figure 2. Sketch of the geometry and boundary conditions for a transversely oscillating circular cylinder

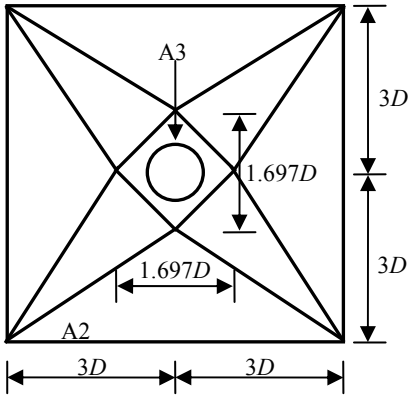

Figure 3. MSA mesh for a circular cylinder

The mesh and time step are considered based on the researches of Prasanth and Mittal [12] and Zhou et al. [11]. The entire computational domain is meshed into 7040 points and 13870 T3 elements. The time step is set to 2.5×10^{-3}. The mass ratio is set to $m^* = 1$, the reduced damping parameter $Sg = 0.01$, the damping ratio $\zeta = Sg/(0.29553\ m^*\pi^2)$ and $Re = 200$. The frequency ratio f_n/f_0 varies from 0.65 to 5.20, where f_0 is the vortex-shedding frequency of a stationary circular cylinder. $\omega/\Delta t = 100$ is selected to implement our computations.

Three mass ratios are considered to research their influence on $2Y_{rms}$, $C_{d,mean}$, $C_{l,rms}$ and f_v/f_0 versus f_n/f_0, as plotted in Figures 4-7. From Figure 4, a smaller m^* brings about a lower value of $2Y_{rms}$ in short. For the case $m^* = 10$ and $Sg = 0.01$, the present data are larger than those of Zhou et al. [11], and comparative with the results of Zhou et al. [11] who consider $m^* = 1$ when $0.87 \le f_n/f_0 \le 1.16$. Unlike Zhou et al. [11], the present $C_{d,mean}$ is less affected by the mass ratio, seen from Figure 5. For $m^* = 1$, the present peak of $C_{d,mean}$ occurs at a higher frequency ratio and significant large values are obtained when $f_n/f_0 = 1.49$ and 1.73. As shown in Figure 6, $C_{l,rms}$ for the smallest m^* is much lower at $f_n/f_0 = 0.65$ but higher when f_n/f_0 is larger than 1.30. The variation trends for $m^* = 5$ and 10 are almost the same. In Figure 7, the f_v/f_0 curve is very smooth for the heavy cylinder with $Sg = 0.01$ studied by Zhou et al. [11], but visible fluctuations are spied under the same conditions in this study. The corresponding peak value of f_n/f_0 appears at $f_n/f_0 = 1.30$. However, the variation trends of f_v/f_0 for all cases are the same.

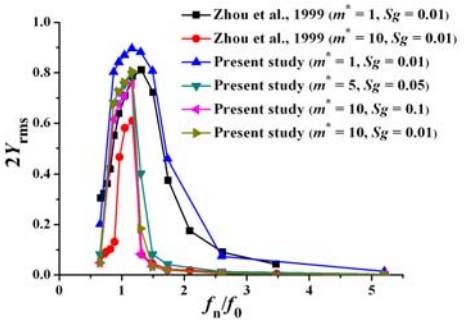

Figure 4. Variation of $2Y_{rms}$ for different mass ratios

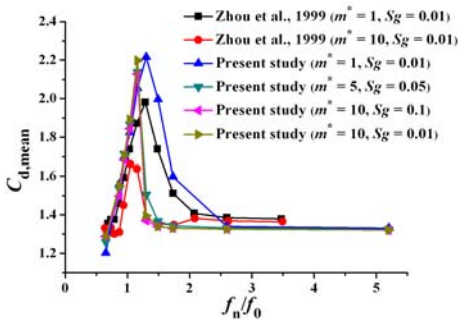

Figure 5. Variation of $C_{d,mean}$ for different mass ratios

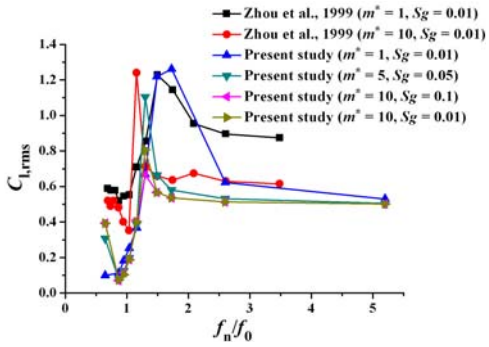

Figure 6. Variation of $C_{l,rms}$ for different mass ratios

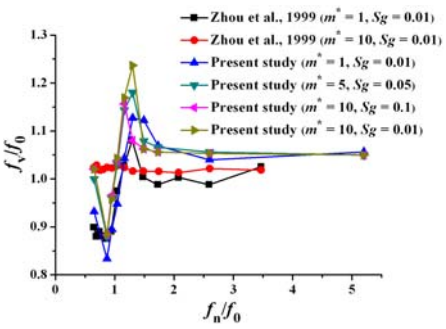

Figure 7. Variation of f_v / f_0 for different mass ratios

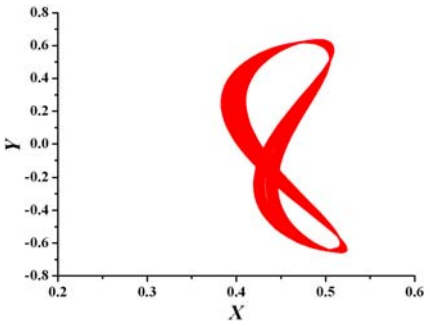
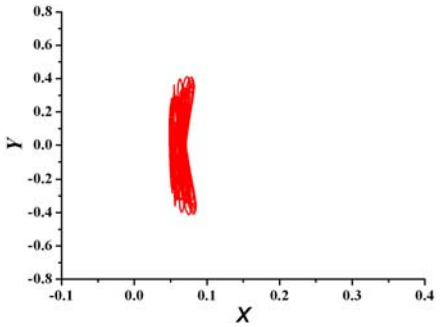
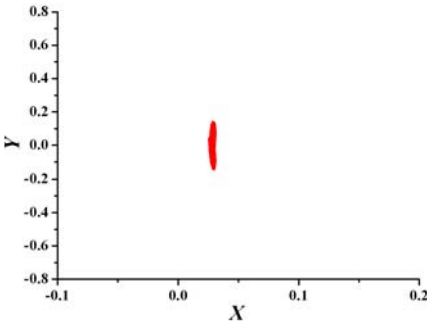
Figure 8 illustrates the cylinder trajectories at f_n/f_0 = 1.30 for different mass ratios, displaying the classical *Lissajous* figure of 8. Figure 8(a) shows the clearest figure of 8 shape, similar to that of Zhou et al. [11]. The mass ratio alters the cylinder displacements notably. A lighter circular cylinder gets the larger displacement, thus the amplitudes in X and Y remarkably decrease for m^* = 5 and 10. In addition, the equilibrium position of the cylinder due to the mean drag changes with m^*.



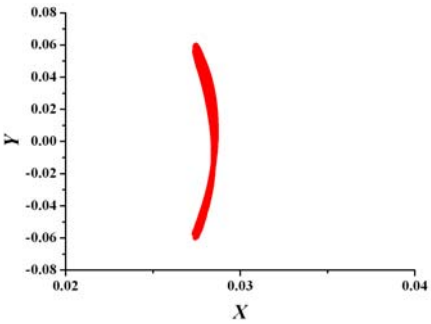
(a) m^* = 1, Sg = 0.01



(b) m^* = 5, Sg = 0.05



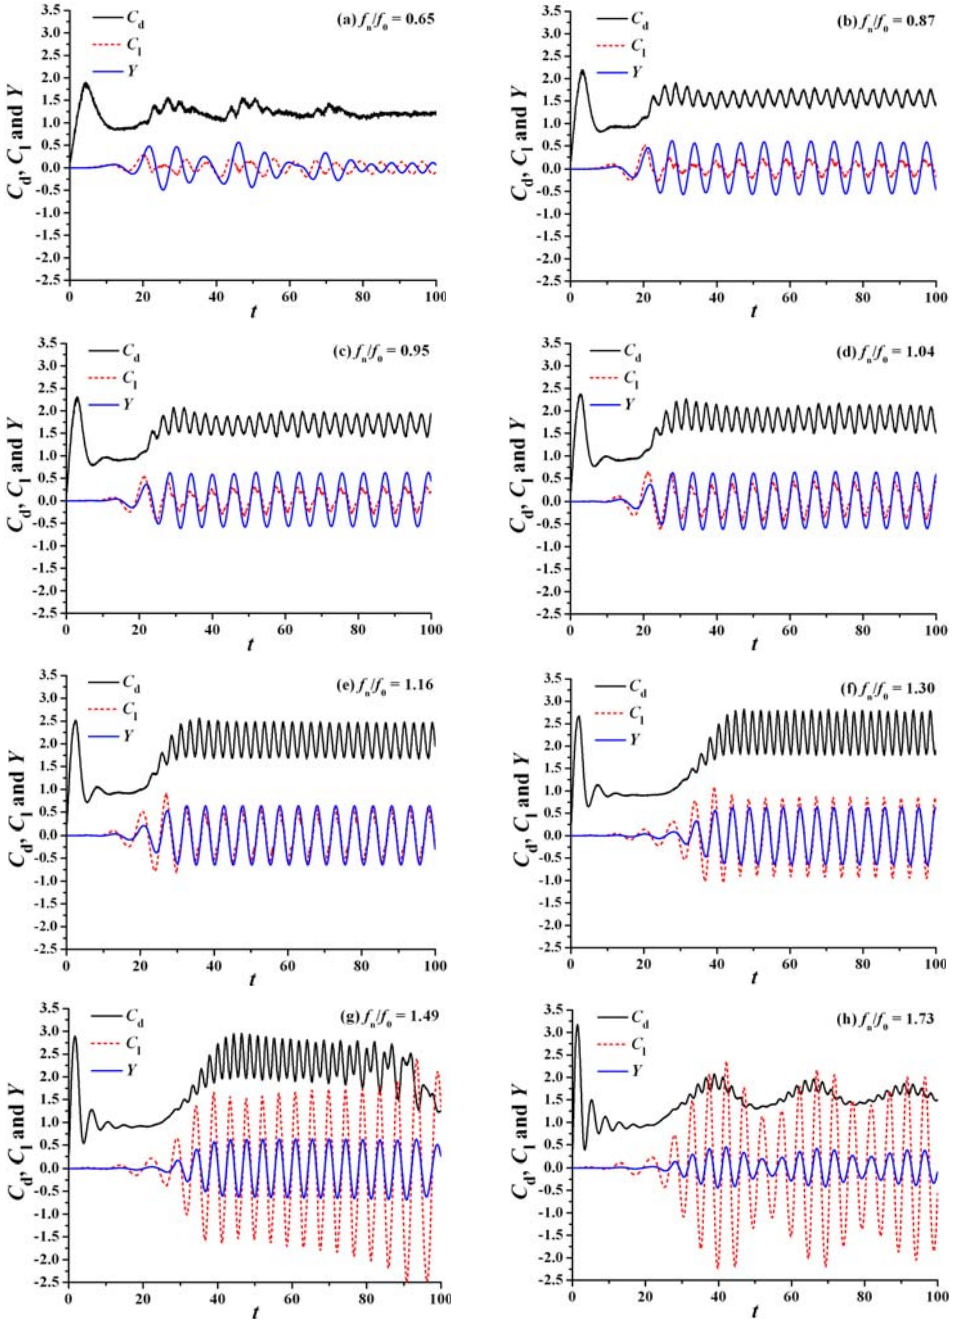
(c) m^* = 10, Sg = 0.01



(d) m^* = 10, Sg = 0.1

Figure 8. Vibration trajectory of the circular cylinder at f_n / f_0 = 1.30

Our attention is drawn to the given case $m^* = 1$ and $Sg = 0.01$. Time histories of the drag and lift coefficients, as well as the transverse displacement, are exhibited in Figure 9. The basic characteristics of the present time histories are similar to those of Zhou et al. [11]. When $f_n/f_0 =$ 0.65, 2.60 and 5.20, the transverse vibrations are feeble. The fact that beating is visualized at f_n/f_0 = 1.73 coincides with that of Zhou et al. [11] at the same frequency ratio. The beating phenomenon can be perceived by time histories of the transverse vibrations and drag coefficient. The variation of C_d bears an analogy to that of Y. The amplitudes of C_l become evidently larger when $f_n/f_0 =$ 1.49 and 1.73. The oscillations of C_l and Y become out-of-phase while $f_n/f_0 =$ 0.65 and 0.87. As f_n/f_0 grows up, the transition from in-phase to out-of-phase appears at $f_n/f_0 =$ 0.95. But this transition is less evident than that of Zhou et al. [11].



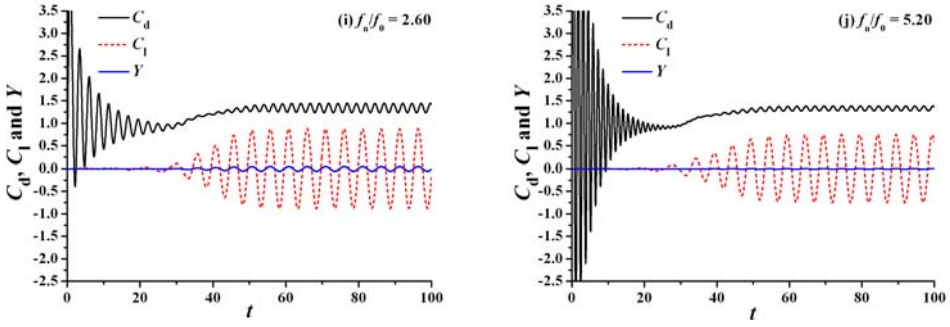


Figure 9. Force coefficients and the transverse displacement of the cylinder at various f_n / f_0

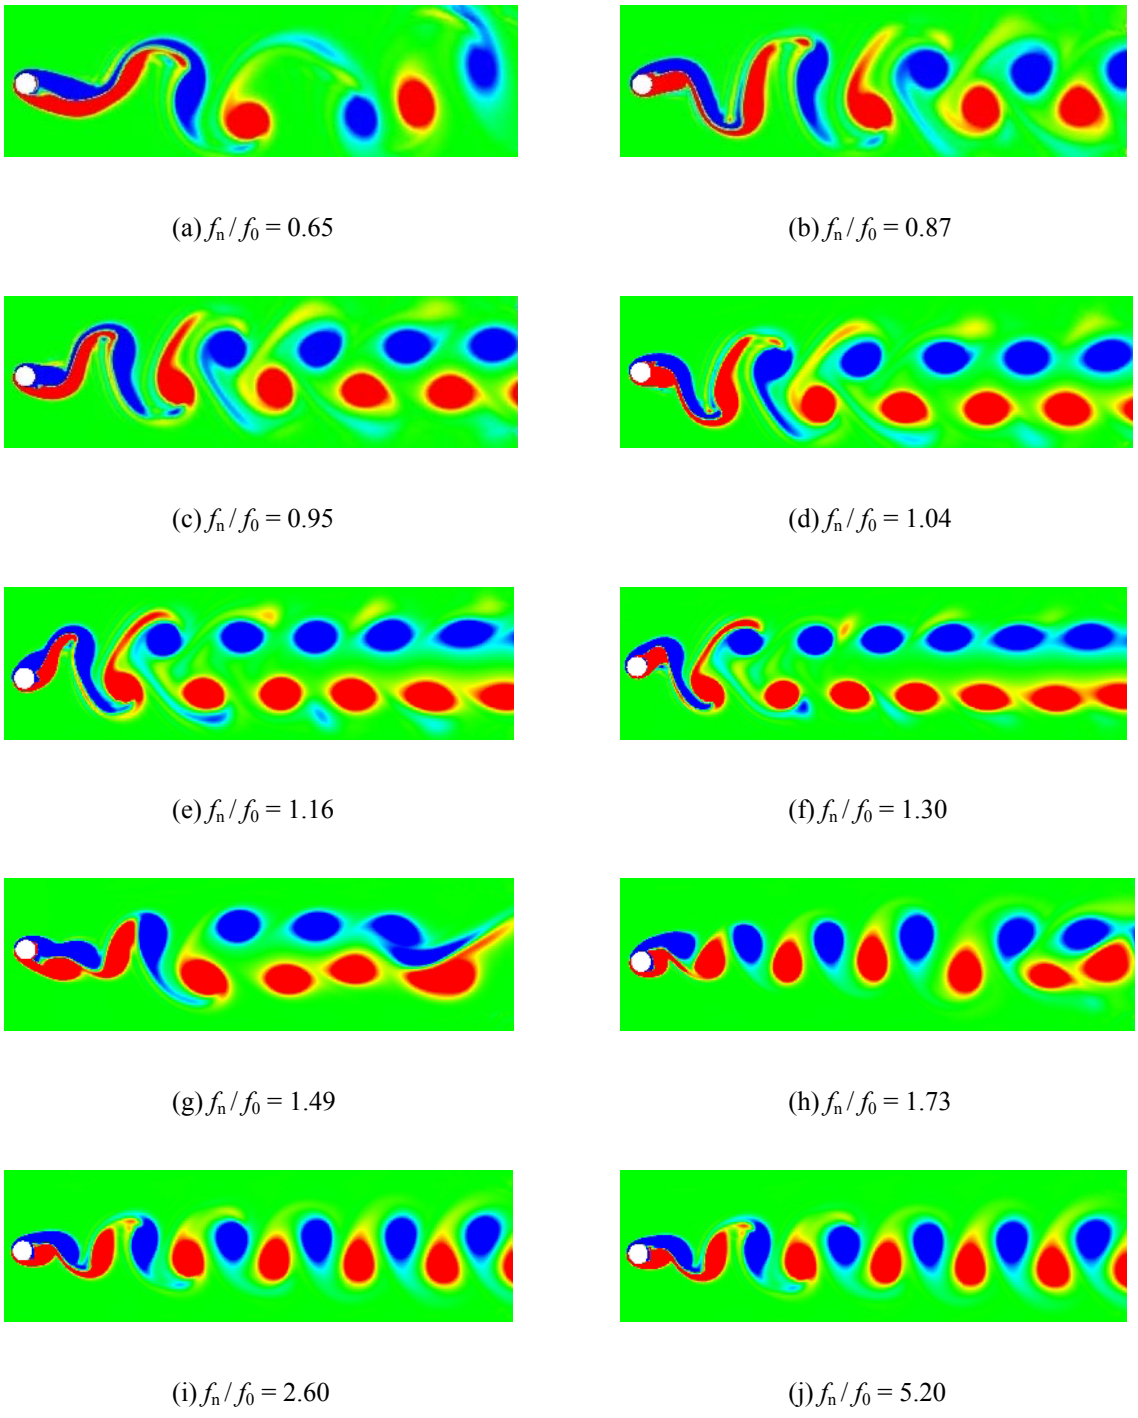
Figure 10 displays the different vortex patterns shedding from the wake of the freely oscillating cylinder. The present vortex-shedding patterns and their transition declare an analogue of those of Zhou et al. [11]. But some scatter is still aware of. Although the classical 2S vortex-shedding mode is watched for all frequency ratios, the region of frequency ratios is split into two parts based on the longitudinal spacings between shedding vortices. The longitudinal spacing for $f_n/f_0 \leq 1.49$ is larger than the one for $1.73 \leq f_n/f_0 \leq 5.20$. The circular cylinder experiences the low-amplitude vibrations at $f_n/f_0 = 2.60$ and 5.20 which imply the vortex-shedding frequencies are far away from the natural frequency, and the regular 2S mode is viewed. When $f_n/f_0 = 1.49$ and 1.73, the vortices apart from the cylinder wake seem to coalesce. This sign indicates that the C(2S) mode [13], a variation of the 2S mode, may occur if the present domain is expansive enough. As the frequency ratio stays at 1.49, the 2S vortices travels a distance, then translates into two batches of the shedding vortices, as the same as the figure shown by Zhou et al. [11]. This change of the vortex shedding consists with the time histories of force coefficients, implying that two different vortex-shedding frequencies exist. The vortices for $f_n/f_0 = 1.16$ and 1.30 are parallel, having large longitudinal spacings. Especially, Zhou et al. [11] analyze that at $f_n/f_0 = 1.16$ the 2S vortices can pass a distance of approximate $20D$, then transform the P + S mode [13]. This conversion can't be realized because of a much shorter downstream scope in the present study. The other explanation is that the P + S mode won't be observed unless *Re* is greater than 300, according to Singh and Mittal [14]. At $f_n/f_0 = 0.95$, 1.04, 1.16 and 1.30, the longitudinal spacings between shedding vortices are larger than those of Zhou et al. [11] apparently. The jack-up of the longitudinal spacings between shedding vortices may explain why a more violently transverse vibration has been received in this study. The transverse peak-to-peak amplitude $2Y_{max}$ is about 1.0 in the analysis of Zhou et al. [11] and 1.504 in this study. The present $2Y_{rms}$ is also roughly larger 10.8% than that of Zhou et al. [11]. Besides, the present lock-in range is a bit wider than that of Zhou et al. [11]. The similarity of the vortex shedding between the present study and work of Zhou et al. [11] emerges once more as the frequency ratio f_n/f_0 goes down to 0.87 and 0.65.



(a) $f_n / f_0 = 0.65$ (b) $f_n / f_0 = 0.87$

(c) $f_n / f_0 = 0.95$ (d) $f_n / f_0 = 1.04$

(e) $f_n / f_0 = 1.16$ (f) $f_n / f_0 = 1.30$

(g) $f_n / f_0 = 1.49$ (h) $f_n / f_0 = 1.73$

(i) $f_n / f_0 = 2.60$ (j) $f_n / f_0 = 5.20$

6 CONCLUSION

In this study a new formulation for the CIBC method has been developed. The main contribution of the proposed methodology lies in overcoming the inconvenience due to the employment of the structural traction uncorrected in the original CIBC method. The developed strategy has been tested on the vortex-induced vibrations of a flexible cylinder at $Re = 200$. The obtained results are in

good agreement with the existing data. Some well-known flow phenomena have also been exposed successfully.

Full-scale measurement of wind pressure on the surface of a circular cylinder

Delong Zuo, Jieying Hua

Department of Civil and Environmental Engineering, Texas The University, Mail Box 1023, Lubbock, TX, USA

ABSTRACT: An experimental campaign was conducted to measure wind pressure acting on the surface of a full-scale circular cylinder. The pressure measurements were used with measurements of cylinder acceleration to investigate the interaction between the cylinder and turbulent wind. Different characteristics of this interaction were revealed for different wind regimes.

KEYWORDS: Circular cylinder, wind-induced vibration, full-scale pressure measurement.

1 INTRODUCTION

Slender structural members with circular cross-sections are often susceptible to wind excitation. For example, cables of cable-stayed bridges are known to vibrate at large amplitudes under the excitation of wind with simultaneous occurrence of rainfall and, in certain situations, only wind (e.g., [1]). Also, traffic signal support structures having mast arms with circular cross-sections have exhibit problematic vibration (e.g., [2]). A number of full-scale studies (e.g., [1-4]) have been conducted to understand the characteristics of the vibrations and their correlation with wind and, in the case of cable vibration, with wind and rain. These studies revealed that large amplitude vibrations can be induced both by vortex-shedding and by wind oblique to the cylinder with reduced velocity that are much higher than those associated with classical vortex-induced circular cylinder vibration. As complements to full-scale studies, circular cylinders have been tested in wind tunnels (e.g., [5-7]). In particular, a number of experiments were conducted to expressly explore the potential inherent susceptibility of yawed or inclined dry circular cylinders to wind excitation. The findings from these studies have varied, with some suggesting the importance of an axial flow component in the wake of the cylinder in generating three-dimensional flow around the cylinder and initiating large-amplitude vibration at high reduced velocity ([7, 8]), and the others focusing on the potential of instability in the critical Reynolds number range (e.g., [6, 9]). In addition to the experimental studies, numerical investigations based on computational fluid dynamics (e.g., [10]) suggested that the three-dimensional nature of the flow can play a key role in the excitation mechanism. This paper presents the outcome of a full-scale study conducted to measure wind pressure on the surface of a circular cylinder. It facilitates a characterization of the mean and fluctuating wind loading on an oscillating slender circular cylinder when it is subjected to wind of various mean and turbulent characteristics.

2 EXPERIMENTAL CONFIGURATION

The specimen was a 7.62 m long circular pipe of 22.4 cm in diameter and 0.8 cm in wall thickness. It consisted of a 6.40 m long steel pipe and a 1.22 m long PVC pipe. As shown in Figure 1,

the steel portion was rigidly mounted horizontally near the top of a tapered circular aluminum pole, which was 30.5 and 36.8 cm in diameter at the top and the base, respectively, and had a wall thickness of 1 cm. A ring of 32 pressure taps evenly spaced at 11.25° intervals, as depicted in Figure 2, was installed at a cross-section that is 2.1 m from the free end of the cylinder; four additional taps were installed on the sides of this ring at locations indicated in Figure 2. The taps were connected to pressure transducers with a range of ±1.245 kPa through tubings of 0.91 m in length and 0.6 cm in diameter. With this configuration, the pressure taps were at least 8 diameters and 23 diameters of the cylinder, respectively, from the free and fixed ends. To minimize undesirable end effects on the flow near the pressure taps, a spherical cap was installed at the free end. Besides pressure measurement, a tri-axial accelerometer with a range of ±4 g was installed adjacent to the pressure tap ring to monitor vibration; an ultrasonic anemometer was installed at a height of 1.5 m above the centerline of the cylinder to monitor the wind, and temperature, relative humidity, and barometric pressure sensors were used to provide measurements for calculation of air density. The data acquisition system recorded 10-minute records at 32 Hz. Two additional 10-second records were sampled before and after each 10-minute record for calibration of the pressure transducers. Due to the inability of the pressure measurement system to function properly in rain, the taps were covered in advance when rainfall was anticipated.

Figure 1 Circular cylinder subjected to study

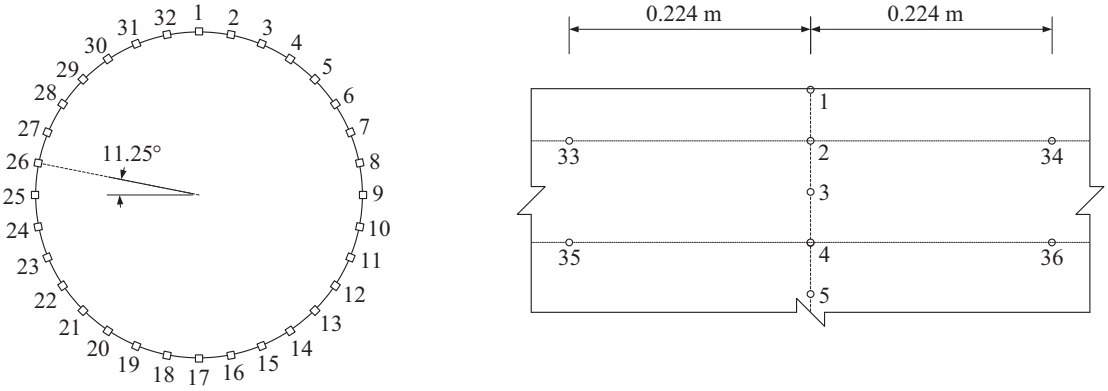

Figure 2 Configuration of pressure taps (not to scale)

3 CHARACTERISTICS OF CYLINDER RESPONSE

To characterize the vibration of the cylinder, the acceleration measurements are numerically integrated to estimate the displacement at the location of the accelerometer. After each integration process, a 5th order high-pass Butterworth filter with a cut-off frequency of 0.2 Hz is applied to

eliminate the spurious effect of low frequency noise. The displacement are then band-pass filtered using a 5th order Butterworth filter to estimate the response in the first two modes of the structure in the in-plane and out-of-plane directions, whose frequencies are identified based on the estimated power spectral density functions of acceleration records. The pass bands of the filter are 0.5 Hz frequency bands centered at the natural frequencies. Finally, the Hilbert transform is applied to the modal displacement to assess the evolution of the amplitude and frequency. The data suggested that during the measurement, the vibration of the cylinder is predominantly in the first in-plane and out-of-plane modes at 2.44 Hz and 2.17 Hz, respectively.

Figure 3 shows the 10-minute mean displacement amplitudes in the first in-plane (A_z) and out-of-plane (A_x) modes against mean speed of the wind component normal to the cylinder axis (V_n). It is seen that the cylinder exhibited significant vibration in the cross-wind direction over a restricted range of wind speeds. This is a clear characteristic of classical vortex-induced vibration. The figure also suggests that at higher wind speeds, the vibration amplitudes increased in both directions with wind speed. This is typical for vibration due to buffeting. Figure 4 shows the mean in-plane vibration amplitude against the reduced velocity (V_r) and the longitudinal turbulence intensity (I_u). The reduced velocity is computed as $V_r=V_n/(fD)$, where f is the mean vibration frequency, and D is the cylinder diameter. It can be seen that vortex-induced vibration occurred over a reduced velocity range centered at a value greater than 5, which is equivalent to the nominal Strouhal number of 0.2 for circular cylinders normal to smooth flow. This can be primarily attributed to two facts. Firstly, according to measurements by an adjacent meteorological tower, the wind speed measured by the anemometer can be 1% to 10% higher than that at the height of the cylinder, depending on the stability of the atmospheric boundary layer. Secondly, according to previous wind tunnel tests [11], organized vortex shedding over circular cylinders can occur over a broad range of Strouhal number, depending on the turbulence intensity of the free stream wind. According to Figure 4, significant vortex-induced vibration did occur over a broad range of longitudinal turbulence intensity.

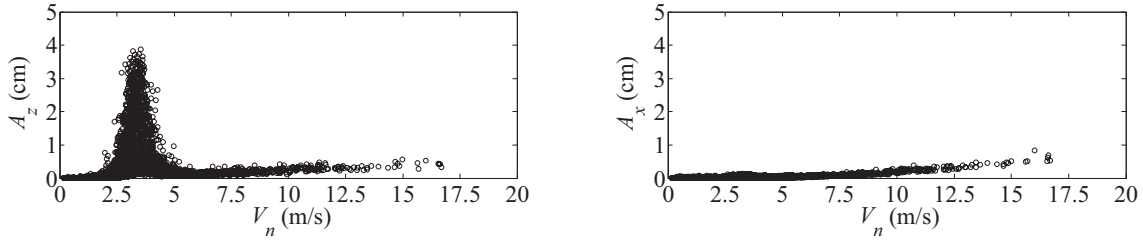

Figure 3 Mean displacement amplitudes in the first in-plane and out-of-plane modes vs. mean wind speed

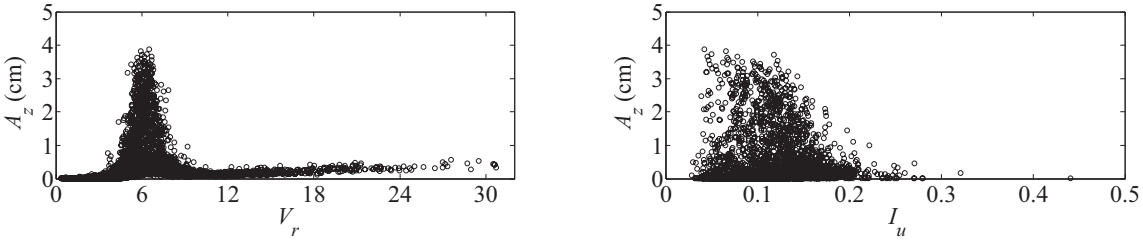

Figure 4 Mean in-plane displacement amplitude vs. reduced velocity and along-wind turbulence intensity

4 INTERPRETATION OF PRESSURE MEASUREMETNS

Incorporation of the measurements by the pressure transducers and the accelerometer have revealed some distinct characteristics of wind loading on the circular cylinder in different wind regimes and different types of wind-structure interaction.

Figure 5 shows the estimated mean drag (C_D) and lift (C_L) coefficients of the cylinder against mean wind speed (V) and the corresponding Reynolds number (Re) for a mean wind direction range of 85° to 95° relative to the cylinder axis. Only records with wind direction variation not exceeding 60° are used here. The Reynolds number is computed based on the mean wind speed, an assumed kinematic viscosity value of 1.5×10^{-5} m^2/s and the cylinder diameter as the reference dimension. It can be seen that when wind is almost normal to the cylinder, the transition from the subcritical to the critical Reynolds number range starts at mean wind speeds between 5 m/s and 7.5 m/s, corresponding to a Reynolds number range of 0.75×10^5 to 1.12×10^5, which is much lower than the Reynolds number (about 2×10^5) at which the transition occurs in smooth flow. Such shifting of critical Reynolds number range is due to the presence of turbulence in the free stream flow, which has been well documented by previous wind tunnel studies (e.g., [11, 12]), although the integral length scale of the wind in these studies were often much smaller than what proper scaling requires for full-scale cylinders such as the one subjected to study herein. Figure 5 also suggests that when the flow is in the subcritical Reynolds number range, the mean lift coefficients are close to zero and that in the critical Reynolds number range, the mean lift coefficients as a trend deviate more from zero. This is also consistent with previous reports (e.g., [9]).

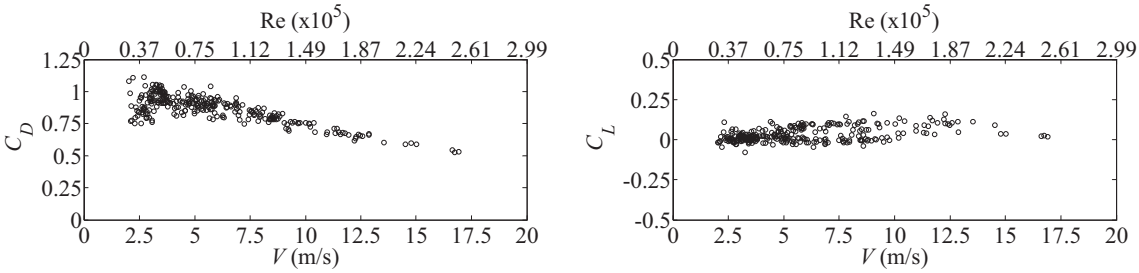

Figure 5 Mean drag and lift coefficients associated winds approximately normal to cylinder axis

It is noteworthy that the mean force coefficients exhibit considerable scatter for low wind speeds. This is partly due to the fact that at these wind speeds, the flow in the lower atmospheric boundary layer is significantly affected by atmospheric stability. The stability state affects not only the ratio of the mean measured wind speed to that at the height of the cylinder, therefore the reference mean dynamic pressure of the wind used for computation of the pressure coefficients, but also the level of shear in the free stream wind, hence the flow-cylinder interaction.

In the following, three representative records with 10-minute mean wind speed and direction (β) as well as turbulence intensity (I_u) listed in Table 1 will be used to illustrate the interaction between the wind and the cylinder when the wind is close to normal to the cylinder.

Table 1 Characteristics of wind of example records with wind approximately normal to cylinder axis

Record Number	V (m/s)	β (°)	I_u
1	3.70	93.40	0.055
2	5.00	89.42	0.140
3	12.22	93.06	0.148

Figure 6 shows the drag and lift coefficients of the cylinder estimated based on the wind and pressure measurements in record 1 and the corresponding spectra. It is evident that the lift coefficient is of narrow band and dominated by a frequency component at 2.43 Hz, indicating organized vortex shedding off the cylinder at this frequency. It also can be seen that the drag coefficient has a significant frequency component at 4.86 Hz, which is twice the dominant frequency of the lift coefficient. This is expected for wind loading of circular cylinders in the along-wind direction due to alternating shedding of vortices at the upper and lower surface of the cylinder. It is of interest to notice, however, that the drag coefficient is also dominated by a frequency of 2.43 Hz. This would not have been expected for stationary circular cylinders.

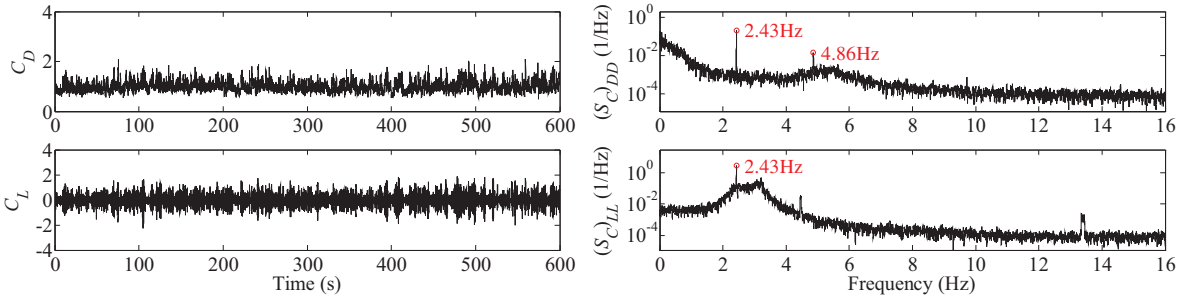

Figure 6 Drag and lift coefficients of the cylinder and the corresponding spectra: record 1

Figure 7 shows the acceleration of the cylinder due to wind loading shown in Figure 6 and the corresponding power spectra. The primarily in-plane vibration (a_z and a_y) is identified to be due to vortex shedding locked-in with the vibration of the structure. It is noteworthy that, in addition to the dominant frequency component at 2.43 Hz, the in-plane vibration also has a component at 4.86 Hz, which is twice the vortex-shedding frequency, despite the fact that this frequency is neither a natural frequency of the structure nor the vortex-shedding frequency. It is believed, therefore, that the in-plane vibration at 4.86Hz is due to a super-harmonic of the excitation at 2.43 Hz. It is of interest to notice that, since the drag coefficient has a significant frequency component at 2.43 Hz, the insignificant along-wind, out-of-plane, vibration also consists of a component at this frequency, which is not a natural frequency of the structure in this direction.

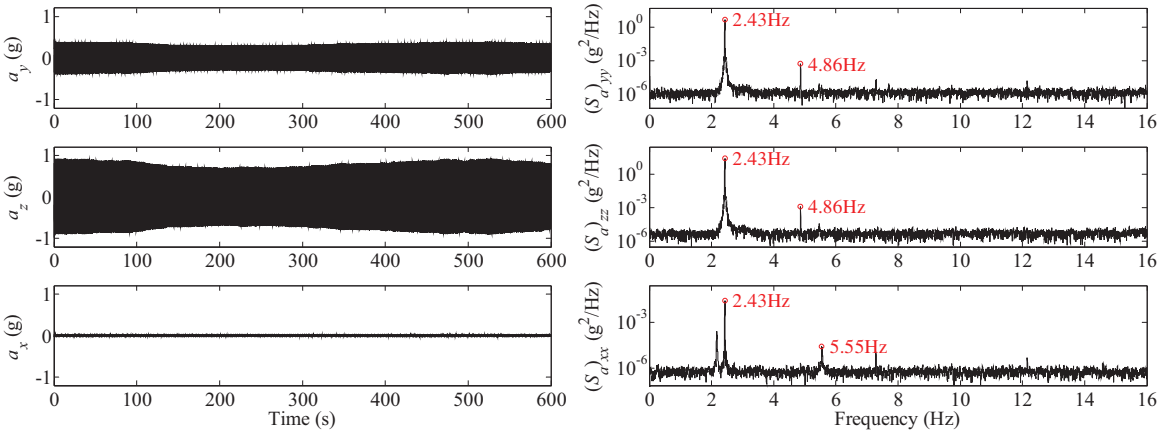

Figure 7 Acceleration time histories and the corresponding spectra: record 1

By comparing the lift coefficient time history shown in Figure 6 and the in-plane acceleration time histories shown in Figure 7, it is apparent that although the response of the structure is quite steady, the lift force acting on the cylinder at the pressure tap ring is not. This is further illustrated in Figure 8, in which can be seen that the lift force and the displacement at the location of the pressure tap ring are only intermittently synchronized due to the interaction of the cylinder and the turbulent wind.

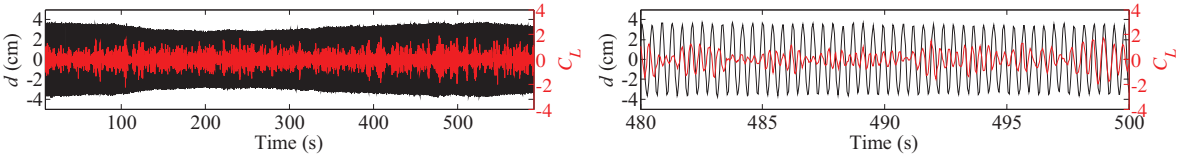

Figure 8 Cylinder displacement and lift coefficient at location of pressure tap ring: record 1

Figure 9 shows the cross-correlation coefficients of the pressures at 5 taps along two axial lines of the cylinder over a time lag of 5 seconds. The subscripts indicate the tap numbers. The measurement by tap number 36 is not used because this tap is determined to have malfunctioned. The coefficients are clearly those of narrow band processes with the same center frequency.

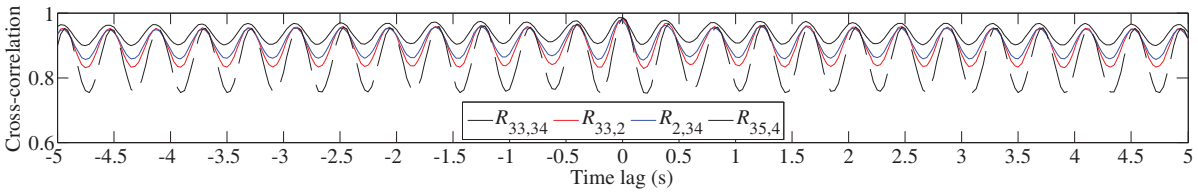

Figure 9 Cross-correlations of pressure measured along the axial direction of the cylinder: record 1

Figure 10 illustrates approximately one cycle of vibration at the pressure tap ring location and the corresponding pressure distribution on the surface of the cylinder, when the vibration and the lift force are nearly synchronized. It is apparent that the pressure distribution on the ring when the cylinder is at symmetric positions during upward and downward movements can be quite different, indicating different vortex shedding patters from the upper and lower surface primarily due to the existence of turbulence. Figure 11 illustrate the distribution of the mean pressure coefficients (C_p) over the 10-minute duration. It can be seen that for this particular record, the distribution of the mean pressure is quite symmetric about the horizontal plane through the centerline of the cylinder. It must be noted that, the pressure distributions illustrated in Figure 10 and Figure 11 might be biased by the reference pressure measured at the ground level and may be different from the static pressure at the height of the cylinder in a stable boundary layer, which is quite likely in this case as low turbulence intensity is a signature of stable boundary layers.

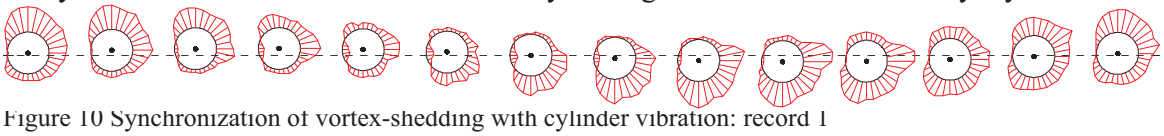

Figure 10 Synchronization of vortex-shedding with cylinder vibration: record 1

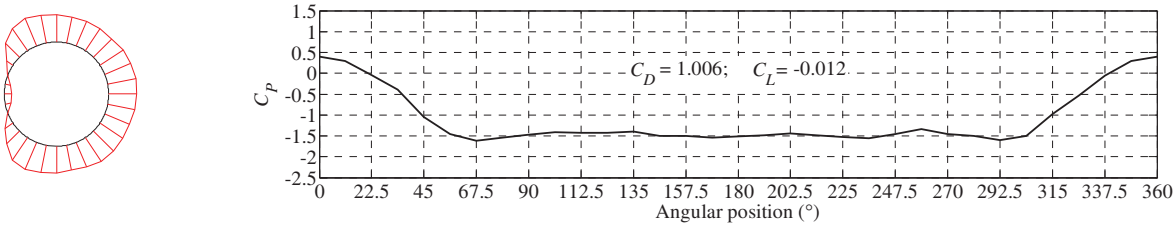

Figure 11 Mean pressure distribution at the pressure tap ring: record 1

According to Figure 5, the mean wind speed over the duration of record 2 is in the subcritical Reynolds number range. Figure 12 shows the drag and lift coefficients of the cylinder for this record and the corresponding spectra. It can be seen that neither the drag force nor the lift force acting at the location of the pressure tap ring have a dominant frequency component, but the lift force does have considerable contribution from components over a frequency band centered between 4 Hz and 5 Hz. This frequency band represents that of unorganized vortex-shedding off the surface of the cylinder. Figure 13 shows the acceleration response of the cylinder. It can be seen that the vibrations in both the in-plane and the out-of-plane directions are at small amplitudes, primarily in the first two modes in these directions.

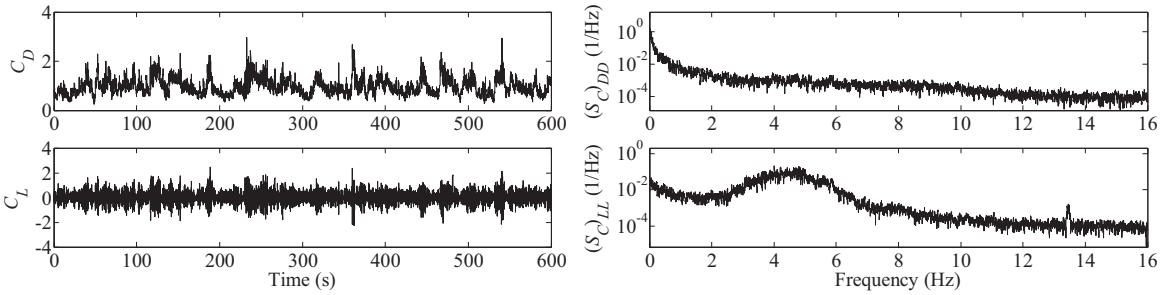

Figure 12 Drag and lift coefficients of the cylinder and the corresponding spectra: record 2

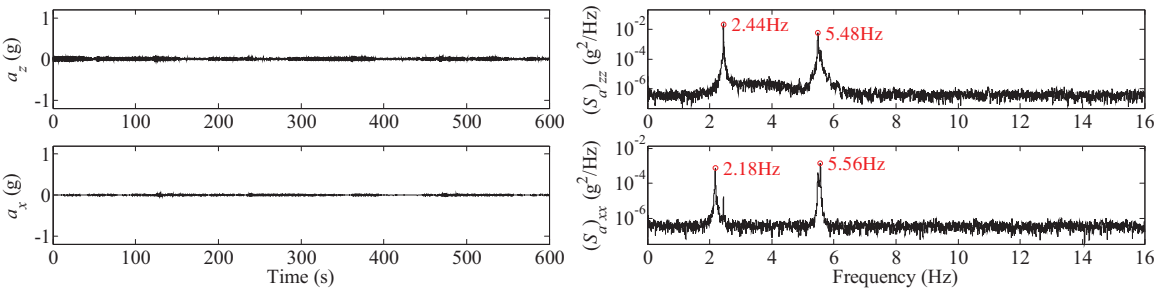

Figure 13 Acceleration time histories and the corresponding spectra: record 2

Figure 14 shows the cross correlation coefficients of the pressures at 5 taps along two axial lines along the cylinder over a time lag of 5 seconds. As expected, the pressures at the locations of the taps are the most correlated when the time lag is zero. The ripples at small time lags indicate the existence of the frequency band centered between 4 Hz and 5 Hz, which, as indicated by the spectra of the lift coefficient shown in Figure 12, is due to unorganized vortex shedding.

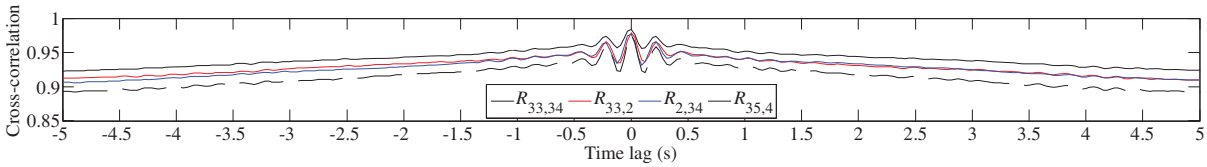

Figure 14 Cross-correlations of pressure measured along the axial direction of the cylinder: record 2

Figure 15 illustrate the distribution of the mean pressure coefficients for the duration of record 2. The angular position is measured clockwise relative to the would-be stagnation point if the cylinder were held stationary. An approximately symmetric pattern is again observed, indicating, on average, approximate symmetric separation of the flow from the upper and lower part of the cylinder during the duration of the record.

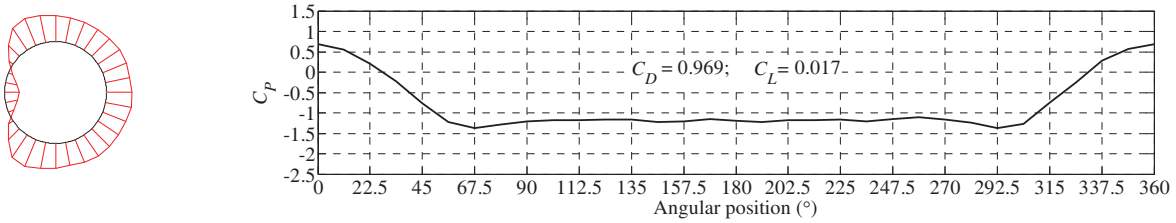

Figure 15 Mean pressure distribution at the pressure tap ring: record 2

According to Figure 5, the mean wind speed over the duration of record 3 is in the critical Reynolds number range. Figure 16 shows the drag and lift coefficients for this record and the corresponding spectra. The spectra of the coefficients show no sign of vortex-shedding, suggesting turbulent separation of the flow off the cylinder surface. Figure 17 shows the acceleration response of the cylinder. It can be seen that the vibrations in both the in-plane and out-of-plane directions are again dominated by the first two modes of the structure in these two directions.

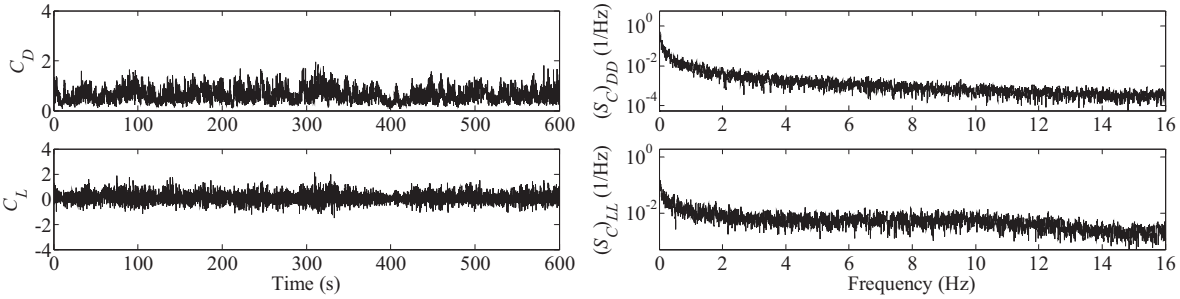

Figure 16 Drag and lift coefficients of the cylinder and the corresponding spectra: record 3

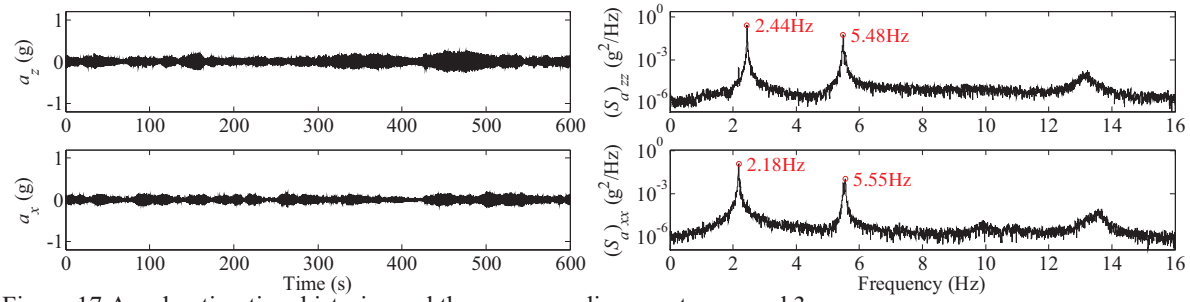

Figure 17 Acceleration time histories and the corresponding spectra: record 3

Figure 18 shows the cross-correlation correlations of the pressures at 5 taps along two axial lines of the cylinder over a time lag of 5 seconds. These are typical of the cross-correlations of correlated broadband processes.

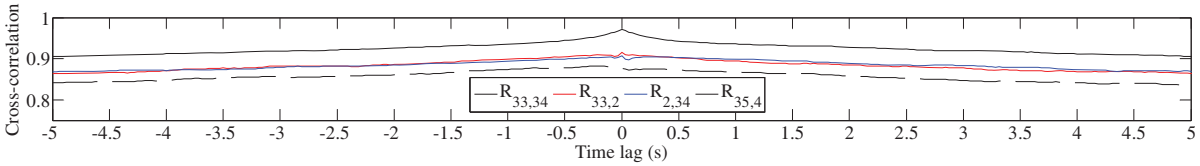

Figure 18 Cross-correlations of pressure measured along the axial direction of the cylinder: record 3

Figure 19 shows the distribution of the mean pressure coefficients for the duration of record 3. It is apparent that the mean pressures acting on the upper and lower parts of the cylinder are not symmetric. This indicates, on average, asymmetric separation of the flow from the oscillating cylinder in the critical Reynolds number range although the wind is approximately perpendicular to the cylinder axis.

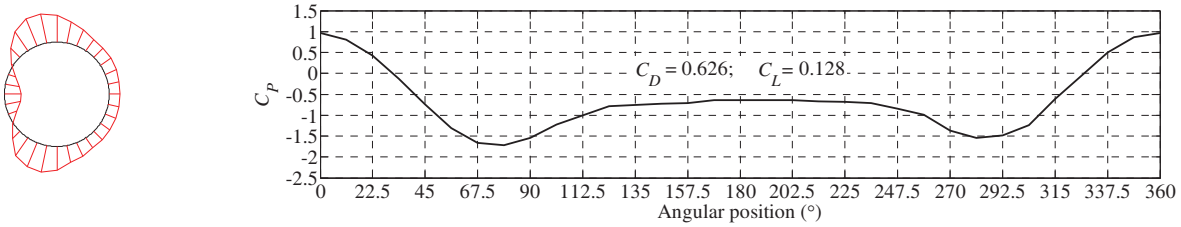

Figure 19 Mean pressure distribution at the pressure tap ring: record 3

The data show that the loading induced by wind oblique to the cylinder can have different characteristics from those of the loading by wind normal to the cylinder. As an illustration, Figure 20 shows the mean drag and lift coefficients against mean wind speed and the corresponding Reynolds number for a mean wind direction range of 55° to 65° relative to the cylinder. Both the force coefficients and the Reynolds number are computed based on the mean free-stream wind speed. The force coefficients show large scatter for low wind speeds. The reason for this scatter has not been positively identified and will be subjected to further investigation. The data does show, however, that the drag coefficient as a trend decrease consistently with wind speed when wind speed is higher than about 7.5 m/s, indicating that the critical Reynolds number range started at about this wind speed, which corresponds to a Reynolds number of 1.12×10^5.

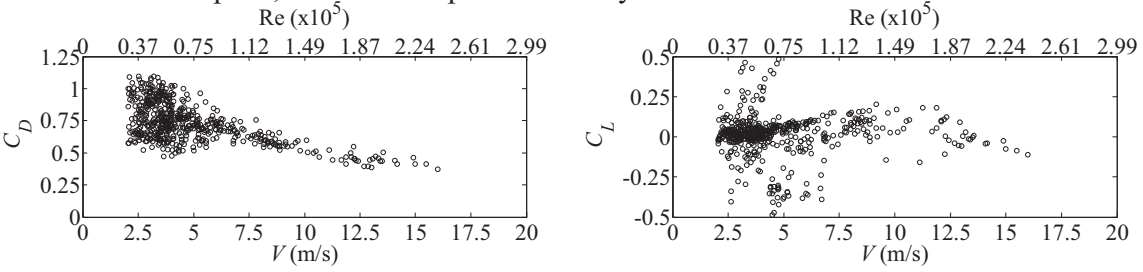

Figure 20 Mean drag and lift coefficients associated oblique to cylinder axis

In the following, a record with V= 11.27 m/s, β=64.5° and I_u=0.171, which is designated record 4, will be used to illustrate the interaction between the cylinder and oblique wind approaching from this direction. Figure 21 shows the time histories and the spectra of the drag and lift coefficients at the pressure tap ring. The spectra indicate that, in this case, the separation of the flow is also turbulent without regular vortex shedding. Figure 22 shows the acceleration response of the cylinder at the pressure tap ring. It can be seen that the low-amplitude response is dominated by the two lowest modes of the structure in the in-plane and out-of-plane directions.

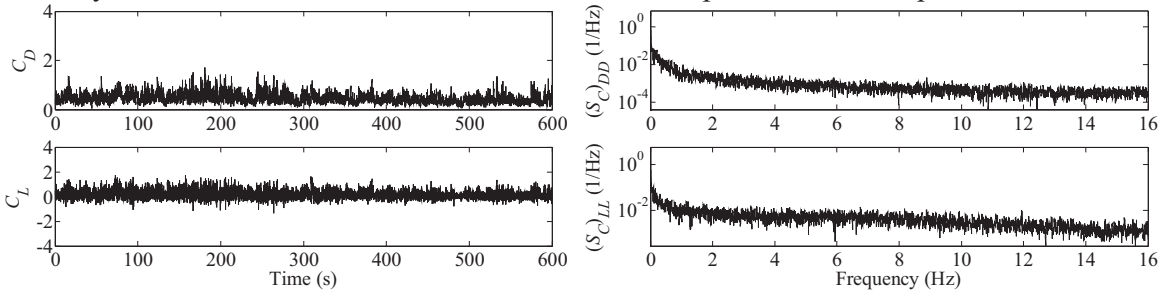

Figure 21 Drag and lift coefficients of the cylinder and the corresponding spectra: Record 4

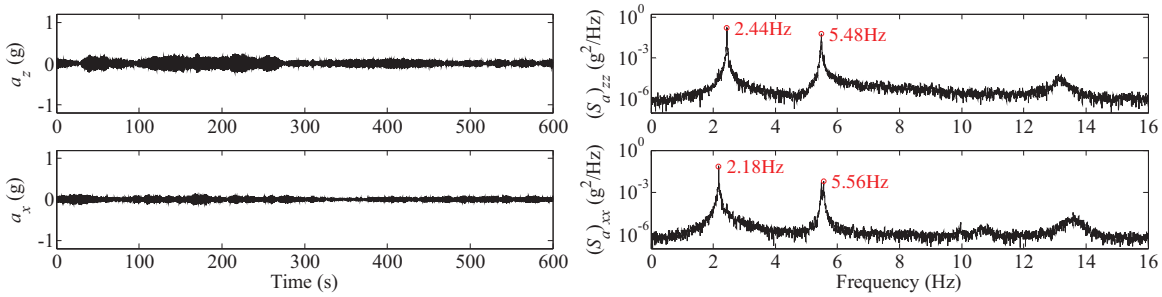

Figure 22 Acceleration time histories of and the corresponding spectra: record 4

Figure 23 shows the cross-correlation coefficients of the pressures at 5 taps along two axial lines of the cylinder over a time lag of 5 seconds. It is evident that the pressures at taps 33, 2 and 34 are the most correlated for zero time lag, indicating no apparent organized flow structure along these three taps. The figure also shows, however, that the maximum correlation between the pressures at taps 35 and 4 occurred for a time lag of ±0.125 second. This indicates the potential existence of an axial flow component along this line.

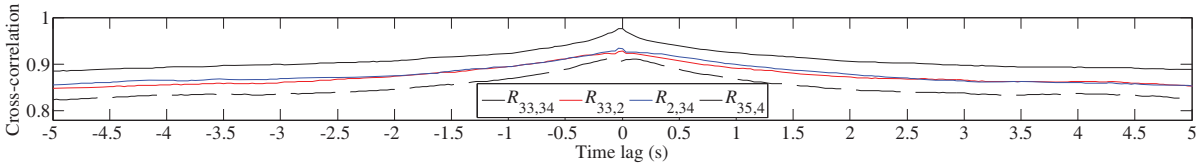

Figure 23 Cross-correlations of pressure measured along the axial direction of the cylinder: record 4

Figure 24 shows the distribution of the mean pressure for the duration of record 4. In this case, the mean pressures acting on the upper part and the lower part of the cylinder are not symmetric, indicating, on average, asymmetric separation of the flow from the oscillating circular cylinder when the oblique wind had mean wind speed in the critical Reynolds number range.

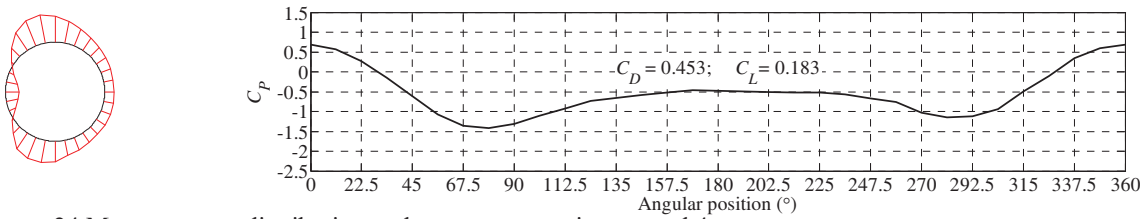

Figure 24 Mean pressure distribution at the pressure tap ring: record 4

5 CONCLUSIONS

A full-scale measurement campaign was conducted to study the dynamic interaction between wind and a circular cylinder. It is revealed that for wind both normal and oblique to the cylinder axis, the presence of turbulence in the free-stream wind shifts the transition from subcritical to critical Reynolds number range toward much lower Reynolds number than that at which the transition occurs in smooth flow. It was observed that when subjected to turbulent wind in the critical Reynolds number range, vortex-shedding does not occur and that in this Reynolds number range, the average flow separation lines on the upper and lower part of the circular cylinder surface are asymmetric about the horizontal plane through the centerline of the cylinder. The data also indicates the potential existence of an axial flow component in the wake of the cylinder when the wind is oblique to the cylinder axis.

ABSTRACT: The properties of unsteady wind force on an elliptic cylinder under a rapid change from steady flow were investigated using a gust wind tunnel. As a result, we confirmed that the overshoot phenomenon of wind force occurred under a short-rise-time gust from steady flow as well as from calm. And it was found that the overshoot coefficient, defined by the ratio of maximum to a steady-state value of wind force, decreased with an increase in the ratio of the initial wind velocity to the target wind velocity. For each ratio of the initial wind velocity to the target wind velocity, the overshoot coefficient was determined by an expanded non-dimensional rise time composed of rise time, body size, and initial and target wind velocities.

KEYWORDS: Overshoot of wind force, Non-dimensional rise time, Gust wind tunnel test.

1 INTRODUCTION

A wind force acting on a structure under a gust with a very short rise time, which occurs in high winds associated with typhoons and tornadoes, differs from a quasi-steady aerodynamic force in consideration of a small turbulent flow, and occasionally reaches a large value not seen in a steady wind flow. Several reports have shown that an overshoot phenomenon bringing a much bigger wind force than in a steady flow occurs on a structure subjected to a short-rise-time gust. Taneda[1] investigated unsteady lift acting on an elliptic cylinder rapidly started at an angle of attack using a water tank test and reported that a remarkably big lift appeared just after starting. Sarpkaya[2] showed that the drag of a body increased by approximately 25 percent during the growth of the first pair of vortices as compared to a steady flow, using an impulsive flow test over circular cylinders in a vertical water tunnel, adding some results of potential flow analyses around the circular cylinders. Morison *et al.*[3] evaluated the force acting on a small cylinder in a flow with acceleration using a semi-empirical equation added to an inertia term proportional to flow acceleration. Nomura *et al.*[4] computed unsteady drag acting on a square cylinder under a sudden change of flow speed and reported that the drag component proportional to flow acceleration played quite an important role in the total unsteady drag when the flow speed was relatively low. Matsumoto *et al.*[5] measured transient drag on a two-dimensional cylindrical model under a suddenly-changing wind speed using a wind tunnel test with a working section of 200mm by 200mm square and reported an overshoot phenomenon in which the drag increased by approximately 20% compared to the force in a steady flow.

We have investigated the unsteady wind force on a body under a short-rise-time gust from calm using a specially-equipped wind tunnel, which could generate gusts with a rise time of 0.2 to 5 seconds from a flat calm by controlling the rotation speed of the blade rows. Takeuchi *et al.*[6] investigated the effects of the rise time of a step-function-like gust on the overshoot phenomenon of wind forces acting on a railcar-like body, and reported that the overshoot phenomenon was

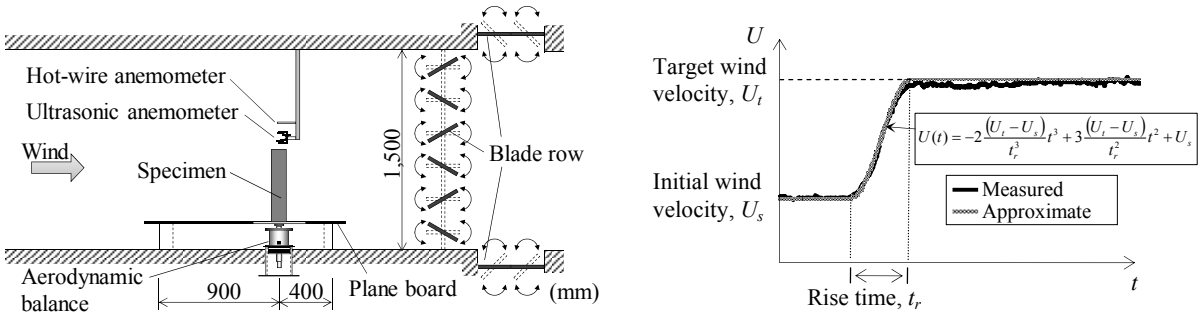
more remarkable in the case of gusts with a shorter rise time. Takeuchi *et al.*[7] confirmed some overshoot phenomena of wind forces acting on an elliptic cylinder with some angles of attack, and reported that a non-dimensional rise time composed of rise time, body size, and target wind velocities considerably influenced the occurrence of the overshoot phenomenon. Takeuchi *et al.*[8] investigated the effect of the inertia force proportional to wind acceleration on the overshoot of wind force on an elliptic cylinder subjected to step-function-like gusts, and reported that the inertia force strongly influenced occurrence of the overshoot phenomenon in the case that the non-dimensional rise time was relatively small, but the overshoot phenomenon was due to other factors in the case of relatively large non-dimensional rise times.

Many of these reports have studied unsteady wind force acting on a body under a short-rise-time gust from calm. The unsteady wind force under a short-rise-time gust from steady flow has not been well studied. However, Tomokiyo *et al.*[9] investigated the features of the short-rise time wind gusts picked up from observation data of NeWMeK (Network for Wind Measurement in Kyushu, presented by Maeda & Ishida[10]), and reported that many of them were short-rise-time gusts from steady flow. Therefore, it is necessary to clarify the unsteady wind force on a body subjected to a short-rise-time gust from steady flow.

In this study, the properties of unsteady wind force on an elliptic cylinder under a short-rise-time gust from steady flow were investigated using wind tunnel tests. Short-rise-time gusts from steady flow were generated by the control of blade rows which were installed for generating a pulsation flow. We measured the unsteady drag and lateral forces on an elliptic cylinder under such gusts and organized the measured data by the non-dimensional rise time expanded to a short-rise-time gust from steady flow.

2 GENERAL SPECIFICATIONS OF THE WIND TUNNEL TEST

We used a wind tunnel of the Eiffel type at Kyushu University. The site plan of our testing system is illustrated in Figure 1a. The section area of the working space was 1.5m by 1.5m and the available length was 3m. The wind tunnel can generate a step-function-like gust to rise from a calm state by controlling the rotation of flat blade-rows. In this study, a short-rise-time gust from steady flow was generated by the following procedures. Firstly, we generated a steady flow with a constant wind velocity controlled by opening the blade rows partially. Secondly, we opened the blade rows quickly and fully, to generate a short-rise-time gust. An example of the time evolution of the wind velocity generated by control of the blade rows is shown in Figure 1b. The rise time of a gust, t_r, is defined as the time required for an approaching wind to reach a target wind, and the initial wind velocity, U_s, and the target wind velocity, U_t, are referred to as the initial and reached winds, respectively.



a) Site plan of wind tunnel. b) Time evolution of wind velocity.

Figure 1. Site plan of wind tunnel and time evolution of wind velocity.

In our earlier study, in which we generated step-function-like gusts from a calm state, we set the time required to open the blade rows as the rise time, because the rise time of a gust was almost equal to the time required to open the blade rows (Takeuchi *et al.*[7]). In this study, the rise time was decided by the following equation:

$$t_r = 2.348\,(t_{80} - t_{20}) \tag{1}$$

where t_{80} = the time for wind velocity to increase by 80% of the difference between U_s and U_t; and t_{20} = the time for wind velocity to increase by 20% of the difference.

The rise time, t_r, in Equation 1 was determined from the cubic function shown in Figure 1b which fits the time evolution of wind velocity. It should be noted that regarding the rise time of a short-rise-time gust from calm, t_r in this paper is different from that in our earlier study for the above reason. The wind velocity in the working space was confirmed by a hot-wire anemometer and an ultrasonic anemometer. The wind velocity was scanned at a frequency of 1000Hz.

We investigated some features of short-rise-time gusts generated by the above-mentioned

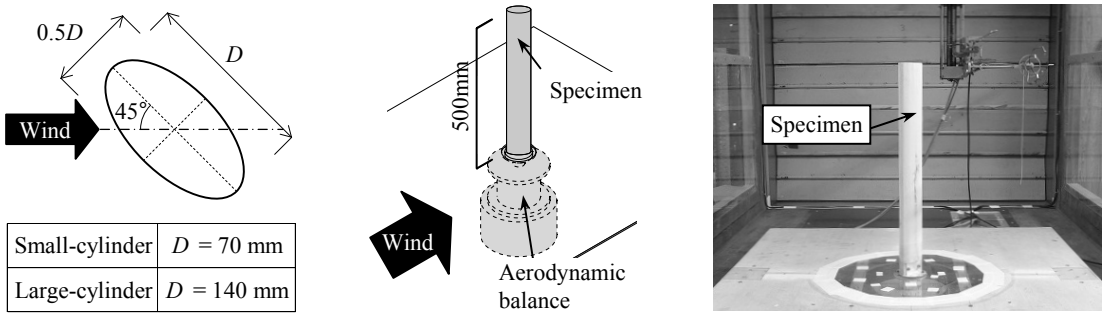
procedures. Figure 2 shows the distribution of the averaged values of wind velocity measured under steady flow controlled by opening the blade rows. We generated steady flows with 20%, 50%, 80% and 100% of wind velocity reached when the blade rows were opened fully, and measured wind velocity at 4 points over the aerodynamic balance, as shown in Figure 2a. Figure 2b indicates that the steady flow controlled by opening the blade rows was uniform. Figures 3 and 4 show the comparisons of the time evolutions of wind velocity measured at two points in the wind tunnel together under a short-rise-time gust. Figure 3 shows the comparisons of the time evolutions of wind velocity measured at points A and B over the aerodynamic balance, and indicates that they rose simultaneously under short-rise-time gusts from steady flow and calm. Figure 4 shows the comparisons of the time evolutions of wind velocity measured at point A and point C located 1000mm windward of point A, and indicates the same result as Figure 3. Thus, it was found that the wind velocity in the wind tunnel on the whole rose simultaneously under a short-rise-time gust from steady flow as well as under a short-rise-time gust from calm.

The specimens were two elliptic cylinders of axial ratio 2:1, both 500mm high, one 70mm and the other 140mm in major axis, as shown in Figure 5, and referred to as "Small-cylinder" and "Large-cylinder", respectively. They were fixed to the aerodynamic balance with a 45-degree angle of attack, and the drag and lateral forces acting on them were scanned at a frequency of 1000Hz. They were subjected to step-function-like gusts with a target wind velocity, U_t, between 2.0m/s and 7.0m/s, with the ratio of the initial wind velocity to the target wind velocity, U_s/U_t, between 0.0 and 0.9 and rise time, t_r, between 0.1sec and 1.4sec.

3 PROPERTIES OF UNSTEADY WIND FORCE ON ELLIPTIC CYLINDER UNDER SHORT-RISE-TIME GUST FROM STEADY FLOW

3.1 *Overshoot of wind forces*

Figures 6-9 show the time evolutions of the wind velocity, drag and lateral force on Large-cylinder, when the wind velocity reached 2.0m/s from 0.0m/s, 0.4m/s, 1.0m/s and 1.6m/s in a rise time of approximately 0.15sec. We confirmed that the overshoot phenomena of drag and lateral forces occurred under a rapid change from steady flow as well as from calm. But the peak of wind force changed with the initial wind velocity. The drag in the case of U_s = 0.0m/s had two peaks at approximately 0.1sec and 0.3sec. The first peak of drag in the case of U_s = 0.4m/s was smaller than that in the case of U_s = 0.0m/s. The drag in the cases of U_s = 1.0m/s and 1.6m/s had just one peak. Referring to Takeuchi *et al.*[8], it would appear that the first peaks of drag in the cases of U_s = 0.0m/s and 0.4m/s were caused by the inertia force proportional to wind acceleration. The inertia force and the wind acceleration decreased with an increase in the initial wind velocity, and the first peak of drag decreased with an increase in the initial wind velocity. In con-



a) Section view of specimen b) Bird's-eye view c) Photograph of installation

Figure 5. Specimens.

trast, it is believed that the second peak of drag was due to unsteady vortex shedding. The value of the second peak of drag in the case of U_s = 0.0m/s was hardly different from that in the case of U_s = 0.4m/s. In cases where initial wind velocity was larger than 0.4m/s, the peak value decreased with an increase in the initial wind velocity.

The lateral force was little affected by the inertia force proportional to the wind acceleration,

and had just one peak due to unsteady vortex shedding. The peak value of lateral force decreased with an increase in the initial wind velocity as well as that of drag.

3.2 *Effects of parameters of short-rise-time gust on overshoot phenomenon*

Figure 10 shows the relationship between the overshoot coefficient and the rise time for Large-cylinder in the case of U_t = 3.0m/s and U_s / U_t = 0.0, 0.3 and 0.6. The overshoot coefficient is defined as the ratio of the peak value to the steady value, as shown in the following equation:

$$Overshoot\ coefficient = \frac{Peak\ wind\ \ force}{Steady\ wind\ \ force} \tag{2}$$

where the peak wind force is defined as the actual maximum force, and the steady wind force is defined as the mean over 20 seconds in a steady flow.

For each ratio of the initial wind velocity to the target wind velocity, both overshoot coefficients of drag and lateral force increased with a decrease in the rise time. Figure 11 shows the relationship between the overshoot coefficient and the target wind velocity for Large-cylinder in the case of t_r = approximately 0.15sec and U_s / U_t = 0.0, 0.3 and 0.6. Both overshoot coefficients of drag and lateral force increased with a decrease in the target wind velocity for each ratio of the initial wind velocity to the target wind velocity.

Figure 12 shows the relationship between the overshoot coefficient and the ratio of the initial wind velocity to the target wind velocity for Large-cylinder and Small-cylinder in the case of U_t = 3.0m/s and t_r = approximately 0.15sec. It was found that both overshoot coefficients of drag and lateral force decreased with an increase in the ratio of the initial wind velocity to the target wind velocity for each elliptic cylinder. And the overshoot coefficient of Large-cylinder was lar-

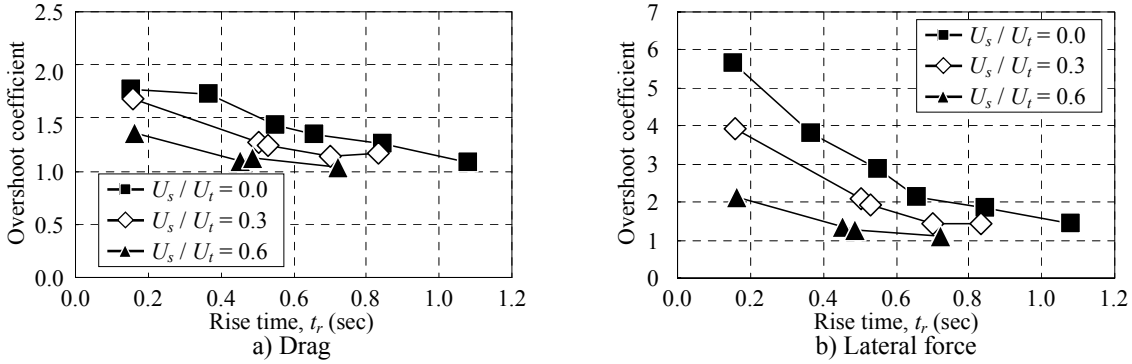

Figure 10. Overshoot coefficient with rise time (D =140mm, U_t =3.0m/s).

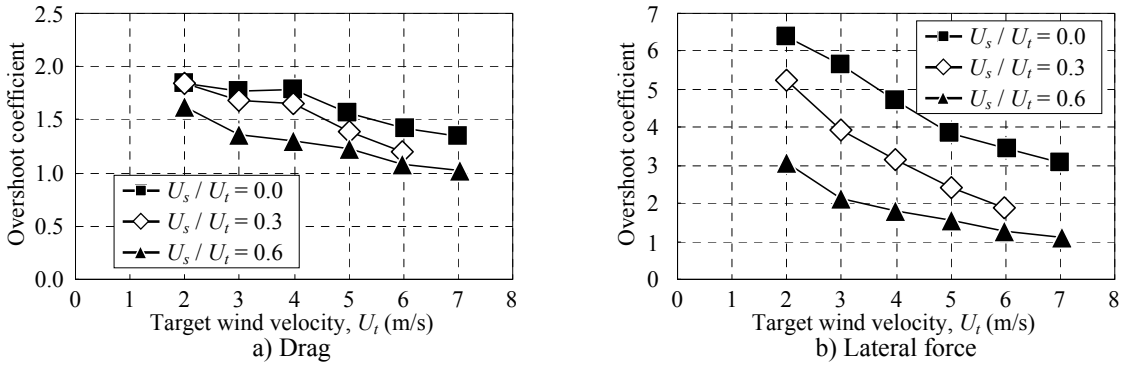

Figure 11. Overshoot coefficient with target wind velocity (D =140mm, t_r = approximately 0.15sec).

ger than that of Small-cylinder for all ratios of the initial wind velocity to the target wind velocity.

Figure 13 shows the overshoot coefficient for Large-cylinder and Small-cylinder in the case of t_r = approximately 0.15sec and the increase of wind velocity of 1.8m/s (U_s = 0.2m/s and U_t =2.0m/s; U_s = 1.2m/s and U_t =3.0m/s; U_s = 4.2m/s and U_t =6.0m/s). Even when the increase of wind velocity was the same, the overshoot coefficient decreased with an increase in the initial wind velocity or the target wind velocity.

3.3 *Relationship between overshoot coefficient and non-dimensional rise time*

In our earlier study, we reported that the overshoot coefficient of wind force on a body subjected to a short-rise-time gust from calm was determined by a non-dimensional rise time, which was composed of a rise time, a gust speed and the body size, as shown in the following equation (Takeuchi *et al.*[7]):

$$t_r' = \frac{U_t \cdot t_r}{d} \tag{3}$$

where U_t = the target wind velocity; t_r = the rise time; and d = a reference length (here, the length of the flow direction of the elliptic cylinder).

However, in this study, the overshoot phenomenon of wind force on a body subjected to a short-rise-time gust from steady flow was affected by the initial wind velocity, as previously mentioned. Thus, we need to consider the initial wind velocity to organize the overshoot coefficient of wind force on a body subjected to a short-rise-time gust from steady flow. In this study,

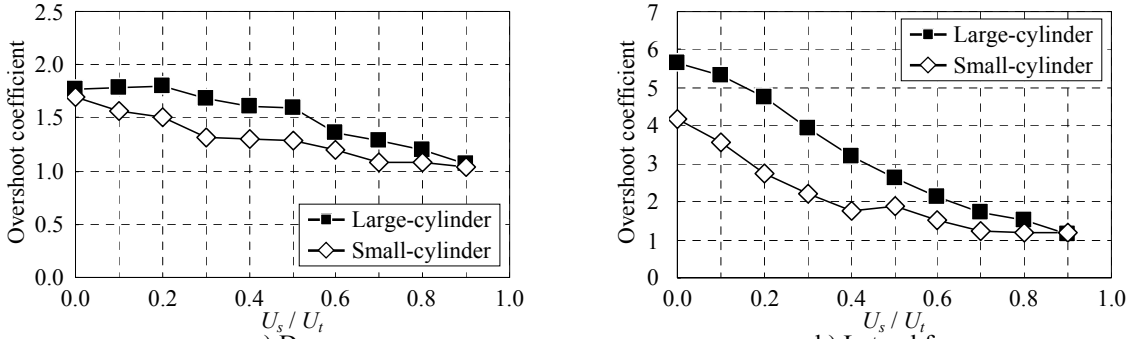

Figure 12. Overshoot coefficient with ratio of initial wind velocity to target wind velocity (U_t =3.0m/s, t_r = approximately 0.15sec).

a) Drag b) Lateral force c) Legend

Figure 17. Relationship between overshoot coefficient and non-dimensional rise time (U_s / U_t = 0.6).

the non-dimensional rise time was expanded in consideration of the initial wind velocity as follows:

$$t_r' = \frac{(U_t - U_s) \cdot t_r}{d} \tag{4}$$

where U_s = the initial wind velocity. When $U_s = 0$, Equation 4 is the same as Equation 3.

Figures 14-17 show the relationships between the overshoot coefficients of drag and lateral force and the non-dimensional rise time obtained by Equation 4 in cases of $U_s / U_t = 0.0$, 0.2, 0.4 and 0.6, respectively. For each figure, the overshoot coefficients for Large-cylinder are plotted on one line regardless of the target wind velocity, and the overshoot coefficients for Small-cylinder are plotted on the line for Large-cylinder. Thus, for each ratio of the initial wind velocity to the target wind velocity, the overshoot phenomenon may be strongly affected by the non-dimensional rise time. And these figures show that the overshoot phenomenon was more remarkable in the case of a gust with the smaller ratio of the initial wind velocity to the target wind velocity. However, the variation in the overshoot coefficient increased with the ratio of the initial wind velocity to the target wind velocity. In future studies we will investigate the presence of a non-dimensional parameter associated with the overshoot phenomenon, additional to the non-dimensional rise time.

4 CONCLUSIONS

The properties of unsteady wind force on an elliptic cylinder under a rapid change from steady flow were investigated using wind tunnel tests. We introduced a procedure for generating short-rise-time gusts from steady flow by the control of blade rows which were installed for generating a pulsation flow. The following features of unsteady drag and lateral forces on an elliptic cylinder under such gusts were found:

1 It was confirmed that the overshoot phenomenon of wind force occurred under a short-rise-time gust from steady flow as well as from calm.
2 The overshoot coefficient, defined by the ratio of maximum to a steady-state value of wind force, decreased with an increase in the ratio of the initial wind velocity to the target wind velocity.
3 For each ratio of the initial wind velocity to the target wind velocity, the overshoot coefficient was determined by an expanded non-dimensional rise time composed of rise time, body size, and initial and target wind velocities. And it was shown that the overshoot phenomenon was more remarkable in the case of a gust with the smaller ratio of the initial wind velocity to the target wind velocity.

Understanding rapid flow separation with spanwise variation

Jaime Wong, Jochen Kriegseis and David E. Rival

Dept. of Mech. Eng., University of Calgary, 2500 University Dr., Calgary, Canada

ABSTRACT: The current study investigates the influence of spanwise flow on three- dimensional vortex evolution. Using a robotic apparatus, a flapping motion was imposed on high aspect-ratio profiles. The flapping motion produced a spanwise variation in separation, and was reproduced for profiles with and without sweep to vary spanwise velocities. An analytical model for leading-edge vortex growth was proposed, based on the transportation of vorticity-containing mass through the shear-layer. When applied to the flapping motion, it was found that the analytical model predicted similar force coefficients with and without spanwise flow, which was confirmed by experiment. The model also predicted that the rate of vortex growth decreased with time in the presence of spanwise flow, although this could not be immediately verified experimentally.

KEYWORDS: Leading-edge vortex, spanwise flow, vortex modeling.

1 INTRODUCTION

Traditionally it is common to analyse flapping wings and rotating blade systems as a series of quasi-two-dimensional elements [1, 2]. However, flapping and rotating systems can exhibit large spanwise gradients in velocity and effective incidence. These spanwise gradients can couple with rapid flow separation to form highly three-dimensional vortex behaviour. The application of two-dimensional models to such highly three-dimensional flows will typically result in large errors when predicting aerodynamic performance [3]. Consider the case of a rotating blade, as on a wind turbine, experiencing a sharp-edged axial gust. The spanwise distribution of angle of attack $\alpha(r)$ from the base flow u_∞ takes the form $\arctan(u_\infty/\omega r)$. As shown in Figure 1, the change in effective incidence for a gust of strength $\Delta u = u_\infty$ would be greatest towards the root. Large, rapid changes in effective incidence towards the root ($r/R \approx 0$) can be expected to cause highly seperated flow, while this effect would diminish when moving towards the tip ($r/R \approx 1$). This can be compared to the root-flapping of a bird's wing. Changes in effective incidence would in this case grow towards the tip. At low speeds, where highly-separated flows are expected, gradients relating to vortical growth would increase towards the tip instead. In both scenarios, the low-momentum of separated flows would be small relative to coriolis and centripetal accelerations [4]. These accelerations would act to drive flow away from the root. Therefore, the direction of spanwise flow can coincide or oppose the gradient of effective incidence. The relationship between these two

effects, i.e. spanwise separation and coriolis/centripetal acceleration, is not immediately obvious.

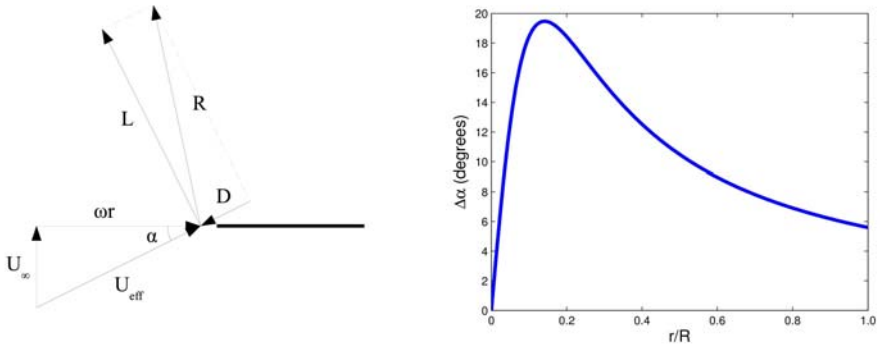

Figure 1: The velocity triangle and resulting forces for a rotating blade (left), and change in effective incidence as a function of span for a rotating blade subjected to a sharp-edged axial gust (right).

Of particular interest is how the leading-edge vortex (LEV) moves in the spanwise direction [5]. However, in highly three-dimensional cases, conventional blade-element schemes would fail to provide insight into spanwise transportation of vorticity. In the current study, analytical models for two- and three-dimensional vortex growth are proposed. These models are then compared with results obtained experimentally so as to verify the robustness of the model. Comparisons can be drawn from the relative influence of these sources of acceleration to spanwise velocity.

2 BACKGROUND

Consider the vorticity transport equation for an incompressible, barotropic fluid with conservative body forces:

$$\frac{\partial \vec{\omega}}{\partial t} + (\vec{u} \cdot \nabla)\vec{\omega} = (\vec{\omega} \cdot \nabla)\vec{u} + \nabla \times \left(\frac{\nabla \cdot \underline{\underline{\tau}}}{\rho} \right) . \tag{1}$$

The physical interpretation of each term from left to right can be described as: the changes in vorticity of the fluid due to unsteadiness, convection, vortex stretching through velocity gradients and the viscous diffusion of vorticity. Let us introduce a coordinate system set to a generic profile such that the z-direction is aligned with the blade span, and the x-direction with the blade chord, with the remaining y-coordinate then necessarily being normal to the blade surface, as shown in Figure 2. For the case of a simple plunging motion on a two-dimensional blade, a number of simplifications can be made. Firstly, viscous diffusion can be ignored under the assumption that timescales of diffusion are much larger than vortex growth itself. Furthermore, all gradients in the z-direction must necessarily be zero. The z-vorticity transport equation will subsequently reduce to:

$$\frac{\partial \omega_z}{\partial t} + u\frac{\partial \omega_z}{\partial x} + v\frac{\partial \omega_z}{\partial y} = 0 . \tag{2}$$

This is not conditional on a spanwise velocity field, caused for instance by a infinitely long wing of finite sweep, or on the existence of ω_x or ω_y. It follows that, after the elimination of z-gradient term, the remaining vortex stretching terms must sum to zero:

$$\omega_x \frac{\partial w}{\partial x} + \omega_y \frac{\partial w}{\partial y} = \left(\frac{\partial v}{\partial z} - \frac{\partial w}{\partial y} \right) \frac{\partial w}{\partial x} + \left(\frac{\partial w}{\partial x} - \frac{\partial u}{\partial z} \right) \frac{\partial w}{\partial y} = \frac{\partial w}{\partial x}\frac{\partial w}{\partial y} - \frac{\partial w}{\partial y}\frac{\partial w}{\partial x} = 0 \ . \tag{3}$$

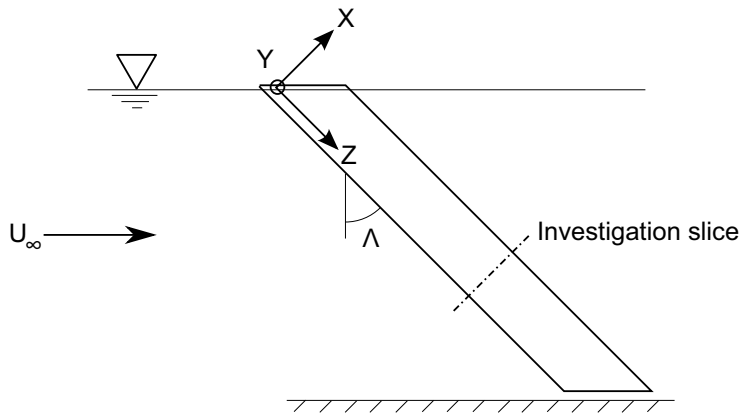

Figure 2: Coordinate system defined relative to a profile of sweep Λ in a quasi-two-dimensional arrangement, where the free surface and walls act as mirror planes.

As it is reasonable to assume a leading-edge vortex (LEV) would form parallel to the leading edge, it follows from equation (2) that the ω_z feeding the LEV would be confined to the $x - y$ plane. If the LEV is continually fed, it would grow until the vortex detaches and convects downstream. Thus, it may be conjectured that there is no two-dimensional mechanism from which one may stabilize the LEV. Consider now instead a three-dimensional case that is superficially similar, but where all gradients in the z-direction are non-negligible. A flapping wing would appear as a spanwise-dependent plunging motion. An order-of-magnitude argument can be made where ω_z is much larger than either ω_x or ω_y. In other words, the LEV can still be considered roughly parallel with the z-axis. The vorticity equation would then reduce to:

$$\frac{\partial \omega_z}{\partial t} + u\frac{\partial \omega_z}{\partial x} + v\frac{\partial \omega_z}{\partial y} + w\frac{\partial \omega_z}{\partial z} = \omega_z \frac{\partial w}{\partial z} \ . \tag{4}$$

Equation (4) introduces the ability for vorticity to be transported and stretched in the z-direction. In some circumstances, the vortex stretching term may be sufficiently large to cancel the convection terms. Only when those terms balance can $\partial \omega_z / \partial t$ be brought to zero and equilibrium be obtained. In other words, vortex stabilization must by definition require a three-dimensional flow. Planforms such as delta wings drain vorticity with spanwise flow to provide stable vortex lift under quasi-steady conditions. However, it is not clear what specific three-dimensional features, such as wing kinematics or shape, would result in an appropriate balance of vortex convection and stretching in highly-unsteady motions. This question ultimately motivates the development of the model described in the following section.

3 ANALYTICAL MODEL

3.1 *Two-Dimensional Case*

An analytical model for the unsteady lift on a plunging flat plate has been developed inspired by the work of Kaden [6]. As described in his model, the growth of a two-dimensional vortex can be attributed to the transport of vorticity-containing mass through the shear layer into the vortex in question. More recently, a model for the steady flux of vorticity in a shear layer has been tested by Sattari et al. [7]. The mass-flux into the LEV may therefore be described through conservation of mass for an incompressible fluid as:

$$m'(t) = \rho \int_0^t \int_0^d u(y,t)\ \mathrm{d}y\mathrm{d}t\ , \tag{5}$$

where $m'(t)$ is the vorticity-containing mass in the vortex per unit span, $u(y,t)$ is the shear-layer velocity profile and d is the shear-layer thickness. If the area of the vortex described by $m'(t)$ is then approximated as a roughly semi-circular shape attached to the blade, as in Figure 3, its radius $R(t)$ would be:

$$R(t) = \sqrt{\frac{2}{\pi}\frac{m'(t)}{\rho}}\ . \tag{6}$$

Knowing $m'(t)$, and thus $R(t)$, we may then compute the circulation of the vortex by the line integral of velocity around the vortex core:

$$\Gamma(t) = \oint \vec{u} \cdot \mathrm{d}\vec{l} = \pi\ u(d,t)R(t)\ , \tag{7}$$

where $u(d,t)$ is the velocity on the outer edge of the shear layer and the velocity along the profile surface is assumed zero. Recently it has been shown by Pitt-Ford and Babinksy that the bound circulation on flat plates in such unsteady conditions is negligible [8]. Thus, the LEV may be assumed to be the sole contributor of circulation. Lift may then be calculated, as a first approximation, by the Kutta-Joukowski equation. Difficulty now arises when attempting to predict the properties of the shear-layer growth from the bulk kinematics of the blade such as the plunge velocity $\dot{h}(t)$ and the effective incidence, $\alpha_{\text{eff}}(t) = \arctan(\dot{h}/u_\infty)$.

In the current model, the LEV is taken as a semi-circular shape located directly over the blade, while the shear layer exists on the outer radius of this semi-circle at position α_{eff}, as seen in Figure 3. The outer velocity $u(d,t)$ is determined by the superposition of three velocities: an acceleration around a cylindrical blockage of radius $R(t)$ at position α_{eff}; the induced velocity from the LEV itself; and the projection of the plunge velocity $\dot{h}$ onto the tangent of the semi-circle at α_{eff}:

$$u(d,t) = \underbrace{u_\infty \left(1 + \frac{R^2(t)}{r^2}\right) \sin(\alpha_{\text{eff}})}_{u_b} + \underbrace{\frac{\Gamma(t)}{2\pi r}}_{u_i} + \underbrace{\dot{h}\cos(\alpha_{\text{eff}})}_{u_p}\ , \tag{8}$$

where $r = R(t) + d$, u_b is the velocity component from blockage effects, u_i is the velocity component induced by the LEV, and u_p is component from the projection of the plunging motion. Furthermore, $u(0,t)$ is taken as the induced velocity component evaluated at $r =$

$R(t)$. From empirical observations, the shear-layer velocity profile was found to have an approximately sinusoidal transition from $u(0,t)$ to $u(d,t)$ such that:

$$u(y,t) = \frac{u(0,t) - u(d,t)}{2} \cos\left(\pi \frac{y}{d}\right) + \frac{u(0,t) + u(d,t)}{2} \ , \tag{9}$$

which then reduces the integral for vorticity-containing mass to:

$$m'(t) = \rho \int_0^t d \frac{u(0,t) + u(d,t)}{2} \ \mathrm{d}t \ . \tag{10}$$

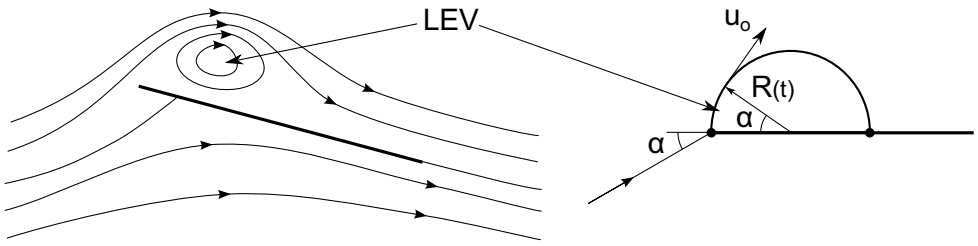

Figure 3: Comparison of the instantaneous streamline system (left) with the simplified model of a leading-edge stagnation point and semi-cylindrical blockage (right).

3.2 *Extension to the Three-Dimensional Case*

Given $\Gamma(t)$ is known for each two-dimensional slice, a blade-element scheme can be implemented to compute lift for three-dimensional motions. In the current study, a model was developed for the case of a high aspect-ratio blade far from the tip regions, such that three-dimensional effects were due exclusively to spanwise flow from sweep or centripetal/coriolis accelerations. In three dimensional flows, it is likely that flow near the blade can be broken into spanwise and chordwise components. While the chordwise-component of velocity contributes to vortex growth through the shear layer, the spanwise component serves to transport mass along the span only. We can revise the term for $u(d,t)$ such that:

$$u(d,t)\Big|_z = u_c \left(1 + \frac{R^2(z,t)}{r^2}\right) \sin(\alpha_{\text{eff}}) + \frac{\Gamma(z,t)}{2\pi r} + \dot{h}(z) \cos(\alpha_{\text{eff}}) \ , \tag{11}$$

where u_c is the chordwise component of u_∞ and α_{eff} is revised accordingly as $\arctan(\dot{h}/u_c)$. In addition, we must include an extra term for $m'(t)$ to account for the mass transfer through spanwise flow:

$$m'(t)\Big|_z = \rho \int_0^t \left(\frac{u(0,t) + u(d,t)}{2} d + \iint_R \vec{u}_s(z,t) \cdot \vec{n} \ \mathrm{d}A \right) \ \mathrm{d}t \ , \tag{12}$$

where z is the spanwise position, R is the surface swept by a semi-circular disc of radius $R(z,t)$ at the blade element z and $\vec{u}_s(z,t)$ is the spanwise component of velocity. It is worth noting that as gradients in the $z-$direction tend towards zero, equations (11) and (12) reduce to the two-dimensional cases represented by equations (8) and (10).

4 EXPERIMENTAL SETUP

Various blade motions were produced using a six degree-of-freedom hexapod manipulator, as shown in Figure 4. The hexapod was mounted over top of a custom water tunnel, which operated at 0.2m/s. A six-component ATI Gamma force/torque balance was flanged to the hexapod with a high aspect ratio flat blade of varying sweep $\Lambda = 0°$ and $-45°$ below. Each of the flat blades has a chord of 5cm measured normal to the leading edge, and a thickness of 3.12mm. In all test cases, the wing pierced the free-surface, which was considered as a mirror plane. Furthermore, the gap between the blade tip and tunnel floor was maintained under 3mm and therefore was similarly modeled as a mirror plane. The Reynolds number based on chord and freestream flow was $Re = 10,000$. Two test motions were considered. The first and most simple motion was of a sinusoidal-plunging movement as shown in equation (13):

$$\dot{h} = 0.1 \sin(2t) \ . \tag{13}$$

where $\dot{h}$ is the plunge velocity. This corresponds to a reduced frequency of:

$$k = \frac{\pi f c}{u_\infty} = 0.25 \ , \tag{14}$$

where f is the frequency of the motion. As a second case, a flapping motion described by equation (15) was considered. Kinematics were such that the plunging motion of case 1 was replicated at the 3/4 span, neglecting centripetal accelerations. The plate rotated about a virtual pin at the tunnel wall, by way of the programmable hexapod controller. The motion of case 2 took the form:

$$\dot{\theta} = 0.15 \sin(2t) \ . \tag{15}$$

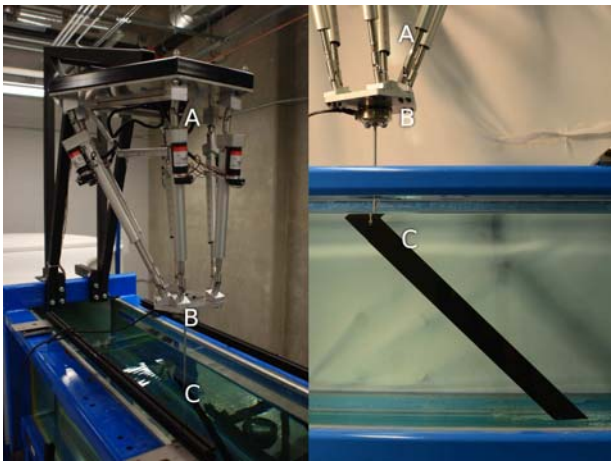

Figure 4: Experimental setup with high aspect ratio blade (A), 6-component balance (B), and hexapod manipulator (C) mounted to water tunnel.

5 RESULTS AND DISCUSSION

A comparison of the temporal evolution and spacial variation of vortex growth demonstrates the differences arising from spanwise flow in the flapping motion. Modeled vortex radii for flapping motion with and without sweep are compared in Figure 5. It can be seen that the rate of vortex growth slows with the period much more pronouncedly in the swept case than the unswept case. This suggests that vortex feeding and draining are tending towards similar rates. The mass flux through the shear-layer, which is roughly proportional to the shear-layer velocities shown in Figure 6, does not decrease with period. Therefore, mass transfer through spanwise flow becomes increasingly large, limiting vortex growth. If the rate of vortex growth would eventually decrease to zero, this would represent a stable vortex. Furthermore, the vortex is smaller in the swept case than in the unswept case across the entire span. This can be partially explained from the smaller chordwise velocity component u_c relative to the freestream velocity u_∞, limiting the rate of vortex feeding. However, since the vortex radius in the swept case is not simply a multiple of the unswept case as the change in chordwise velocity is, spanwise mass transfer towards the tip may also contribute to the smaller radius.

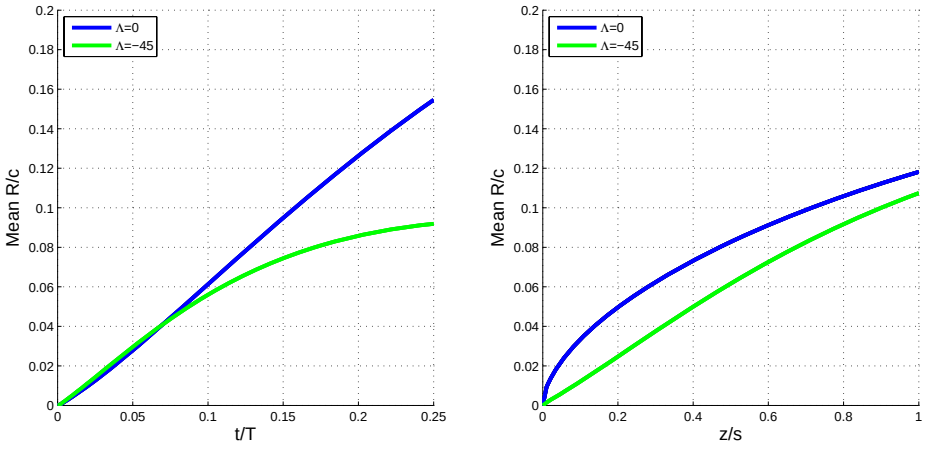

Figure 5: Modeled vortex radius as a function of period (left, averaged with span), and as a function of span (right, averaged with period).

To better understand the differences between swept and unswept cases, the individual components of shear layer velocity are compared in Figure 6. Note that the velocity component due to blockage effects is higher in the swept case than in the unswept case despite the smaller blockage radius. For this velocity component u_b, the effect of a smaller LEV radius in the swept case is balanced by a larger effective incidence. This effect of effective incidence can also be seen in the plunging component of velocity u_p. The equal induced velocity components u_i imply that unswept cases have a higher LEV circulation, given the larger vortex radius in unswept cases.

Measurements of lift coefficients show reasonable agreement with the analytical model for both two- and three-dimensional cases, shown in Figure 7. The largest discrepancies occur

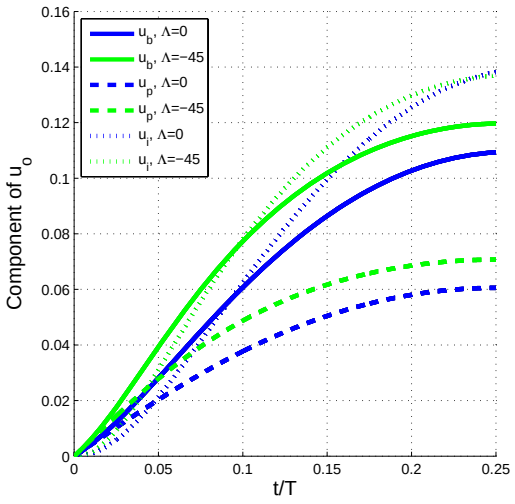

Figure 6: A comparison of terms contributing to $u(d, y)$ as a function of period, for cases with and without spanwise flow; u_b is velocity due to blockage, u_p is velocity due to plunging, and u_i is velocity induced by the LEV (see eq. (8)).

at $t/T = 0$, where the analytical model predicts a slope of zero. All measurements show a finite slope at $t/T = 0$, as the LEV begins to grow instantaneously. It is speculated that this effect is related to the vorticity-containing mass in the boundary layer contributing to the initial stages of LEV growth. Furthermore, agreement between the analytical model and measurements are also poor after one-quarter cycle, as the model cannot account for the vortex eventually detaching and convecting downstream.

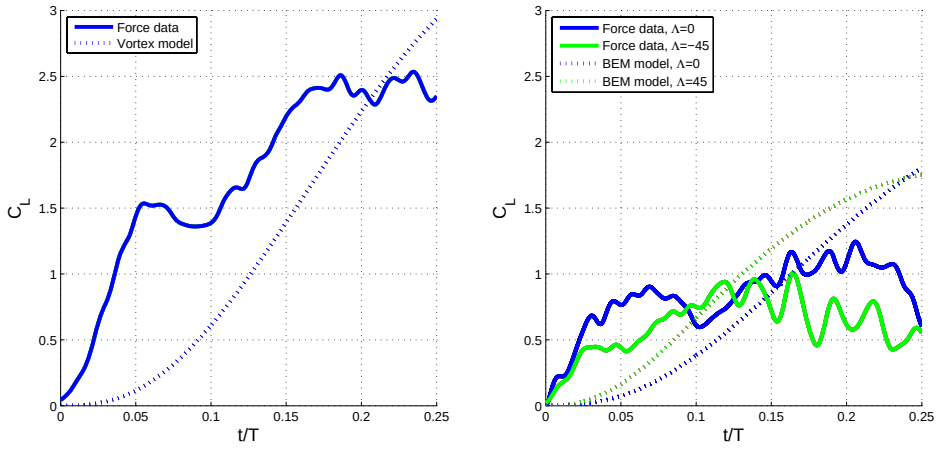

Figure 7: Lift coefficient as a function of period for plunging motion (left) and for flapping motion (right).

6 CONCLUSIONS

In this study, an analytical model for LEV growth has been developed and tested. When compared to physical measurements, rates of vortex growth between $0.05 \leq t/T \leq 0.2$ were reasonably accurate. Furthermore, the model predicted that the rate of LEV growth decreased across the first quarter period for a flapping motion in the presence of spanwise flow. This may contribute to vortex stability, however the reduction in vortex growth rate could not be immediately confirmed experimentally. The model was shown to be incapable of correctly predicting early-stage vortex growth. The model was also not developed to account for the eventual separation of the vortex from the profile. Nevertheless, the simple analytical description of the model and the ease of implementation are highly desirable. Future work will include verification that vortex growth can be limited by spanwise flow. Furthermore, the influence of an existing boundary layer on early-stage vortex growth and the influence of additional components of spanwise acceleration will be investigated.

ABSTRACT: Large drag encountered by a blunt-nosed body, flying at a hypersonic speed, is primarily due to the high-pressure zone caused by the detached shock at the nose of the body. Spike has been identified as a passive technique to render the strong bow-shock at the nose to become weaker, thereby resulting in reduced pressure over the nose as a consequence of generated vortices, leading to drag reduction. However, all the previous studies were focused mainly on drag reduction quantification, without addressing the physical process causing the drag reduction. Therefore in the present work, attention is focused on understanding this aspect of the flow process at low Reynolds number (incompressible flow) and estimating its relevance for prospective hypersonic validity. It is known that the vortices at the attached end of the spike are responsible for reducing the high-pressure over the nose, leading to drag reduction. These vortices at the root of the spike would also influence the vortices at the base. It would be of great significance for drag reduction if the functional dependence of the size of these vortices on the Reynolds number can be established. Therefore, emphasis was focused on ascertaining the vortex size dependence, at the nose and at the base, on the flow Reynolds number and spike geometry, by visualizing the flow past a blunt-nose body with and without spike. Flow field around the blunt-nosed body, without spike and with spikes of various configurations, have been studied at Reynolds number 3170. It is found that there is a specific length-to-diameter ratio for every spike nose-configuration, resulting in the largest vortex at the spike base and at body base, for a given Reynolds number.

1 INTRODUCTION

The drag reduction of a blunt-nosed body plays an important role in both low-speed and high-speed applications. This assumes a lot of importance in the case of hypersonic flying objects because of the extremely high drag caused by the high-pressure zone at the nose, owing to the blunt nature of the geometry. But the blunt shape is essential for the nose of the hypersonic vehicles to safeguard the body from ablation caused by aerodynamic heating. Considerable numbers of research articles are published in open literature with both experimental and computational studies on spiked blunt-nosed bodies at hypersonic Mach numbers [1]. For reducing the drag, secondary objects projecting ahead of the blunt nose (forward-facing) has been found to be an effective method. These secondary objects are termed spikes, in general. When a spike is fixed to a blunt nose, it essentially shifts the forward stagnation point away from the surface of the blunt nose, as shown in Figure 1. Because of this, the extent of the positive pressure zone over the blunt nose comes down consequently resulting in reduced drag. The flow process associated with the shifting of the stagnation point upstream of the blunt nose would result in weakening of the detached shock, and reduction of the extent of the zone influenced by the detached shock. However, for quantifying the dependence of the influence zone and the positive pressure zone over the nose, no information is available in the open literature. All the reasons given for the drag reduction, with the spikes, at hypersonic speeds are based on speculations about the zone of influence and the positive pressure zone over the nose, based on the end results obtained, mostly from direct measurements of force with wind tunnel balances. Therefore, there is an urgent need to understand the process associated with the flow over the basic body, with and without spike, for optimizing the spike geometry, resulting in efficient drag reduction. To gain an insight into the essential features of the flow physics associated with the drag reduction, it is essential to measure these parameters, if possible, directly. The present work is an attempt in this direction to assess and measure the extent of vortices near the fore-body stagnation area and in its wake, with and without spike, by direct means. For this, flow past the desired blunt-nosed body, with and without spikes, was visualized in a simple two-dimensional water channel, at a specific Reynolds number. The objective here is essentially to gain an insight into the important features governing the flow physics with the introdution of spike in front of the body nose, and its functional dependence on spike characteristics together with looking into the prospective application aspects governing the hypersonic flows.

Numerous researches in the past have proven that the positive pressure at the nose and the negative pressure at the base, together, amasses the large drag associated with blunt nosed bodies meant for high-speed applications. Therefore, it is essential to reduce the positive pressure at the nose and the negative pressure at the base to bring down the drag over the blunt nosed body. Vast quantity of studies, reported in literature, investigated these aspects of positive pressure at the nose and the negative pressure at the base, in isolation. For example, the first report in open literature which addresses both the nose and base fields is the work by Takama et.

al [2]. However, there is no direct address to the magnitude of the positive pressure at the nose and the base pressure at the rear, in this study. Also, the recent work of Kalimuthu et. al [3], though addressed drag reduction of blunt-nosed body, focuses mainly on reducing the positive pressure at the nose. It has been found that there is an optimum length for a spiked blunt-nosed body at a specified Mach number, resulting in maximum drag reduction. However except for the optimum length of the spike no information about the flow characteristics, causing the maximum drag reduction, was presented. From vortex dynamics, it is known that larger the vortex the higher is the suction caused by it. This feature is envisaged as the reason for the modification of the pressure flow field, resulting in maximum drag reduction. It can be visualized that if the suction caused by the vortex at the base end of the spike is large, the oblique shock formed at the spike tip and traveling towards the body nose will be attracted towards the body. If the suction created by the vortex is just enough to make the shock become tangential to the shoulder of the body, as illustrated in Figure 1, it would result in the optimum reduction of the pressure field over the body-nose, resulting in significant reduction of pressure drag. The subsequent work by Ashish and Rathakrishnan [4] is the first of its kind, which quantifies the shock strength, the base pressure field and the drag on a blunt nosed breathing body, by directly measuring the pressure distribution over the body and the drag force acting on it. In this work, a breathing blunt nose (BBN) concept has been employed successfully for reducing the drag at Mach 2. Sheard *et al.* [5] computed the flow normal to a cylinder, with hemispherical ends, using a spectral-element/Fourier method. They concluded that with variation in the ratio of cylinder length to diameter, the body varies smoothly from a sphere to a straight circular cylinder, providing an insight into the relationship between body topology and wake dynamics. Khurana *et al.* [6] performed the shallow water visualization experiments in a two-dimensional water channel around a blunt-nosed body, with and without spike, at Reynolds number 3070 and successfully captured the changes in flow field with the introduction of a spike, by quantification of different parameters namely zone of influence, pressure head and nose vortices.

It is also required to address the impact of introducing a spike on the flow field at the base area of the body. The higher the pressure field distributed over the nose area with spike at stagnation surface, the weaker will be the suction at the body base; consequently resulting in higher base pressure and a lesser pressure gradient in the flow direction for a lesser drag. Therefore, it will prove to be of great value and importance to understand the flow process responsible for total drag reduction (including nose and base) achieved with spike. Moreover, visualizing the vortex at the spike base at hypersonic Mach numbers is not possible because of extremely high inertia. Keeping this in mind the present work of vortex-size variation with spike-nose geometry and length-to-diameter ratio has been investigated in a water flow channel at Reynolds number 3170 and for different spike geometries shown in Figure 2.

2 EXPERIMENTAL SETUP

In the current investigation, the flow around a spiked body, comprising of vortices near the stagnation area, was visualized using a rectangular water flow channel [2,6,7,8] in the Suzuki K. Laboratory, The University of Tokyo. Schematic diagram and a pictorial view of the channel are shown in Figures 3(a) and 3(b), respectively. Water from the chamber, spills over the inclined plate and is conditioned using an array of wire-meshes, before reaching the downstream of the

test-section. The flow quality is ensured to be fairly uniform in the test-section. The velocity of the flow is measured using the floating-particle method technique, over the length of the test-section. The average of a set of 5 readings measured velocities is taken as the representative velocity of the flow. The test models and spike geometries were manufactured from ABS material for main body and Bakelite for spikes, using PC-controlled Modela MDX-504A (Roland DG Corporation) Rapid-prototyping machine available onsite in the laboratory (Fig. 2). The axis of the model was aligned parallel to the flow direction at the middle of test-section for every test. The model consists of a hemisphere-cylindrical fore-body with various spike-nose configurations (hemispherical, conical, flat and a specific case of square cross-section with side or equivalent diameter equal to $[(\pi/4)^{0.5}\, d]$. All the tests of the present study were carried out at Reynolds number 3170, based on the main body diameter. After the proper alignment has been ensured, some time is given for the flow to develop properly. The flow field in the test-section was ensured to be parallel and uniform by observing parallel streak lines of dye injected upstream of the empty test-section. Then the model was placed in the test-section and the flow field was recorded on a video camera (PANASONIC, Model DMC-ZX3) with resolution of 1280 x 720 and at 60 frames per second. The videos recorded clearly exhibit the flowfield comprising the vortices generated (V) at the body nose (spike base) and in the wake region (body base), as illustrated in Figure 4.

3 FLOW VISUALIZATION

The visualization results from the shallow water experiments have been presented in Figs. 5-8, with and without spike, for the varying length-to-nose-diameter ratios (l/D) from 0.5 to 2.0. Figure 5 shows the flow field for hemispherical-cylinder forebody with different spikes for l/D=0.5. The change in the streamlines after deflection from encountering an object (spike) in front of the nose can be easily concluded. The high pressure area that envelops the nose, is replaced by weak streamlines that gets deflected towards the shoulder of the body and again gets deflected towards the low pressure region of the wake. The flow field with different spikes, in front of the forebody for l/D=1.0, has been depicted in Figure 6. With the increase in l/D-ratio, the deflection of the streamline from the spike nose gets nearer to the shoulder of the forebody, confirming the suction that is created near the spike nose from the twin vortices on either sides. Together, the flow gets attracted towards the base of the body owing to the low pressure location in the wake. On further increasing the l/D-ratio to 1.5 (Fig. 7), it can be observed that the flow is nearly tangential to the forebody shoulder signifying an optimum value of l/D, for the generation of sufficiently larger vortices, which attracts the flow towards the nose-shoulder, thereby reducing the positive pressure on the nose. Beyond l/D=1.5, the flow starts dissipating at the spike nose, re-attaching near the spike root location resulting in negligible vortices. Contrary to this fact, the flow downstream of the forebody stays near to body base in the wake region, as the extent of vortices (low pressure region) behind the body decreases with increasing l/D-ratio.

4 RESULTS AND DISCUSSIONS

In the present investigation, the quantification of nose vortices around the spike root and stagnation area and those generated in the wake region have been completed. Figures 9 and 11 shows the flow field near-nose region with (l/D=1.5) and without spike and in the wake region with (l/D=2.0) and without spike respectively. These pictures of the flow field clearly exhibits the vortex length V and W, which were measured by projecting the visualization pictures on screen, for all the models studied. Figures 10 and 12 depicts the non-dimensional (V/D and W/D respectively) plots of vortex size variations with spike-nose configurations and different l/D-ratio around the nose and wake region. The ordinates of these graphs represent the non-dimensional lengths and the abscissa represents the type of spike-nose.

Considering the vortex-size variation around the nose, the representative and optimum l/D-ratio has been estimated to be 1.5 for the present case of Reynolds number. From Figure 10, it can be seen that a conical aerospike, irrespective of l/D-ratio, is incapable of generating vortices near the spike root, whereas a hemispherical spike reduces the zone of influence drastically (bringing the deflected flow near the shoulder). This may be envisaged as a direct indication of reduced positive pressure over the nose of the basic body. The generation of the vortices near the spike root results in low pressure recirculation region which attracts the deflected flow thereby keeping it near the shoulder. The radius of curvature of the approaching streamline is reduced; the deflection of the streamline is towards the shoulder of the basic body,

resulting in a narrow zone of the positive pressure hill at the nose. Therefore, integral of this positive pressure over the nose assumes lesser magnitude, compared to the positive zones for the spikes with conical or flat face, resulting in relatively smaller drag.

The wake-region behind the forebody is directly influence by the magnitude of the pressure on its nose and the deflection of the flow. The higher the magnitude of positive pressure on the nose, the stronger the deflection and larger the wake region, consequently resulting in increased drag. Figure 11 focusses on the flow field showing the wake region with (l/D=2.0) and without spikes and Figure 12 quantifies the magnitude of the vortex lengths by taking an average of the left and the right vortices (depicted in Fig. 11), generated on either side of the midspan, to avoid inaccuracy in case the wakes are not symmetrical. The equivalent vortex length is given by $\{(W_{right}+W_{left})/2\}$, which is plotted as a non-dimensional length (W/D) against the spike type for various l/D-ratios. From Figure 12, it can concluded that a spike (a forward-facing object in front of the nose), irrespective of its nose-type or size, is capable of reducing the low pressure void behind the forebody by significantly affecting the flow physics. For l/D=0.5, the deflection provided by the spike to the flow remains considerably away from the body and cannot reach the wake region inspite of the existing large suction zone at the base. Similar is the case with a conical spike, which provides large radius of deflection to the streamline. For a flat-faced spike, the radius of deflection gets reduced, resulting in lesser confinement zone of the wake vortices, where as hemispherical spike stands a sole candidate capable of positively affecting the wake region, and simultaneous reduction in drag.

About the practical application, considering the physics of flow around nose as well as base vortices, simultaneous action on both will provide the best solution for minimization of drag offered. This has been proved to be the function of forebody dimensions, flow velocity (Reynolds number) and spike configurations, which will hold its importance in deciding its utility for use in hypersonic conditions.

5 UNCERTAINTY ANALYSIS

The velocity of the uniform flow in the water channel, before the conduct of the experiments, was measured by floating-particle method, by placing a small bit of paper on the surface of the flow and noting the time taken to traverse the length of the test-section. A set of 5 readings were taken, and the cumulative average of the same is taken as the representative value for the particular test case to calculate the flow Reynolds number, for this research to be conducted at Reynolds number 3170. The error in the measurement of the velocity was estimated to be within ±4%. The accuracy in the evaluation of characteristic lengths of the vortex zones from the captured videos near the nose and at the base, at a conservative estimate of ±2 pixels, stood at ±5%.

6 CONCLUSIONS

Flow around a blunt-nosed body without spike and with spike with different nose-configurations and varying spike length/body-nose-diameter ratios were visualized using a water flow channel. The vortices near the stagnation area of the spiked body and in the wake region were captured in the visualization. The flow field clearly exhibits the vortex characteristic lengths *V* and *W*. These parameters were measured by projecting the visualization pictures on a screen, for all the models studied. The results clearly show that, hemispherical nosed spike is a potential candidate from drag reduction point of view compared to the conical and flat nosed spikes. It is found that, there is a specific length-to-diameter ratio for every spike nose-configuration, resulting in the largest vortex at the spike base, at a given Reynolds number. Furthermore, the dependence of vortex at the base of the body has also been found to be a strong function of length-to-diameter ratio for spikes for the current low-speed incompressible flow. Larger the *l*/*D*-ratio weaker will be the vortices at the base and smaller will be the confinement zone of the wake region.

7 ACKNOWLEDGMENT

The authors would like to thank Mr. Yusuke Izumi for the help with the working of the Rapid prototyping machine and to Mr. Yasumasa Watanabe for the support extended with the preparation of the logistics during the conduct of the experiments.

Excitation mechanism of rain-wind induced vibration of cables: unsteady and nonlinear aspects

Teng Wu [a], Ahsan Kareem [a], Shouying Li [b]

[a] *Nathaz Modeling Laboratory, University of Notre Dame, Notre Dame, IN, USA*
[b] *Wind Engineering Research Center, Hunan University, Changsha, China*

ABSTRACT: Two aerodynamic effects, i.e., unsteady and hysteretic behavior on the water rivulet along a stay cable are considered in the proposed analytical models for rain-wind induced vibration (RWIV). Neither the unsteadiness nor hysteresis can be considered using conventional quasi-steady (QS) model. The new analysis framework is also convenient to effectively take into account the turbulence effects in RWIV. Besides, the higher-order spectrum is utilized to detect the potential nonlinear interactions in RWIV. Numerical examples for unsteady and hysteretic considerations are illustrated based on the wind-tunnel data. The results are compared with the QS results.

KEYWORDS: Rain-wind induced vibration; Unsteadiness; Nonlinearity; Higher-order spectrum

1 INTRODUCTION

Among various wind-induced vibrations of cables of cable-stayed bridges (such as ice galloping, Karman vortex shedding induced vibration, wake induced vibration, vortex-induced oscillation at high wind velocity, rain-wind induced vibration (RWIV) etc.), RWIV is significant due to its large amplitude, frequent occurrence and low critical wind speed. Since the first observation of this phenomenon during the construction of a cable-stayed bridge (Hikami and Shiraishi 1988), focus has been on this topic to better understand and model these vibrations.

Though considerable research effort has been made, no consensus exists regarding the underlying mechanism due in part to the extremely complex nature of the gas-liquid-solid interaction. On the other hand, agreement exists among researchers regarding the formation of rivulet on the cable surface due to the rain and the attendant axial flow formation (Matsumoto et al. 2005) as two main factors responsible for RWIV. Predictive models have been established based on the quasi-steady (QS) assumption (e.g., Gu et al. 2009), where the rivulet formation on the cable is regarded as a dominant excitation factor. The QS assumption obviously leaves room for improvement due to extremely complicated flow field around the rivulet. For example, observation in wind tunnel has pointed out that the rain-wind induced vibrations have the self-excited characteristics (Verwiebe and Ruscheweyh 1998).

In this paper, the unsteady effect is considered with a scheme parallel to Scanlan's analysis framework of self-excited forces on bridge decks (Scanlan and Tomko 1971). The aerodynamic coefficients in the proposed unsteady model are first identified in the wind tunnel based on the measurement of the oscillatory pressure. On the other hand, RWIV is well recognized as a nonlinear interaction between the solid, liquid and air. However, neither the QS model, which is able to simulate static nonlinearity, nor the developed unsteady model, which is able to simulate the linear fluid memory effect, can take into account the hysteretic (dynamic) nonlinearity with the higher-order memory effect in the RWIV. As a result, a new analytical model based on the Moore-Penrose pseudoinverse identification scheme is developed to capture the nonlinear hysteretic aerodynamics of RWIV in this paper. A detailed discussion is given in the end of this paper to investigate the excitation mechanism of RWIV.

2 ANALYTICAL MODELS

This paper focuses on the analysis of the RWIV in plane, the consideration of the out-of-plane coupling effect is referred to the research work by Li et al. (2011).

2.1 *Conventional Quasi-Steady Model*

The basic assumption of the QS theory is that the wind velocity should be high enough where the unsteady aerodynamic forces acting on a oscillating structure could be modeled by utilizing the steady-state situation without the fluid memory consideration. Actually, an underlying assumption is that it is convenient to define the steady-state situation of the aerodynamic system (Van Oudheusden 1995). The main reason that the simulation fidelity is usually degraded as the QS model is applied to the torsional oscillation case is bacause it is intractable to define a steady-state situation for the torsional case as each point of the cross section has a different local relative angle of attack. Though it is never explicitly stated in the literature, the basis of the applicability of the QS assumption in the RWIV, where the torsional motion is critical, is that: (1) for the cable only one local relative angle of attack is sufficient to define the steady state of the cable since the rotational motion is uniquely determined by the rivulet position and (2) for the rivulet the rotational center is far from the geometric center where the situation approaches the translational case.

The QS based scheme recently developed treats the rivulet-cable system as a coupled one. A two dimensional model is applied to simulate the motions of cable and rivulet based on QS assumption. The coupled equations of motion are given as (Gu et al. 2009)

$$\ddot{y} + 2\xi_y \omega_y \dot{y} + \omega_y^2 y = -F_y / M \tag{1a}$$

$$m\left(\frac{D}{2}\right)\ddot{\theta} + F_0 sign(\dot{\theta}) + c_r\left(\frac{D}{2}\right)\dot{\theta} = F_r + m\ddot{y}\cos(\theta) - mg\cos(\varphi)\cos(\theta) \tag{1b}$$

where M is the mass per unit length of cable; y is the vertical displacement of cable; and ω_y and ξ_y are circular frequency and damping ratio of the cable, respectively; m is the mass per unit length of upper rivulet; θ is the position of the rivulet; c_r and F_0 are the linear damping coefficient and the Coulomb damping force between the rivulet and cable surface; and φ is the cable inclined angle; the aerostatic forces F_y and F_r are obtained based on QS assumption, which could be represented as

$$F_y = \frac{1}{2}\rho D U_{rel}^2 \left[C_L(\phi')\cos(\phi) + C_D(\phi')\sin(\phi)\right] \tag{2a}$$

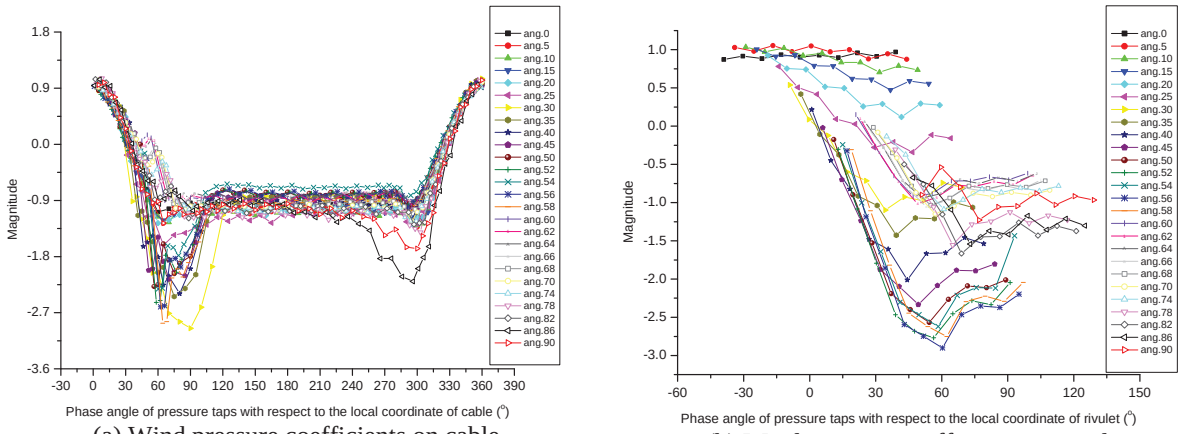
$$F_r = \frac{1}{2}\rho R U_{rel}^2 \left[c_l(\phi')\cos(\phi') + c_d(\phi')\sin(\phi')\right] \tag{2b}$$

where D and R are the characteristic sizes of the cable and upper rivulet, respectively; ρ is the air density; C_L and C_D are lift and drag force coefficients of the cable, respectively; c_l and c_d are lift and drag force coefficients of the upper rivulet; ϕ represents the angle between relative wind velocity and x axis; and ϕ' the angle between relative wind velocity and position of upper rivulet.

2.2 *Unsteady model of RWIV*

The aerodynamic forces on the cable may be modeled well based on QS assumption since the RWIV usually happens at a high reduced wind velocity. However, the QS assumption is not appropriate for the upper rivulet since the flow around it usually becomes very unsteady, which could be observed form the intense changes of the pressure coefficients around the rivulet with

various locations, as shown in Fig. 1, where the data is obtained from the wind tunnel tests to be discussed in the following section. As indicated in the figure of wind pressure coefficients on cable, in the range of 25° to 58° for the angles of attack (also rivulet position) there is large difference between the pressures of the points before and after the rivulet, which may indicate the flow separates around the rivulet. After this range, the difference is gradually decreasing with respect to the increasing of angle of attack, which indicates the flow separates before the rivulet. The similar observation is also reported in recent literature (Gu et al. 2009). The wind pressure coefficient on rivulet further consolidates this observation. As indicated in the figure of wind pressure coefficients on rivulet, in the range of 25° to 58° for the angles of attack (also rivulet position) there is large difference between the pressures of the two portions of points on rivulet which are on windward side and on leeward side. The CFD results obtained from Direct Numerical Simulation (DNS) also show the similar behavior of flow around the rivulet (Li and Gu 2006). As indicated in the CFD results, the flow separates at the point of rivulet for both large and small angles of attack. However, when the angle of attack is small, the separation will reattach soon. This phenomenon is difficult to observe in the wind pressure coefficient results.



(a) Wind pressure coefficients on cable

(b) Wind pressure coefficients on rivulet

Figure 1. Wind pressure coefficients on cable and rivulet with different angles of attack.

These observations represent the extremely complicated interaction of the wind-rivulet-cable system especially around the rivulet. However, the averaged aerostatic force cannot take into account the unsteady effect since there is little discrepancy between lift and drag coefficients of the static and oscillatory situations. As a result, a more advanced unsteady model for RWIV is proposed in this paper. The unsteady aerodynamic load on the rivulet is represented as

$$F_r^u = \frac{1}{2}\rho R U^2 \left[c_d(\theta_0)\sin(\theta_0) + c_l(\theta_0)\cos(\theta_0)\right] + \left[-L\cos(\theta_0) + D\sin(\theta_0)\right] \tag{3}$$

$$L = \frac{1}{2}\rho U^2 (2R)\left[K_y H_{R1}^*(K_y)\frac{\dot{y}}{U} + K_{\tilde{\theta}} H_{R2}^*(K_{\tilde{\theta}})\frac{\dot{\tilde{\theta}}R}{U} + K_{\tilde{\theta}}^2 H_{R3}^*(K_{\tilde{\theta}})\tilde{\theta} + K_y^2 H_{R4}^*(K_y)\frac{y}{R}\right] \tag{4a}$$

$$D = \frac{1}{2}\rho U^2 (2R)\left[K_{\tilde{\theta}} P_{R2}^*(K_{\tilde{\theta}})\frac{\dot{\tilde{\theta}}R}{U} + K_{\tilde{\theta}}^2 P_{R3}^*(K_{\tilde{\theta}})\tilde{\theta} + K_y P_{R5}^*(K_y)\frac{\dot{y}}{U} + K_y^2 P_{R6}^*(K_y)\frac{y}{R}\right] \tag{4b}$$

where F_r^u represents the wind induced force on the rivulet using unsteady theory; θ_0 means the equilibrium potion of rivulet and $\tilde{\theta} = \theta - \theta_0$ is the dynamic circumferential displacement of rivulet on the cable; H_{R1}^*, H_{R2}^*, H_{R3}^*, H_{R4}^*, P_{R2}^*, P_{R3}^*, P_{R5}^* and P_{R6}^* are aerodynamic coefficients

(flutter derivatives) with respect to the reduced frequency $K_y = \omega_y R/U$ or $K_{\tilde{\theta}} = \omega_{\tilde{\theta}} R/U$. These aerodynamic coefficients play transfer-function roles in this unsteady model, e.g., H_{R1}^* takes into account the lift force exerting on the rivulet induced by the velocity of vertical vibration. In the case of bridge deck, usually some aerodynamic coefficients are negligible, e.g. the value of aerodynamic coefficient H_4^* of the vertical displacement is very small comparing to other aerodynamic coefficients because the aerodynamic stiffness is extremely small comparing to the bridge deck stiffness. However, this conclusion cannot apply to the RWIV system since the stiffness of rivulet is negligible as mentioned in the proceeding content.

2.3 *Nonlinear hysteretic model*

Recently, the nonlinear hysteretic behavior of bridge aerodynamics is observed and analyzed (Diana et al. 2010). Similar to the bridge deck, intense hysteretic behavior is observed in the wind-rivulet-cable interaction, which indicate that the higher-order memory in the wind-rivulet-cable system is another indispensable effect. Typically, the steady-state aerodynamic coefficients are modeled by a nonlinear polynomial in terms of the angle of attack. However, the hysteretic behavior can be best described by higher-order (nonlinear) polynomial involving the dynamic angle of attack (Resulting from turbulence components and deck motions) and its derivative, e.g. (Wu and Kareem 2012),

$$c_l^{hyst}(\tilde{\theta},\dot{\tilde{\theta}}) = \sum_{j,k}^{n} \eta_{j,k} \tilde{\theta}^j \dot{\tilde{\theta}}^k \tag{5}$$

where subscript "l" represents "L", "D" or "M", which denotes coefficients related to lift, drag and pitch, respectively; $\eta_{j,k}$ is the coefficient corresponding to $(j+k)^{th}$-order term; 2n is the highest order of the polynomial possible to parsimoniously model hysteretic behavior. The actual order of the model depends on the data used for fitting and the identification scheme used. Besides, the contributions of some of the terms in the polynomial may be negligible which leads to simplified expression. For example, for the lift coefficient of a stay cable of a cable-stayed bridge, the following model can represent the hysteretic behavior:

$$c_L^{hyst}(\tilde{\theta},\dot{\tilde{\theta}}) = \left[c_L(\theta_0)\right] + \eta_{0,0} + \eta_{1,0}\tilde{\theta} + \eta_{0,1}\dot{\tilde{\theta}} + \eta_{2,0}\tilde{\theta}^2 + \eta_{1,1}\tilde{\theta}\dot{\tilde{\theta}} + \eta_{3,0}\tilde{\theta}^3 + \eta_{4,0}\tilde{\theta}^4 \tag{6}$$

where the steady-state coefficient $c_L(\theta_0)$ corresponding to the equilibrium position is extracted from the constant term in order to emphasize the difference between the steady-state and the hysteretic cases.

3 PARAMETER IDENTIFICATION

3.1 *Wind tunnel test set-up*

The 'artificial' rivulet is applied in the wind tunnel test set-up since the pressure on the rivulet will be measured. Only the upper rivulet is simulated. The end plates are installed at each end of the two dimensional rigid cable to control the end flow condition. The rigid cable is mounted inside the wind tunnel to form a closed type test condition, which is presented in Fig. 2. Negligible turbulence is generated in the incoming laminar flow. The overall steady wind force on the cable-rivulet system and the pressures on cable and upper rivulet surfaces are measured under the forced pitching and plunging vibrations. The frequency of both pitching and plunging vibrations is 1 Hz. The double-amplitudes are 4 mm for pitching and 10 degrees for plunging. There are total four sections of the rigid cable in which the pressure taps are installed, and 63 pressure taps for each section. The position of these pressure taps is defined by the angle ψ, which is deter-

mined from the stagnation point to the center of taps. Since the pressure on the rivulet will be recorded, the sizes of rivulet and the corresponding cable are amplified comparing to the ones in the real world. The rigid cable is made of acryl glass with the diameter of 350 mm and the length of 1540 mm while the rigid rivulet is made of polyethylene. The shape of the rivulet is one section of arc of 42 mm which belongs to a circle with a 25 mm radius. The schematic illustrations of the test section coordinates, the rivulet and pressure holes positions, and the rivulet and cable sizes are presented in Fig. 3. The angle θ represents the position of upper rivulet and α the relative angle of attack induced by vertical motion of cable.

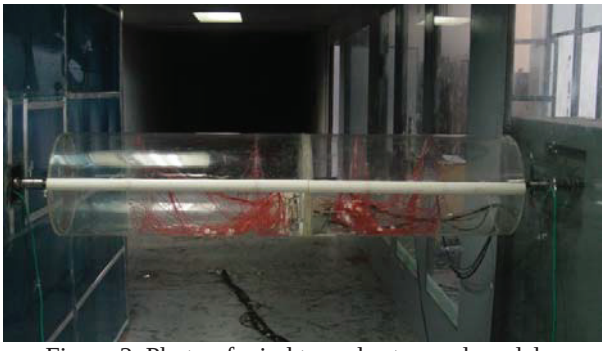


Figure 2. Photo of wind tunnel setup and model.

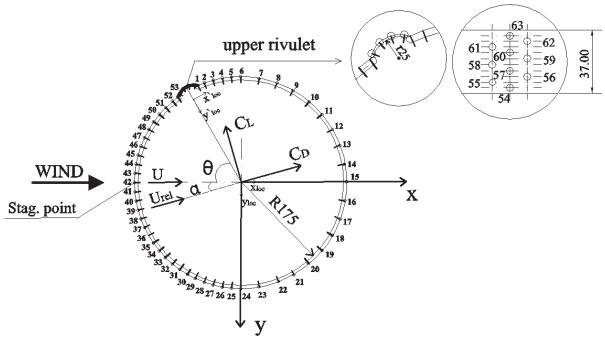

Figure 3. Coordinate system and arrangement of pressure taps.

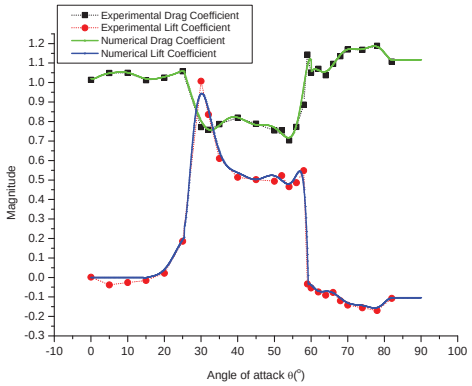
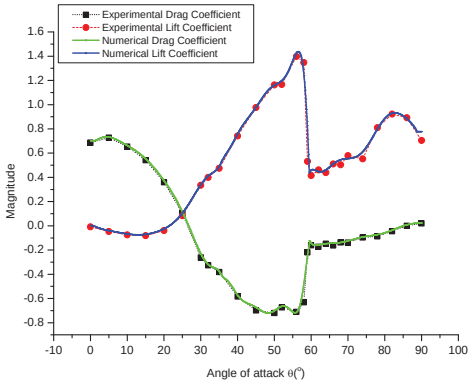
3.2 *Steady-state coefficients utilized in quasi-steady model*

The steady-state coefficients for cable and rivulet are measured through wind tunnel experiment and shown in Fig. 4. In order to conveniently obtain their derivatives in terms of the angle of attack, which will be used in the calculation of RWIV, both of them are fitted using nonlinear least square technique.



(a) Steady-state coefficients of cable



(b) Steady-state coefficients of rivulet

Figure 4. Experimental and numerical steady-state coefficients.

3.3 *Aerodynamic coefficients utilized in unsteady model*

The scheme based on the measurement of the oscillatory pressure is applied to extract the aerodynamic coefficients of the rivulet. A detailed validation procedure for the identified aerodynamic coefficients are carried out. For example, in order to validate the identification results based on pressure measurement, the forced oscillation scheme is also utilized for the cable. Fig. 5 shows

the identified aerodynamic coefficients (only aerodynamic coefficients for the lift force are presented here) of the upper rivulet. As shown in Fig. 5, the aerodynamic coefficients vary tremendously with respect to the wind angle of attack (e.g., the position of rivulet). The values of these aerodynamic coefficients become very large in the range of 58^{o}-62^{o}, which indicates the intense unsteady load in this range. This range is critical for RWIV since the existing of large negative slope of the life coefficient of cable which induced the large amplitude oscillation based on the galloping theory. Besides, the aerodynamic coefficient H_4^* of the vertical displacement is not negligible comparing to other aerodynamic coefficients, which indicates the large difference with bridge system. If the aerodynamic coefficients are presented utilizing Zasso's form (Zasso 1996), the identified aerodynamic coefficients per se straightforwardly show the intensive unsteadiness of the aerodynamic forces on the rivulet in the wind velocity range of interest.

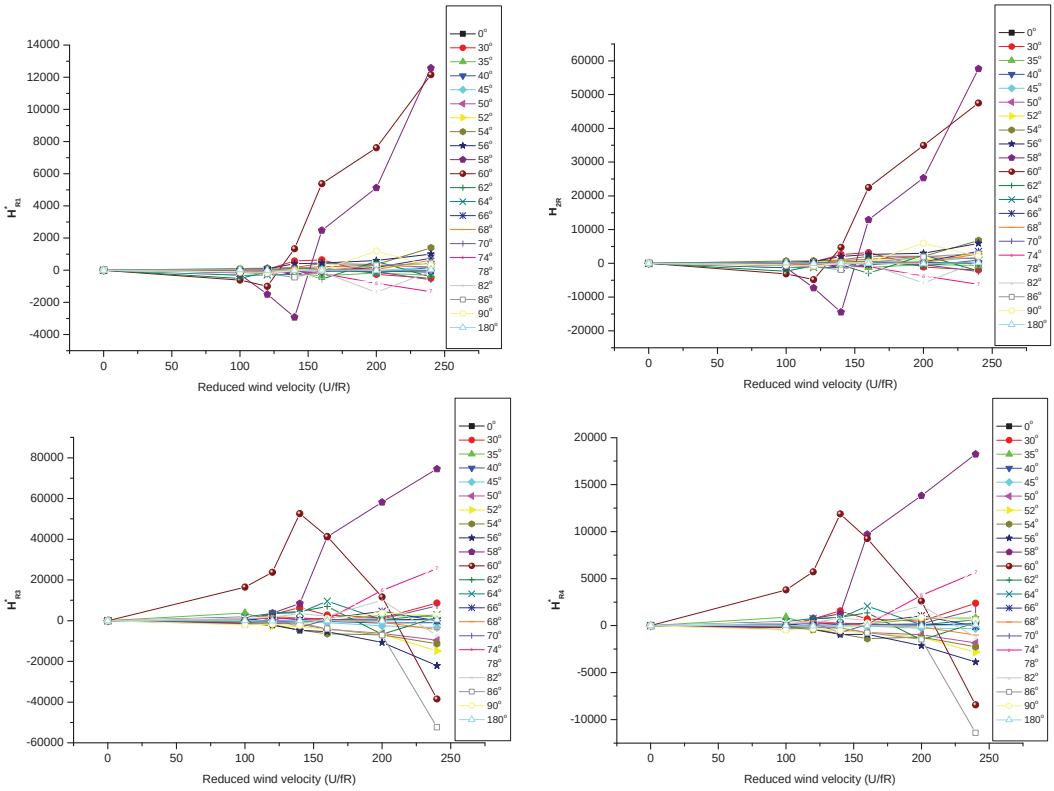


Figure 5. Identified aerodynamic coefficients for upper rivulet.

3.4 *Hysteretic loop utilized in nonlinear hysteretic model*

The Moore-Penrose pseudoinverse scheme is applied to identify the coefficients of the hysteretic numerical model. The hysteretic behavior in terms of steady-state coefficients and the numerical simulation results are shown in Fig. 6 (here only the lift coefficient are presented) at some certain reduced wind velocity. Because the facility in the wind tunnel can only oscillate with the maximum double-amplitude 10^{o}, the results shown in these figures are limited consideration of nonlinear hysteretic phenomenon of the RWIV.

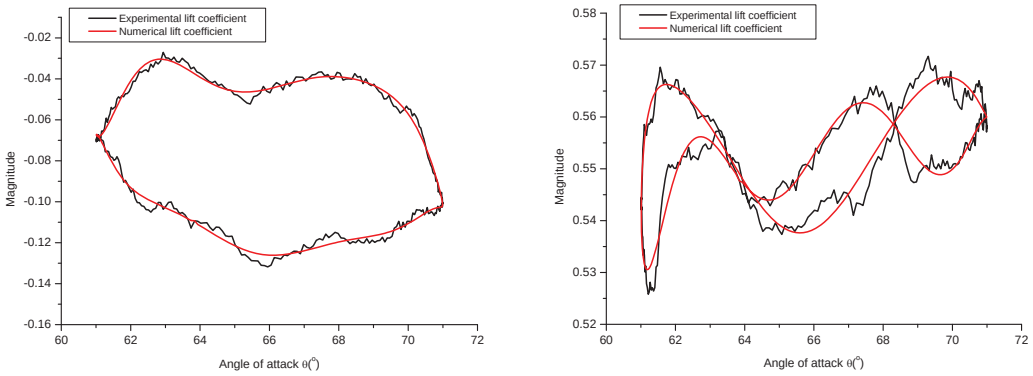

Figure 6. Hysteretic simulation of (a) cable and (b) rivulet (θ0=66o).

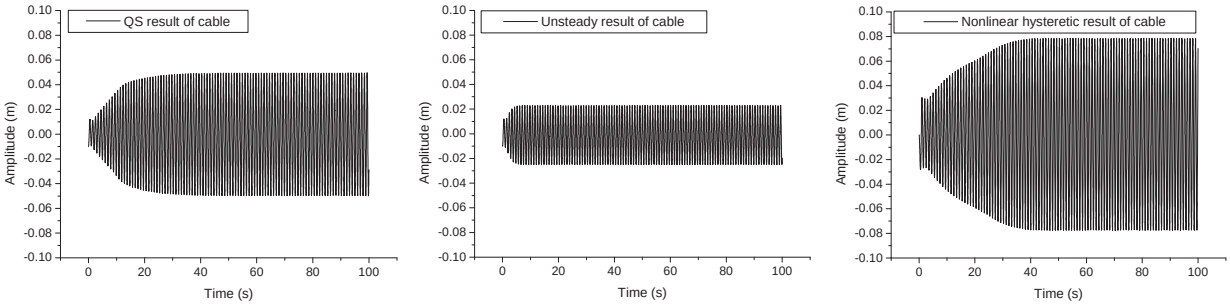
4 NUMERICAL EXAMPLE

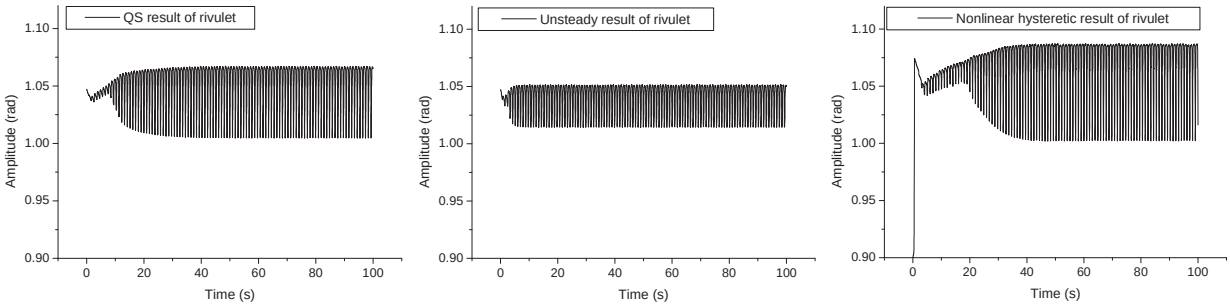
The rivulet-cable model used in the numerical example is described in the proceeding section. Besides, the natural frequency of the cable is set the same with the frequency of forced vibration for aerodynamic coefficients identification. The mass and damping ratio of cable are 6 kg per unit length and 0.001, respectively. The linear damping coefficient and the Coulomb damping force between rivulet and cable are set as 0.0008 N·s/m^2 and 20% of the weight of rivulet, respectively. The mass of rivulet is set 0.0098 kg per unit length according to the density of water and the assumed area of the upper rivulet on the cable. Moreover, the reasonable range of the circumferential motion of rivulet is assumed between 0 to π/2. For the unsteady model, the equilibrium position needs to be determined firstly. The equilibrium position of the rivulet on the cable based on the QS model is utilized in this example. Although the equilibrium position based on QS assumption is somehow different with the observation in the wind tunnel, fortunately the results of unsteady model proposed in this paper are not sensitive to the equilibrium position of rivulet. As long as this equilibrium position in a reasonable range, the calculation of this unsteady model will converge to the same result. The equilibrium position of the rivulet on the cable based on the QS model could be replaced in the proposed unsteady model if reliable data based on the wind tunnel results are available. Some reliable records using an ultrasonic transmission thickness measurement system (UTTMS) are given in recent literature (e.g., Li et al. 2010).

A range of wind velocities are calculated for the RWIV utilizing these three models. The calculation responses of the cable based on the QS, unsteady and nonlinear hysteretic models at the wind velocity 9.5 m/s are shown in Fig. 7 while the responses of the rivulet are presented in Fig. 8.



(i) QS model (ii) Unsteady model (iii) Nonlinear hysteretic model

Figure 7. Comparison of calculation results of the cable based on various models.



(i) QS model (ii) Unsteady model (iii) Nonlinear hysteretic model

Figure 8. Comparison of calculation results of the rivulet based on various models.

As shown in this figure, the vibration behaviors of the cable and rivulet obtained from QS, unsteady and nonlinear hysteretic models are similar while the vibration amplitude of unsteady results is smaller and the vibration amplitude of nonlinear hysteretic results is larger compared with the calculation based on the QS model. This comparison indicates that the linear unsteadiness will alleviate the RWIV while the nonlinear hysteretic behavior will intensify the responses of the rivulet-cable system.

Fig. 9 shows the comparison of the amplitudes of cable and the wind velocity range in which the large limited amplitude oscillation appears between numerical results based on QS and unsteady models (here the comparison with nonlinear hysteretic results are not presented due to the large number of computational work). As indicated in the figure, both of these models could obtain wind velocity limited and amplitude limited results. The limited wind velocity is almost the same for these two models while the limited amplitude obtained from unsteady model is just half of the one obtained based on QS model.

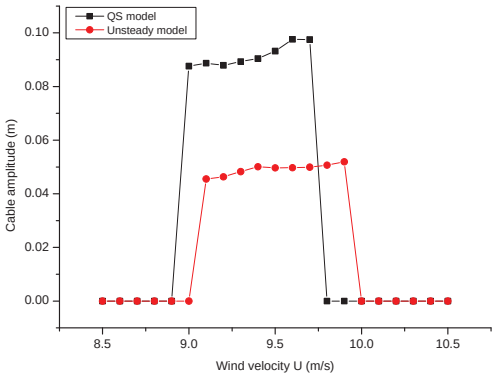


Figure 9. Comparison of cable responses based on QS and unsteady models.

It should be noticed that the oscillation frequency of the rivulet is set to be 1 Hz during the calculation process. In other words, the reduced frequency K_y and $K_{\tilde{\theta}}$ are not changed under a certain wind velocity. A more sophisticated procedure involving iterative calculation may give the unsteady results with higher accuracy, in which the oscillation frequency of the rivulet is treated as an unknown. However, based on the experience of the flutter analysis on bridge deck, this simplification will change the result negligibly. This unsteady model mainly focuses on the investigation of the wind induced force on the rivulet, while other parameters of the motion of rivulet especially the Coulomb damping force is very important and needed to be investigated in the future research.

Besides, although the turbulence has significant effect on the motion of the rivulet-cable system, this effect has not been well understood to date. It is challenging to take into account the

turbulence effect reasonably and conveniently based on the conventional QS model. On the other hand, this proposed unsteady model could effectively calculate the turbulence effect based on the hybrid scheme proposed by Chen and Kareem (2003). As the aerodynamic coefficients identified in the turbulent condition are available the effect of turbulence could be taken into account immediately with this proposed unsteady model.

5 DISCUSSION

One of the main features of RWIV is that the vibration is wind velocity and amplitude limited. Based on the observation of the lift coefficient curve, the mechanism of galloping is a reasonable explanation of RWIV phenomenon. Under this assumption, the effective cross-section of cable or the circumferential motion of rivulet on the cable is critical to the RWIV. Current coupling model based on the QS assumption successfully reproduce the wind velocity and amplitude limited characteristics of RWIV (e.g., Gu et al. 2009). However, it is not difficult to reproduce this "limited" property of RWIV regardless of the motion of rivulet. For example, with the assumption of the rivulet vibrating as a harmonic or a narrow banded stochastic process, the obtained results also present the "limited" feature in a similar range of wind velocity and with the same order of the magnitude of vibrating amplitude. Since the amplitude of RWIV is very sensitive to the test conditions (Gu and Du 2005), there is no strong evidence to support the superiority of any of these mentioned models with respect to reproducing the RWIV phenomenon.

Furthermore, even if the rivulet rests on the cable at the equilibrium position, which belongs to the classical galloping class, the calculation results of the example in this paper show that at the same range of wind velocity, the magnitude of the limited amplitude is in the same order as the harmonic/stochastic/QS results. Since the equilibrium position of the rivulet is changed as the wind velocity increasing, only in a certain range of wind velocity the position of rivulet is in the negative slope range of the lift coefficient where the large amplitude vibration occurs. The relatively small magnitude of the vibration amplitude for this "classical" galloping may result from the extremely narrow range of the negative slope of the lift coefficient. Assuming the cable vibrating harmonically, the amplitude of velocity of the cable, which contributes to the "relative" angle of attack, will be the amplitude of the displacement multiplied by the vibrating frequency. As a result, as the amplitude of the vibration increases, the "total" angle of attack is very easy to escape out of the negative slope range, especially for the large vibrating frequencies or high modes.

The higher-order spectrum could be utilized to analyze the data in RWIV (Wu and Kareem 2012). It is shown that there are intense nonlinear coupling and interactions that exist in RWIV. The harmonic distortion and super-harmonic (or sub-harmonic) behaviors could be a potentially convincing illustration of the appearance of the lower or higher frequency components in the aerodynamic forces on the cable or rivulet, where usually the axial flow theory is utilize (Matsumoto et al. 2005).

The current state of the art for the RWIV cannot predict the wind velocity range in which the large amplitude oscillation appears and the amplitude of the limited cycle oscillation with high accuracy. The main reason may be the inaccurate simulation of the forces exerting on the rivulet, which is the primary motivation of this research. The main objective of this paper is to reveal the mechanism of RWIV, especially the aerodynamic forces exerting on the rivulet. The effort of simulating the forces exerting on the rivulet with high fidelity is a promising venue of research to improve predictive capability of RWIV. The proposed unsteady model and nonlinear hysteretic model are more advanced and necessary. Other forces exerting on the rivulet especially the Coulomb damping force is also very important and needs to be investigated in the future research.

6 CONCLUDING REMARKS

It is shown that the flow around the rivulet in the rivulet-cable system is extremely complicated. Current model to calculate the rain-wind induced vibration (RWIV) is mainly based on the quasi-steady (QS) assumption, which is probably not appropriate for the circumferential motion of the rivulet on the cable. The unsteady model which parallels Scanlan's analysis framework for the bridge aerodynamics and the nonlinear hysteretic model which utilizing the Moore-Penrose pseudoinverse identification scheme are proposed in this paper. Both of these new models could take into account the unsteady effect of the aerodynamic forces exerting on the rivulet. Besides, the turbulence effect could be reasonably and conveniently considered with the unsteady model. The aerodynamic coefficients are identified based on the measured oscillatory pressure data. To the authors' knowledge, this is the first time that the aerodynamic force coefficients of rivulet are identified in the literature. The results of the QS, unsteady and nonlinear hysteretic models are significant different with each other. This comparison indicates that the linear unsteadiness will alleviate the RWIV while the nonlinear hysteretic behavior will intensify the responses of the rivulet-cable system. The unsteady aspects of the aerodynamic load on the cable are not considered in this paper for the sake of simplicity, however, it is straightforward to incorporate this effect in the proposed models.

ABSTRACT: This paper combines experimental study and CFD simulation together to investigate the influence of dynamic properties and position of rivulet on rain-wind induced vibration (RWIV) of stay cables. The reproduction of the RWIV of a stay cable model is firstly carried out based on an artificial rainfall wind tunnel tests with an ultrasonic transmission thickness measurement system (UTTMS), which can obtain the characteristics of rivulets on the surface of the stay cable model. Based on the test results, the CFD simulations are next employed to study the aerodynamic influence of upper rivulet using different CFD models: the vibrating cable model with the moving upper rivulet and the vibrating cable model with the fixed upper rivulet. CFD simulations suggest that the existence of the upper rivulet do not sufficiently to excite RWIV. CFD simulations indicate that the presence of upper rivulet in certain region can significantly vary the aerodynamic force acting on cable. When the upper rivulet oscillates is in this specific range with the same frequency of cable, the aerodynamic resonant excitation will induce the occurrence of RWIV.

KEYWORDS: Stay cables, rain-wind-induced vibration, ultrasonic transmission thickness measurement system, CFD simulation, artificial rainfall wind tunnel tests and upper rivulet.

1 INTRODUCTION

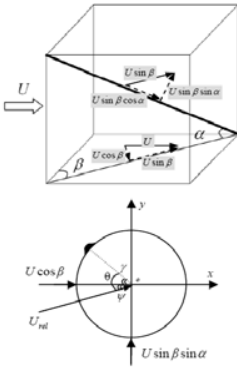
Many studies have been carried out for the rain-wind induced vibration (RWIV) phenomenon in the past two decades through field measurements (Hikami and Shiraishi, 1988; Matsumoto *et al*, 2003a; and Zuo & Jones, 2010), wind tunnel tests (Matsumoto *et al*, 2003b; Flamand, 1995; Gu and Du, 2005, Cosentino *et al*, 2003), and theoretical analyses (Yamaguchi, 1990; and Peil, 2003). Study results indicate that water rivulet vibrations around the stay cable play a key role when RWIV occurs, indicating that it is necessary to investigate the characteristics of water rivulets around cables. Li *et al*. (2010a) employed an ultrasonic transmission thickness measurement system (UTTMS) based on the UT technique to obtain rivulet information. The shape, thickness, equilibrium position, oscillation amplitude, and frequency of water rivulets are obtained from the reconstructed images of the circumferential water rivulet distribution. In this paper, two types of CFD models are established and computed to verify the effect of upper rivulet oscillation.

2 WIND TUNNEL TESTS OF RWIV WITH UTTMS AND RESULTS

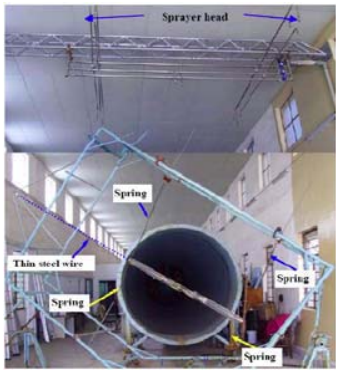
2.1 *Setup of experiment*

The wind tunnel test of RWIV of an inclined stay cable model is carried out in the TJ-1 atmosphere boundary layer wind tunnel located at Tongji University. The inclination angle of the cable

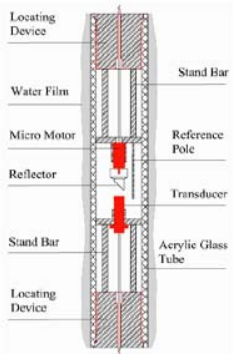
model α and the wind yaw angle β can be easily adjusted as shown in Figure 1(a). The length is 2.0 m and the diameter is 0.1 m for the cable model with a mass of 17.15 kg. The natural vibration frequency is 0.952 Hz and the damping ratio is 0.0017. The test measurement setup for the stay cable model with the UTTMS is shown in Figure 1 (b) and (c).

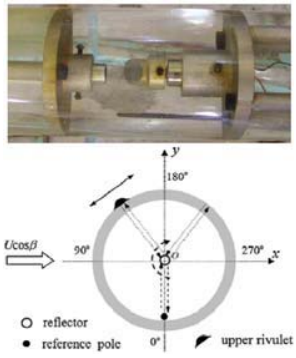


(a) Schematic diagram of the inclination angle



(b) Photograph of testing set-up of RWIV





(c) Assemblage of UTTMS

Figure 1. Test measurement setup with UTTMS (Li and Chen, 2010a)

2.2 *Dynamic characteristics of cable vibration*

The reduced velocity and Reynolds number are respectively defined as U/fD and UD/ν, where U and ν are the wind speed and kinematic viscosity of the air, respectively. The test conditions of RWIV of cable are listed in Table 1.

Table 1 Test conditions of RWIV of stay cable

Wind speed (m/s)	Reduced velocity	Reynolds number	Rainfall intensity (mm/h)	Inclination Angle (°)	Yaw angle (°)
6-10	63-105	$(3.8\text{-}6.4)\times10^5$	20-60	30	20-25

According to previous study (Gu and Du, 2005), a rainfall intensity of 30mm/h with the inclination angle of 30° for two test cases (the yaw angles of 20° and 22.5° for the first and second tests, respectively) is employed. The cross-flow displacement amplitudes of cable versus wind velocity are shown in Figure 2. It can be seen that the RWIV occurs over the range of 6.76-8.04 m/s.

The time history and frequency response of cross-flow displacement at the velocity of 6.76 m/s, 7.72 m/s and 8.69 m/s are shown in Figure 3(a), (b) and (c), respectively.

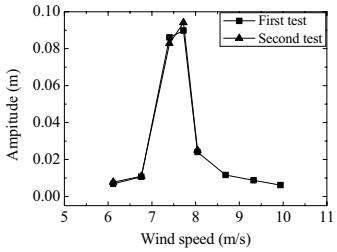


Figure 2. Amplitude versus wind speed

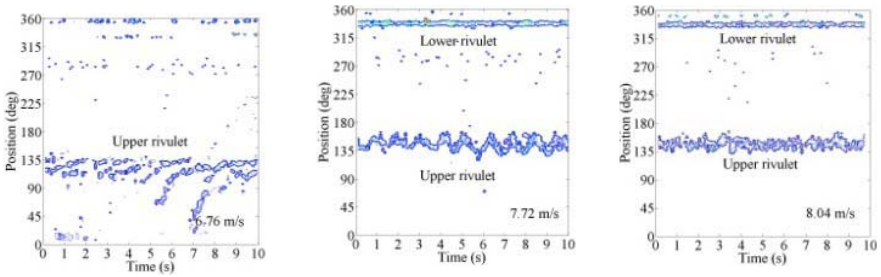
Figure 3. Time histories and frequency spectra of cable vibration

2.3 *Dynamic characteristics of water rivulets during RWIV*

Figure 4(a), (b) and (c) presents the water rivulets distribution on the surface measured by the UTTMS in the second test at the wind speeds of 6.76, 7.72 and 8.69 m/s, respectively. At the wind speed of 6.76 m/s, there are a number of continuous rivulets, while they do not flow along axial direction of the cable but slide to the windward side. At 7.72 m/s, the RWIV of the cable model occurs; at the same time, it can be seen that only one continuous upper rivulet forms and comes into a steady circumferential oscillation from Figure 4(b). The continuous lower rivulet also forms but barely moves in circumferential direction. As the wind speed continuously increases, no RWIV is observed, yet the upper rivulet still remains, but the steady circumferential oscillation of the upper rivulet gradually disappears as shown in Figure 4(c). Compared with Figure 4(b), the oscillation of the upper rivulet is quite different, i.e. one is disordered and unsystematic (Figure 4(c)), while the other is regular and behaves like a simple harmonic vibration (Figure 4(b)), although the state of the lower rivulet is almost the same.



(a) 6.76 m/s (b) 7.72 m/s (c) 8.69 m/s

Figure 4. Water rivulet contour along circumferential direction measured by UTTMS

Figure 5 obviously indicate when the RWIV occurs the upper rivulet oscillation behaves large amplitude with one dominant frequency which is the natural frequency of the cable at the velocity of 7.72 m/s. At the velocity of 8.69 m/s, the cable vibration is disordered with no dominant frequency.

3 TWO-DIMENSIONAL CFD SIMULATIONS OF CABLE MODEL WITH UPPER RIVULET

3.1 *One degree-of-freedom cable model with an oscillating upper rivulet*

A mechanical model of cable is established as shown in Figure 6. The upper rivulet is given a pre-programmed harmonic oscillation expressed in Eq. (1) with the frequency same as cable vibration. The cable is considered as a one degree-of-freedom vibrating system under the aerodynamic lift force, and its dynamic equation is given in Eq. (2).

$$\theta = \mathrm{a}\sin(\omega t) + \theta_0,\ \mathrm{a}=10^\circ \tag{1}$$

$$\ddot{y} + 2\xi\omega\dot{y} + \omega^2 y = \frac{\rho R U_{rel}^2}{m_c} C_L(\theta) \tag{2}$$

where y is the displacement of cable in cross-flow direction; θ is the relative position angle between flow direction and upper rivulet; and θ_0 is the relative equilibrium angle of upper rivulet. $\xi = 0.17\%$ is the damping ratio and $\omega = 2\pi \times 0.952 = 5.98\,\mathrm{rad}/s$ is the natural circular frequency. m_c is the mass per unit length of the tested cable section model, which equals to 8.575 $\mathrm{kg/m}$. $R = 0.05$ m is the radius of cable. The above parameters are the same as those of the cable model used in the wind tunnel tests. ρ is the air density. $C_L(\theta)$ is the aerodynamic lift coefficient automatically computed by the FLUENT, which is a function of the angle θ. From Figure 1(a), the U_{rel} can be calculated as Eq. (3) by taking $\alpha = 30^\circ$, $\beta = 20^\circ$ and $U = 7.5\,\mathrm{m/s}$ which is in the range where RWIV occurs.

$$U_{rel} = \sqrt{(U\sin\alpha\sin\beta)^2 + (U\cos\beta)^2} = 7.16\ \mathrm{m/s} \tag{3}$$

The upper rivulet is represented by a rectangle with the height of 2 mm and the width of 8 mm in CFD simulations. Figure 7 shows the grid partition and the size of the fluid field in the CFD model. The number of triangular cells is roughly 60,000, and the first grid normal to the cable surface is set as 0.5 mm. The boundary conditions are defined as follows: left side is "velocity inlet"; right-hand side is "pressure outlet"; upper and lower sides are "symmetry", the cable and upper rivulet are considered as two separating "wall" surfaces. The shear stress transport (SST) $k-\omega$ turbulent model based on the Reynolds-averaged Navier-Stokes (RANS) method is employed to simulate the turbulent behavior of the flow. The time interval is set as 0.001 s, and dynamic meshing is applied because both cable and rivulet are moving in the flow field. Eq. (2) is solved by a user defined function (UDF) based on Newmark method to obtain the displace-

ment which defines the location of cable and rivulet in the problem domain. Moreover, the UDF also defines the oscillation of upper rivulet on the cable surface through Eq. (1).

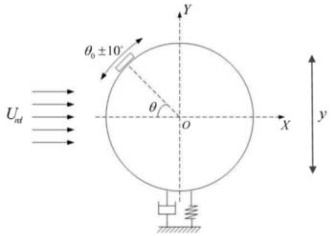

Figure 6. Dynamic model of vibrating cable with an upper rivulet

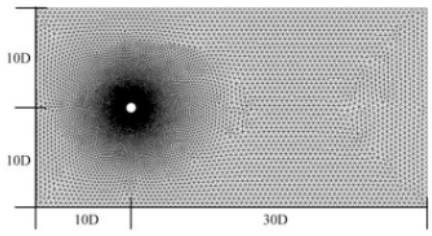
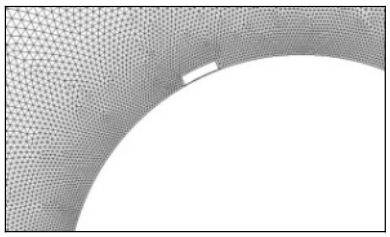


(a) Overall size of flow field (D=100mm)



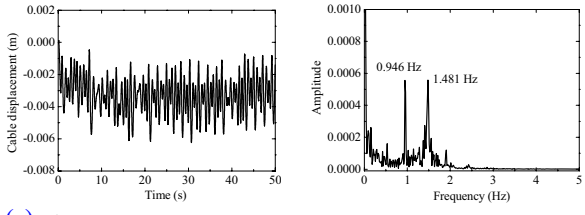
(b) Fractionate gain around the upper rivulet

Figure 7. Grid partition of CFD simulation

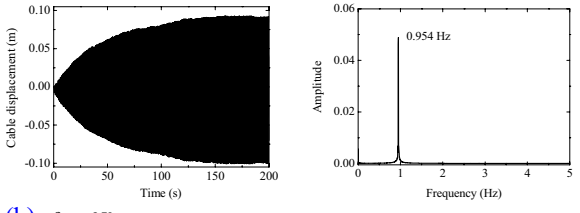
Three different conditions are chosen to study how the cable vibration is affected by different ranges of the oscillation of upper rivulet. The simulation results of the cases when equilibrium angles equal to 50°, 65° and 80°, are shown in Figure 8. In Figure 8(a) and (c), small vibrations with amplitude less than 5 mm are observed. Moreover, the displacement histories of the cable seem very random. Comparing with the large and systematic cable vibration captured in wind tunnel test (Figure 3(b)), CFD simulations indicate that RWIV does not occur when the relative equilibrium angles of upper rivulet is 50° or 80°.

A systematic and regular vibration of cable with large amplitude is only observed when the upper rivulet oscillates in the range of 55°-75° (Figure 8(b)). In this case, the amplitude increases to about 0.1 m when the vibration reaches its steady state, which agrees well with the observation in wind tunnel test (Figure 3(b)). Hence RWIV is also successfully reproduced by this CFD simulation with an upper rivulet oscillating harmonically in the same region.

The time histories and spectra of aerodynamic lift coefficients at the equilibrium angles of 50°, 65° and 80° are shown in Figure 9(a), (b) and (c), respectively. Since the amplitudes of lift coefficients are close, but the frequency components are different for three cases. When the equilibrium angles are 50°and 80°, the dominant frequencies do not include the natural frequency of the cable. But, for the equilibrium angle of 65°, the dominant frequencies are multiple of the natural frequency, also include the natural frequency. It is the mainly reason that the RWIV of the cable at this equilibrium angle can occur.



(a) $\theta_0 = 50^\circ$



(b) $\theta_0 = 65^\circ$

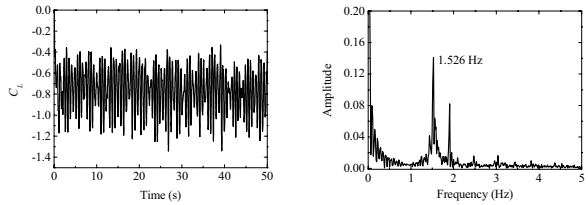
(c) $\theta_0 = 80^\circ$

Figure 8. Displacement response of the CFD cable model with an oscillating upper rivulet



(c) $\theta_0 = 80^\circ$

Figure 9. Lift coefficients of the model with an oscillating upper rivulet

3.2 *One degree-of-freedom cable model with a fixed upper rivulet*

Similar CFD simulations are conducted using almost the same set-up as moving rivulet case except that the UDF only solves Eq. (2) for the displacement of cable and rivulet while the relative location between cable and the upper rivulet is fixed. The displacement history of the cable vibration illustrated in Figure 10 shows no RWIV exists when the upper rivulet is fixed at the position of 50°, 65° and 80°. All give the similar results that the amplitudes of the vibrations are much smaller than that of the RWIV observed in wind tunnel tests and Figure 8(b).

The time histories and spectra of aerodynamic lift coefficients at the fixed position angles of 50°, 65° and 80° are shown in Figure 14(a), (b) and (c), respectively. The lift coefficients do not represent the natural frequency of the cable for all cases and cannot induce the RWIV of the cable.

4 CONCLUSIONS

The wind tunnel test with UTTMS and CFD numerical simulation are carried out to investigate the influence of dynamic properties and position of rivulet on rain-wind-induced vibration of stay cables. The comprehensive study presented in this paper draws the following conclusions:

1. The experimental results indicate that when the RWIV occurs, the upper rivulets regularly oscillate following the natural frequency with large amplitude. At other cases when the RWIV does not appear, the upper rivulet does not form (low velocities) or irregularly vibrate with no dominant frequencies with small amplitude.

2. CFD simulations suggest that the existence of the upper rivulet do not sufficiently to excite RWIV. In order to excite RWIV, the upper rivulet should not only oscillate, but also oscillate in a certain region with the same frequency as that of cable vibration.

Experimental study on the relation of water rivulet-Reynolds number effect-cable vibration

Qingkuan Liu, Yi Wang, Yunfei Zheng, Wenyong Ma

Wind Engineering Research Center, Shijiazhuang Tiedao University, 17 Northeast Second Inner Ring, Shijiazhuang, Hebei 050043 China

ABSTRACT: Rain-wind induced vibration of stay-cables is a worldwide problem of great concern in bridge engineering. In all factors that induce this vibration, water rivulet formed on cable surface in rainy and windy condition is considered as the most inportant one. Taking drag/lift force coefficients and vibration amplitudes in different Reynolds numbers as parameters, by wind tunnel tests, the influence of water rivulet on Reynolds number effect and mechanism of vibration caused by such facters were studied by means of force-measurement and vibration-measurement tests of stay-cable models with water rivulets attached in different positions. Resrults show that water rivulet has great influence upon changing rules of force coefficients with different Reynolds numbers; force coefficients value and changing rule have very close relationship with vibration.

KEYWORDS: stay cable; rain-wind induced vibration; wind force coefficients; water rivulet; Reynolds number

1 INTRODUCTION

Inclined cables often show violent vibration in rainy and/or windy days due to low structural damping. Among cable vibrations, rain-wind induced vibration is a worldwide problem, as its large amplitude and serious harm to cable-stayed bridges.

To make clear the mechanism and control methods of this vibration, by field observation[1-3],wind tunnel tests[4-11]and numerical analysis[12-13], reseach work have have been carried out for more than two decades, and galloping theory of water rivulet[4,14], high wind speed vortex induced vibration[5], water rivulet movement theory [6,7,9,15] have been put forward by different researchers.

In all the factors that induce this vibration, water rivulet formed on cable surface in rainy and windy condition is considered as the most inportant one, as it can change the cabel shape and wind force.

As we know that Reynolds number is a key parameter in study of fluid mechanics, particularly for the structures which have smooth surface, since flow fields around such structures vary with Reynolds number, as well as the aerodynamic force and vibration characteristics. In this research, from the viewpoint of Reynolds number effect, taking drag/lift force coefficients and vibration amplitudes in different Reynolds numbers as parameters, the influence of water rivulet on Reynolds number effect, the influence of Reynolds number on cable vibration were studied by means of force-measurement and vibration-measurement tests. The cable model used is a circular cylinder with water rivulets attached in different positions. The aim of this paper is tried to understand the mechanism of rain-wind induced vibration of stay-cables from the new viewpoint of Reynolds number effect.

2 WIND TUNNEL TEST

Two series of wind tunnel tests were performed to determine the exact relationship between Reynolds number effect and cable vibration. One series of tests is aerodynamic force measurements using fixed rigid cable models; the other one is vibration amplitude measurements using spring supported rigid cable models.

The wind tunnel used in this study is a open/closed circuit type with two sections, located at Shijiazhuang Tiedao University. The tests were performed using the small section of the wind tunnel, which is 2.2m in width and 2.0m in height and can reach a wind velocity up to 80m/s. The cable model in wind tunnel, the water position and shape are shown in Fig.1. The wind tunnel test cases are shown in Table 1.

3 RELATION BETWEEN WATER RIVULET POSITION AND REYNOLDS NUMBER EFFECT

Drag and lift force coefficients of cable model with water rivulet in different positions are shown in Fig.2.

It can be seen that the Reynolds number effects of force coefficients have a very close relation with water rivulet position.

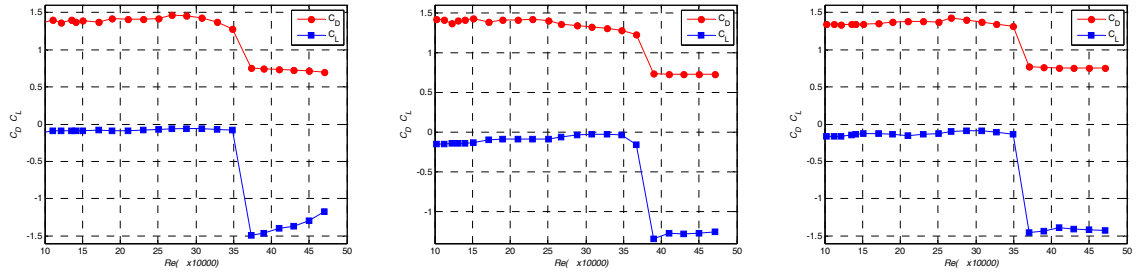
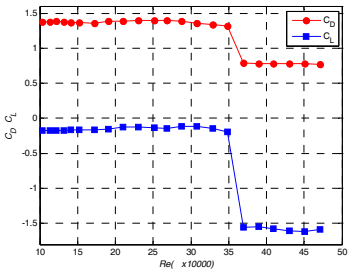
θ=55° θ=57.5° θ=60°



θ=62.5° θ=65° θ=67.5°

Fig.2 Drag and lift force coefficients of each water rivulet position



θ=70°

The results of Fig.2 can be classified into two types based on drag/lift force coefficients changing with Reynolds number, one type is results from water rivulet position θ=10° to θ=30°, the another type is other water rivulet positions.

In the first type, the changing rule of drag force coefficients with Reynolds number is steady-decreasing-steady-decreasing-steady, the changing rule of lift force coefficients is steady-increasing-steady-decreasing-steady. Refering to the changing rule of force coefficients of cable with smooth surface [19], it can be deduced that the first steady range of the two force coefficients belongs to subcritical Reynolds number range, and the following range belongs to critical Reynolds number range with the decreasing of drag force coefficient and increasing of lift force coefficient, the last steady range of the two force coeffients belongs to super-critical Reynolds number range.

In the second type, from the Reynold number range shown in the figures, the first stage of the two coefficients (drag force decreasing and lift force increasing) is not shown, the process of the two coefficients are steady-decreasing-steady.

Based on all the cases, defining the maximum of drag force coefficient as *Dmax* (ex. Point 1 in Fig.2, case of θ=10°), minimum of drag force coefficient as *Dmin* (Point 2), the drag force valve when it begins to decrease in the last decreasing stage as *Dst* (Point 3), the decreasing amplitude of drag force in the last decreasing stage as *DA* (drag force difference from Point 3 to Point 2), maximum of lift force as *Lmax* (Point 4), minimum of lift force as *Lmin* (Point 5), lift force value when it begins to decrease as *Lst* (Point 6), the decreasing amplitude of lift force in the last decreasing stage as *LA* (drag force difference from Point 6 to Point 5), the Reynolds number when drag force coefficient begins to decrease in the last stage as *Dstre* (Reynolds number of Point 3), Reynolds number when drag force coefficient gets its minimum as *Dminre* (Rey-

nolds number of Point 2), the distance of Reynolds number when drag force coefficient shows steady range as *Lpl* (Reynold number difference from Point 7 to 6), Reynolds number when lift force coefficient gets its maximum as *Ltre* (Reynolds number of Point 7), these parameters changing rule with water rivulet are concluded in Fig.3.

Base on Fig.2 and Fig.3, it can be seen that the change of water rivulet can induce obvious change of drag/lift force coefficients; the coefficients value and parameters above-mentioned are different in different water rivulet positions.

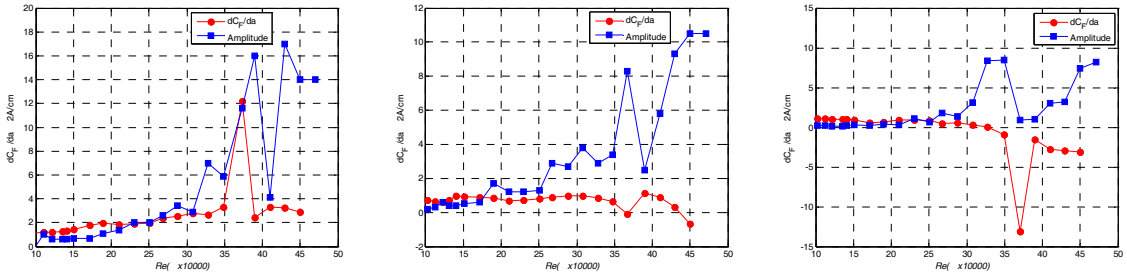
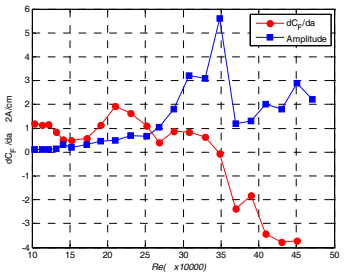
θ=60°



θ=62.5° θ=65° θ=67.5°

Fig.4 $dC_F/d\alpha$ and vibration amplitude of each water rivulet position



θ=70°

From Fig.4, it can be seen that there are two main vibration types of cable model.

When water rivulet is at a low position (θ is small), with the increasing of Reynolds number, drag force coefficient decreases and lift force coefficient increases dramatically. The similar critical Reynolds number effect occurs. The change of force coefficients induce minus $dC_F/d\alpha$. The large amplitude vibration of cable model under such condition can be explained by both critical Reynolds number effect and galloping.

When Reynolds number is relatively high (between 300000 and 450000), with the decreasing of drag force coefficient and lift force coefficient, varying amplitude vibrations of cable model occur for every water rivulet position test cases. The vibration under such condition is similar to the vibration induced by critical Reynolds number effect.

5 CONCLUSION

Base on Reynolds number effect, water rivulet effect on Reynolds number effect and mechanism of water rivulet effect on cable vibration are studied, the conclusions are as follows:

(1) Water rivulet can influnce the changing rule of force coefficients with Reynolds number; there is close relationship between cable vibration and coefficients value and their changing rules.

(2) In low water rivulet positions, with the increasing of Reynolds number, drag force decrease and lift force increase, the galloping coefficients are minus, cable shows large amplitude vibration. This vibration can be explained by Reynolds number effect and galloping.

(3) In high water rivulet positions, with the decreasing of drag force coefficient, lift force coefficient changes heavily; cable vibrates in different amplitude in each water rivulet position. The mechanism of these vibrations is similar to vibration induced by Reynold number effect.

Along-wind self-excited forces of two-dimensional cables under extreme wind speeds

Zhiwen Zhu

Center of Wind Engineering, Hunan University, Changsha, Hunan, China

ABSTRACT: Self-excited characteristics of cables under extreme wind speeds in along-wind direction currently is not clear, but may be of great interests for cable-supported bridge when dealing with flutter critical conditions. The flutter derivative with respect to along-wind aerodynamic damping is first derived according to the quasi-steady theory. For reduced wind speeds ranged from 53~1050, the flow fields around the along-wind forced vibration cable are simulated at Reynolds number of 5.18×105, followed by identifying flutter derivatives of P^*_1. The present results are in good agreement with the values from the quasi-steady theory, which suggests that the quasi-steady theory can be applied to obtaining flutter derivatives of P^*_1 at extreme wind condition. It is found that for cables under such condition, the vortex-induced forces dominate the variation of aerodynamic forces, and the self-excited forces can be negligible. Since the cable oscillation does not change the vortex-shedding frequency, it seems that the vortex-shedding pattern become very stable under extremely high wind speeds.

KEYWORDS: cable; along-wind vibration; self-excited forces; CFD; extreme wind; flutter derivatives.

1 INTRODUCTION

For cable-supported bridges with super-long spans, flutter instability at extreme wind condition may be a great concern. Normally, when carrying out flutter analysis, self-excited forces acting on bridge girders are always included, which can be determined through wind tunnel tests. However, it is found that the self-excited forces on cables are rarely considered among available references (Ge, 2008). But for super-long span bridges at flutter critical condition, the wind-induced forces on the cable may become significant since the increasing length and lower damping ratio of the cable. Based on this consideration, self-excited characteristics of cables in along wind under such kind of extreme wind condition should be first addressed.

It is well known that flow around circular cylinders show Reynolds-dependent characteristics, including vortex mode, separation point, mean and fluctuating drag and lift coefficients and so on. For flow around cables, such kind of characteristics always requires a full Reynolds simulation, which may help to provide meaningful results against the reality. This is also the case when dealing with cable aeroelasticity. If one considers a cable with diameter of 0.12m under extreme wind speeds, the corresponding Re number may be above 5×10^5, and if the cable oscillates at very low frequency, such as 0.1Hz, the resultant reduced wind speeds may be over several hundreds or even above thousand, which is far above the normal reduced wind speed relative to bridge girders elasticity. Meanwhile, under extreme wind speeds, the mean wind forces on the cable may be significantly large compared to the self-excited forces. Such kind of conditions almost prevents any test set and application dealing with identification of flutter derivatives of cables in wind tunnel.

The striking advantages of CFD in application to identification of flutter derivatives is that, neither test set nor model inertia forces are involved (Zhu, 2007). This helps to overcome many difficulties in wind tunnel test, and allows one to carry out self-excited simulations at the real Re

number under extreme wind speeds. In the following, one cable is picked up from a real bridge engineering, and is forced to undergo along-wind oscillation under high wind speeds. The flutter derivative of the cable corresponding to the along-wind degree of freedom is extracted, and compared to values from the quasi-steady theory.

2 FLUTTER DERIVATIVES OF CABLES IN QUASI-STEADY FORM

Under extreme wind speeds, the cables in cable-supported bridges are assumed to undergo small-amplitude vibration with a low frequency, which means a small velocity compared to the incoming wind. Therefor, the resultant wind angle of attack relative to cables will be small.

Consider a two-dimensional cable immerged in the incoming wind with velocity of U_∞, and oscillated both in along-wind direction and cross-wind direction, as shown in Figure 1. The synthesized wind velocity to the cable can be expressed as,

$$U_r = \sqrt{(U_\infty - \dot{p})^2 + \dot{h}^2} \approx U_\infty - \dot{p} \tag{1}$$

where $\dot{p}$ and $\dot{h}$ are the vibration velocities in along-wind and cross-wind directions on the coordinate system *oxy* with the *x* axis along the incoming wind, respectively. Obviously, Equation 1 recognizes the assumption that both $\dot{p}$ and $\dot{h}$ are small enough compared to incoming flow.

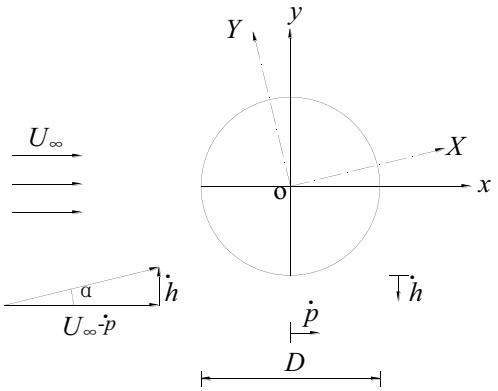

Figure 1 Cable in motion in incoming wind

The unsteady drag and lift forces acting on the cable can be rewritten as,

$$F_D = 0.5\rho U_r^2 D C_D(t) \tag{2a}$$

$$F_L = 0.5\rho U_r^2 D C_L(t) \tag{2b}$$

in which ρ denotes the air density; D the cable diameter; $C_L(t)$ and $C_D(t)$ are the unsteady lift and drag coefficients, and is depended on the relative wind angle of attack.

Under extreme wind speeds, the angle between the velocity of the cable and resultant wind velocity can be expressed as,

$$\alpha(t) = \tan^{-1}\left(\frac{\dot{h}}{U_\infty - \dot{p}}\right) \approx \frac{\dot{h}}{U_\infty - \dot{p}} \approx \frac{\dot{h}}{U_\infty} \tag{3}$$

with $\sin\alpha(t) \approx \alpha(t)$ and $\cos\alpha(t) \approx 1$ because of very small value of angle.

If one transfers Equation 2 onto the structural coordinate system OXY located at the center of the cable, with X axis along the synthesized wind direction, Equation 4 can be obtained as,

$$F_V = F_D \sin\alpha(t) + F_L \cos\alpha(t) \tag{4a}$$

$$F_H = F_D \cos\alpha(t) - F_L \sin\alpha(t) \tag{4b}$$

where F_V and F_H represent the wind forces normal to and along the resultant wind velocity, respectively.

This paper limits the study only on the along-wind oscillation and hence the drag force of the cable. Since the cable oscillates around the reference position with a small amplitude, Equation 4 can be expanded at the zero angle of attack based on Taylor's theory. If high-order terms are ignored, Equation 4b can be derived as,

$$\begin{aligned} F_H &= F_D - F_L\alpha(t) \\ &= 0.5\rho(U_\infty - \dot{p})^2 D\left[C_D(t) - C_L(t)\alpha(t)\right] \\ &= 0.5\rho(U_\infty - \dot{p})^2 D\left[C_{D0} + C_{D0}^{'}\alpha(t) - (C_{L0} + C_{L0}^{'}\alpha(t))\alpha(t)\right] \\ &= 0.5\rho(U_\infty - \dot{p})^2 DC_{D0} = 0.5\rho D(U_\infty^2 C_{D0} - 2U_\infty \dot{p} C_{D0}) \\ &= 0.5\rho D U_\infty^2 (C_{D0} - 2\frac{\dot{p}}{U_\infty} C_{D0}) \end{aligned} \tag{5}$$

in which C_{D0} and $C_{D0}^{'}$; C_{L0} and $C_{L0}^{'}$ are mean drag and lift coefficient, and their slopes at zero angle of attack, respectively.

It can be seen that the first term in Equation 5 is the drag force at steady state, while the second term represents the self-excited force induced by along-wind oscillation, which corresponds to aerodynamic damping as shown in the following.

In along-wind direction, if comparing the unsteady forces acting on the cables with the well-known Scanlan formulation (1971), the flutter derivative in along-wind direction can be obtained as,

$$P_1^* = -2C_{D0} / K \tag{6}$$

where $K = \omega D / U_\infty$ is the reduced frequency; $\omega = 2\pi f$ the circular frequency; f the cable vibration frequency.

3 NUMERICAL SIMULATION STRATEGIES

Under extreme wind speeds, the Re number is very high. If one considers the spanwise correlation of the flow and then performs full three-dimensional simulations, significantly high requirement will be put forward on computer resources. So, this paper limits the research only on the two-dimensional situation.

3.1 *The governing equations*

The two-dimensional incompressible flow around the circular cable cross section can be described by the unsteady Reynolds-averaged Navier-Stokes equations as follows,

$$\frac{\partial}{\partial x_i} u_i = 0 \tag{7}$$

$$\rho \frac{\partial}{\partial t} u_i + \rho \frac{\partial}{\partial x_j} \left(u_i u_j \right) = -\frac{\partial p}{\partial x_i} + \mu \frac{\partial}{\partial x_j} \left(\frac{\partial u_i}{\partial x_j} \right) + \rho \frac{\partial}{\partial x_j} \left(-\overline{u_i' u_j'} \right) \tag{8}$$

where μ denotes air viscosity; p and t are the pressure and time; u_i and u_i'; u_j and u_j' (i=1, 2 ; j=1, 2) represent the mean and fluctuating velocities along the axis in Cartesian coordinate system, respectively; $-\rho \overline{u_i' u_j'}$ the Reynolds stress.

If Eddy Viscosity Model is employed to close the equations, the Reynolds stress can be expressed as,

$$-\rho \overline{u_i' u_j'} = \mu_t \left[\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i} \right] \tag{9}$$

where $\mu_t = \rho C_\mu k^2 / \varepsilon$ is the turbulent viscosity; C_μ the empirical constant; k the turbulent kinetic energy and ε the dissipation rate of turbulent kinetic energy.

The standard $k-\varepsilon$ model employs wall functions in near wall region in order to avoid fine mesh, which results in significant saving on computer power. It has been widely used in engineering practice due to its robust formation and lower computational overhead. However, such kind of treatment is not sufficient to resolve complex flow accurately. The model often over-predicts the turbulence near stagnation regions, and presents the length scale which is too large in adverse pressure gradient flow. In many engineering applications, it fails to represent flow field due to the presentation of swirling flows and curved boundary layers flows.

By defining the turbulent viscosity in form of $\mu_t = k / \omega$, and the dissipation rate per unit kinetic energy $\omega = \varepsilon / k$, the $k-\omega$ turbulence model, which have been developed to improve the performance of the standard $k-\varepsilon$ (Menter, 1994). It is observed that the standard $k-\varepsilon$ model performed well in the shear layer flow while the $k-\omega$ model is excellent near to the wall. This leads to the development of the Shear Stress Transport (SST) model combining the advantage of both models, in which the $k-\omega$ model is employed near the wall and the standard $k-\varepsilon$ model is used near the boundary layer edge. To achieve this, the $k-\omega$ model is multiplied by a blending function F_l and the $k-\varepsilon$ model by (1-F_l) such that F_l has a value of one near wall region and switches to zero at the boundary layer where $k-\varepsilon$ model is recovered. It is found that the SST $k-\omega$ model can predict better flow separation compared to both the $k-\varepsilon$ and $k-\omega$ models (Liaw, 2005).

3.2 *2.2 Numerical strategy*

The cable with a diameter of D=0.12m, is located near the center of the computational domain, with all of outer boundaries extended over 25D, as shown in Figure 2. Such domain arrangement

can largely avoid numerical interference coming from outside boundaries. Since the cable is forced to undergo imposed vibration in CFD simulation, dynamic mesh system will be activated in Fluent which requires a suitable grid arrangement. In order to ensure good mesh quality, the whole computational domain is divided into four zones. The Zone Z1 around the cable is covered with body-fitted structured quadrilateral girds, which will oscillate with the cable but the grids topological structure will not be changed all the time. In this zone, the mesh orthogonality is always kept, as shown in Figure3, which helps to improve the accuracy and capture flow features. The Zone Z2 is paved with unstructured triangle grids, and will be re-meshed after each time step as to reflect the displacement of cable. Re-mesh quality can be ensured based on suitable selection of spring constant in spring-based smoothing method. Zone Z3 is also covered with structured orthogonal quadrilateral girds, but Zone Z4 is paved with unstructured quadrilateral girds. The grids in Z3 and Z4 are fixed all the time although the cable is undergoing along-wind oscillation.

Three different grid systems are created, with the closest grid space near the cable wall of h_0=0.000005m, 0.0001m and 0.0002m, respectively, as shown in Table 1. For all grid systems, the adjacent cell expansion ratios are always controlled under 1.1, which provides a smooth grid dimension over the whole computational domain. The total number of cells is shown in Tab.1. Numerical simulations show that the maximum Y^+ values on the wall are less than one in all grid systems, which satisfy grid resolution requirement for the SST $k-\omega$ turbulent model. Figure 4 shows the Y^+ distribution around the cable for G1.

Temporal discretization of the governing equations is performed with a second-order implicit scheme, while the convective terms are approximated with a second-order upwind scheme. The SIMPLEC algorithm is used to decouple the pressure and velocities field.

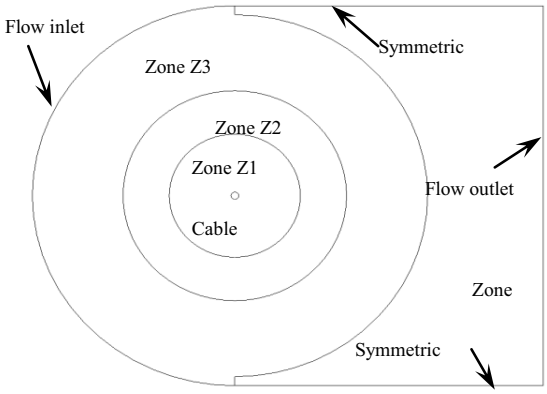

Figure 2 Partition and boundary conditions in computational domain

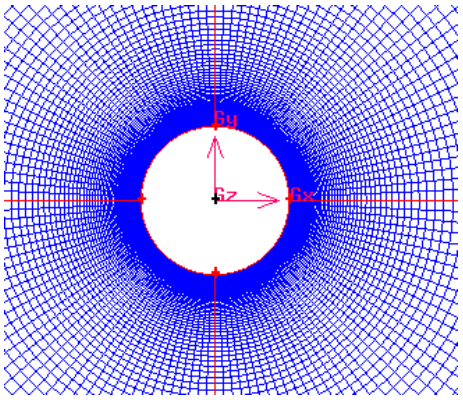

Figure 3 Grids arrangement around cable

Table 1. Grid parameters

Grid	h_0/m	Nodes	Y^+_{max}
G1	0.000005	26950	0.095
G2	0.00001	25270	0.22
G3	0.00002	23730	0.42

2.3 Cable motion and boundary conditions

In order to represent the body motion-induced forces acting on the cable and identify flutter derivatives, during CFD

simulations, the cable will undergo imposed along-wind sinusoidal vibration, i.e.,

$$p(t) = p_0 \sin(2\pi ft) \tag{12}$$

where p_0 is the vibration amplitude with a value of 0.025D, which is very small as to ensure small disturbance on flow field; f the vibration frequency. Since all simulations under different reduced wind speeds are performed at the same Re number, f needs to be changed as to obtain the desired reduced wind speeds.

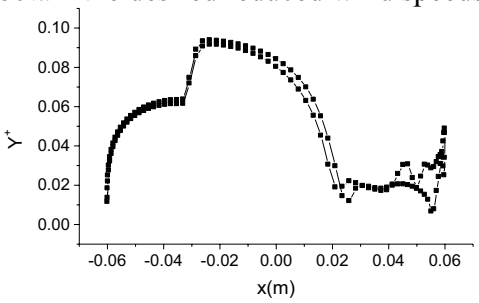

Figure 4 Y^+ values on cable surface of G1

In order to reflect surface roughness on the cable, a roughness height is assumed to be of 3×10^{-5}D (Poulin, 2007). Suitable boundary conditions are imposed on the computational domain, as shown in Figure 2. The flow inlet boundary is defined as velocity inlet with a value of 63m/s in horizontal direction (corresponds to the Reynolds number of 5.18×10^5), while flow outlet boundary is defined as the outflow boundary condition. The symmetric boundary condition is imposed on the top and bottom boundaries. As for the cable surface, no-slip condition is applied on it, which means the flow on the wall shares the same velocity as the cable when the cable undergoing imposed motion.

2.4 Grid-independence check

Simulation tests show that, even under extreme wind speeds, vortex shedding is still a dominating feature in flow around the cable. As to effectively capture vortex shedding, non-dimensional time step size is set to 0.01.

Define unsteady drag and lift coefficients on the cable as,

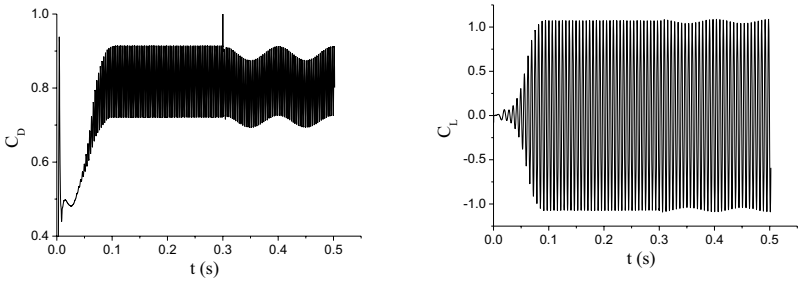
$$C_D = F_D / (0.5\rho U_\infty^2 D); \quad C_L = F_L / (0.5\rho U_\infty^2 D) \tag{13}$$

where F_D and F_L are drag and lift, which are positive in downstream and upside direction, respectively.

Grid check is performed for the fixed cable. Except the cable motion, boundary conditions and time step size will be the same. Data will be collected after 0.1s simulations as to avoid any influence from initial computation and thereafter the flow attains stable stage. As shown in Figure 5, time histories before 0.3s are force coefficients when the cable is fixed. It indicates that the flow around the cable experience a steady vortex shedding, with the St number indicated in Figure 4, which are slightly high compared to other reports (Norberg, 2003).

The results obtained on three different grid systems, including the mean drag and lift coefficients, RMS values of drag and lift coefficients, as well as the strouhal number are displayed in Figure 6. One can see that the results agree well with each other, especially the G1 and G2, which

means the simulation results will not be influenced by grid refinement. In this paper, G1 is selected for the further study on the moving cable.



(a) (b)

Figure 5 Aerodynamic force time histories on cable

The mean drag coefficient from G1 is of 0.81, which matches well with the suggested value under extreme wind speeds (Poulin, 2007). This value will be used for the quasi-steady theory in the following.

Figure 7 is the vortex shedding plot around the fixed cable at four key states. It shows the vortex generation, elongation, shedding and drifting with the flow in the wake.

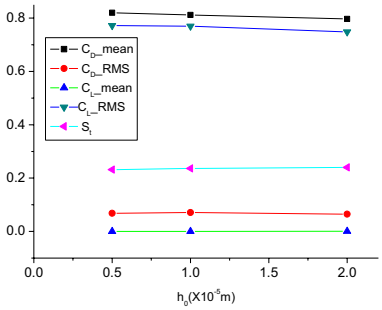


Figure 6 Aerodynamic coefficients and Strouhal number for flow around fixed cable

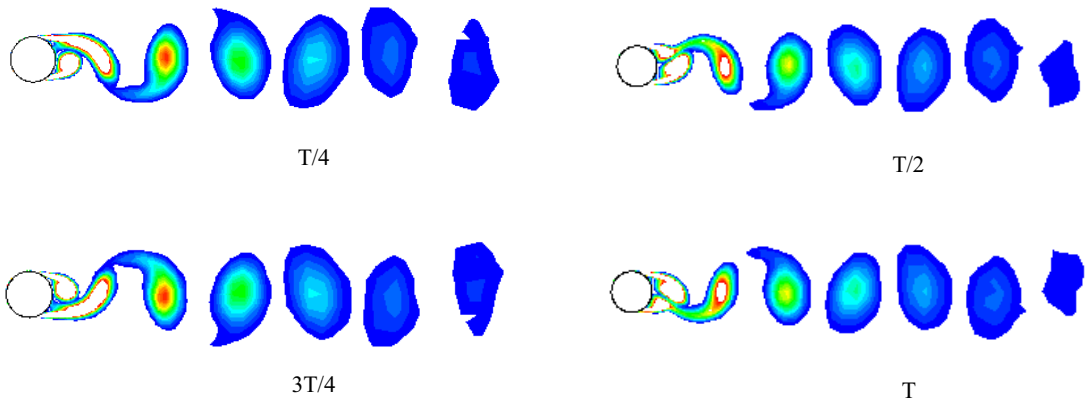

Figure 7 Vortex contour plot in wake of the fixed cable during one cycle of vortex shedding period

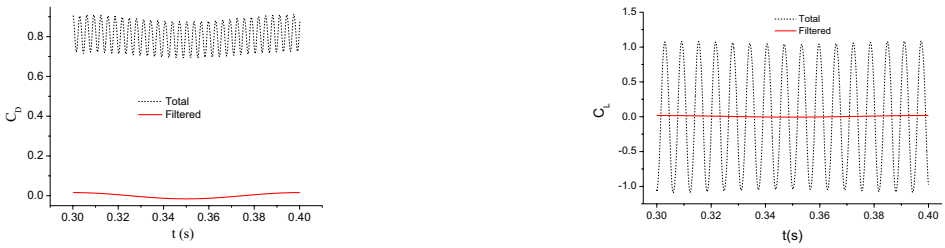
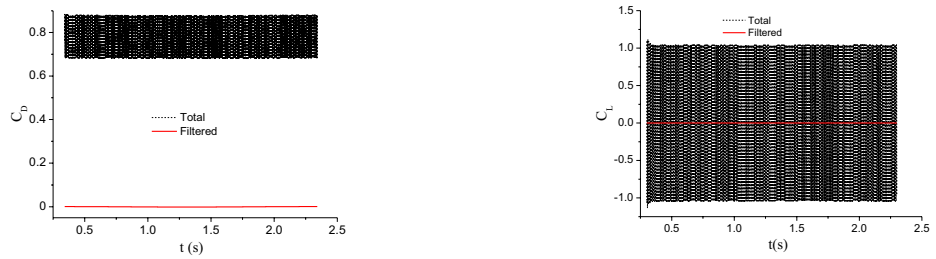
4 SIMULATIONS ON MOVING CABLE AND RESULTS

Considering simulations on the moving cable, enough time step simulations are first carried out for the fixed cable in order to establish a steady vortex shedding flow configuration, as shown in Figure 5. Then forced vibration is imposed on the cable, and force time histories are recorded on each time step. As shown in Figure 5 and more detailed in Figure 8, two cycles of data are plotted under the reduced wind speed v_r=53. Figure 9 also shows the total aerodynamic force time histories at a extreme high reduced wind speed of v_r=1050.



(a) (b)

Figure 8 Total and self-excited aerodynamic force time histories on forced vibration cables (V_r=53)



(a) (b)

Figure 9 Total and self-excited aerodynamic force time histories on forced vibration cables (V_r=1050)

Figures.8 and 9 appears that both of the total force time histories are formed by superposition of a high frequency wave on a low frequency oscillation. Frequency analysis indicates that two frequencies are included in the time histories, with the dominating one equals to the vortex shedding frequency, while the low one equals to the forced vibration frequency. It is worth noting that under such extreme wind speed, the oscillated cable still keeps its vortex shedding frequency as in the fixed situation. It seems that the vortex shedding mechanism will not be changed even the cable is under oscillation. Hence the vortex shedding mode is very stable under extreme wind speeds.

Based on assumption of linear superposition of aerodynamic forces, the self-excited forces can be separated from the total forces. Since the vortex-shedding frequency is significantly higher than the imposed motion frequency, the low-pass filtering technology can be used to obtain the self-excited forces, as shown in Figures.8 and 9. One can see that the self-excited mean and RMS value of drag is much smaller than the total one, while the RMS value of lift is significantly smaller than the total lift, especially at extreme high reduced wind speeds. In other words, the self-excited forces on the vibration cable are very small compared to the vortex-shedding forces. If comparing the self-excited drag coefficient with the mean total drag coefficient at the reduced

wind speed of 1050, one can conclude that the self-excited component may be negligible at extreme high wind speeds.

With the obtained self-excited drag time history, the flutter derivative of P^*_1 can be identified based on the least square method (Zhu, 2009). The present results are plotted against the quasi-steady ones from Equation 6 with C_d=0.81, as shown in Figure 10. One can see that the CFD results agree well with the quasi-stead theory. Hence if the self-excited drag force is considered under extreme wind speeds, the value of P^*_1 can be obtained straightforward from the quasi-stead theory.

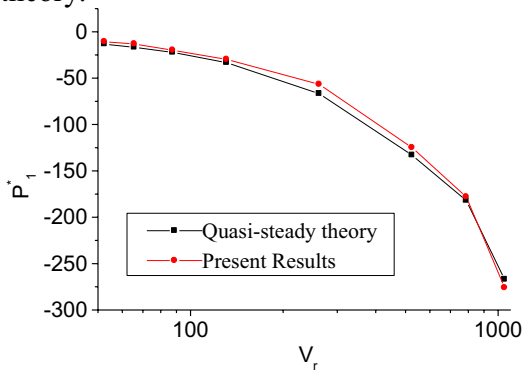


Figure 10 Identified flutter derivatives P^*_1 in comparison with quasi-steady theory

Table 2 also shows the value of KP^*_1, where $K=2\pi/v_r$ is the reduced frequency. If $C_{D0}=0.81$, the quasi-steady theory will give the value of $K\,P^*_1$= -1.62, which matches well with the present results at extreme high reduced wind speeds.

Table 2 CFD simulation cases and results

Vibration frequency/Hz	0.5	0.75	1	2	4	6	8	10
V_r	1050	788	525	263	131	88	66	53
K	0.006	0.009	0.012	0.024	0.048	0.072	0.096	0.12
$K\,P^*_1$	-1.65	-1.58	-1.5	-1.36	-1.42	-1.43	-1.25	-1.29

One striking feature in Figure 10 is that the P^*_1 become more negative with the increase of reduced wind speed, which means the aerodynamic damping relative to along-wind oscillation is always positive. It can be deduced that the one degree-of-freedom cable under along-wind oscillation is always stable.

Figure 11 shows the vortex-shedding patterns of the cable during one cycle of forced vibration, where T is the forced vibration period and denotes the cable coming back to the reference position. Since the vortex-shedding mechanism dominates the flow around the cable, the vortex street is apparent in the wake of vibration cable.

4 CONCLUSIONS AND REMARKS

The along-wind vibration of a cable is simulated by CFD method in this paper, with the following conclusions and remarks,

1) The identified flutter derivatives P^*_1 are in good agreement with the quasi-steady theory, which demonstrates the feasibility of CFD method to address the aeroelastic features of cables under extreme high wind speeds.
2) The quasi-steady theory, based on drag coefficient of 0.8, can provide a reasonable estimation

of the along-wind flutter derivatives of the cables at extremely high wind speeds.

3) It is found that under extreme wind speeds, the vortex shedding pattern will not be influenced by the cable vibration, and the vortex shedding still dominates the fluctuation on aerodynamic forces. It should be highlighted that the self-excited forces induced by along-wind vibration is negligible compared to the vortex-induced forces, i.e., the self-excited component may be negligible at extreme high wind speeds.
4) From aerodynamic point of view, the one degree-of-freedom cable oscillating in the along-wind direction is always stable, even under extreme high wind speeds.

If more computer resources are available, three-dimensional simulations may be carried out as to get further insight and extend the study to cross-wind vibration.

Aerodynamic force coefficients of plain bridge cables in wet conditions

Giulia Matteoni[a,b], Christos T. Georgakis[b]

[a]*Department of Civil Enginering, Technical University of Denmark, Brovej, Building 118, Kgs. Lyngby, Denmark*

ABSTRACT: In this paper, the aerodynamic forces and force coefficients from preliminary static wind tunnel tests on a plain cable in wet conditions are presented. The presented results are for several different relative cable wind-angles. A comparison is made with tests in dry conditions. In dry conditions, tests were performed for wind velocities between 2 and 31 m/s, whilst in wet conditions tests were performed for the range of wind velocities where rain rivulet formation was found possible, i.e. between 8-18 m/s. For all of the tested relative cable-wind angles in wet conditions, a reduction in the drag coefficient with increasing Reynolds number, accompanied by a near-zero lift coefficient, was observed. A theoretical evaluation of the aerodynamic damping assuming quasi-steady conditions reveals that changes in drag and lift coefficient are nonetheless not sufficient to generate negative aerodynamic damping. Analysis of the fluctuating lift component shows the presence of "enhanced" vortex shedding at specific wind velocities – similar to what might be observed in the presence of a tripping wire.

KEYWORDS: inclined bridge cable, yawed flow, drag, lift, rain, enhanced vortex shedding

1 INTRODUCTION

Rain-wind-induced vibrations (RWIVs) constitute 95% of all large amplitude vibrations of inclined bridge cables [1]. Vibrations may reach peak-to-peak amplitudes of 10 times the cable diameter, leading to serviceability issues and concerns over a much-decreased bending fatigue life for the cables. From both full scale and wind tunnel observations, it has been found that the vibrations occur mainly for cables declining in the wind direction, characterized by relative cable-wind angles Φ in the range of 60°-73°, under low to moderate rain intensities, in a restricted range of wind velocities of U = 5-18 m/s, and cable structural frequencies f = 0.6-3.3 Hz [2]. Physical parameters such as cable size and shape, surface roughness and wettability also affect the vibration mechanism [3]. Although the phenomenon is well known, the mechanisms that lead to this form of vibration are not thoroughly understood. Characterised by relatively low frequencies and large amplitudes of oscillation, RWIVs are generally not assumed to be a form of vortex-induced oscillation. Nevertheless, Matsumoto et al. [4] explained that wet bridge cables can undergo three types of unstable response, i.e. a "galloping type" which includes both divergent type galloping and velocity-restricted galloping, a "vortex shedding type" with a long period and a hybrid type. The galloping type response has been explained in terms of the negative slope in the lift coefficient with wind angle-of-attack, due to the formation of the upper water rivulet and/or the axial flow. Cosentino et al. [5] attributed RWIVs to the oscillation of the upper water rivulet on the vibrating cable model. They explained that during the cable's vibration cycle, the rivulet thickness, and the angular distance between the water rivulet and the stagnation line, changes as function of the cable's acceleration. When the rivulet reaches the farthest position from the flow stagnation line, it has gained its maximum thickness and the shear layer separating from the rivulet reattaches behind it, resulting in a single bubble on the cylinder surface. On the

other hand, when the upper rivulet is at the position nearest to the leading stagnation point, the rivulet thickness is minimum, and the shear layer separating from the rivulet does not reattach on the cylinder surface, leading to a flow pattern similar to that around a clean cylinder at a subcritical Reynolds number. Both explanations are inadequate though. For the stable formation of a balanced rain rivulet in the first case, cable wind angles-of-attack must remain in a very narrow range, thus eliminating the possibility for large changes in wind angle-of-attack. In the second case, the mechanism requires the relatively large oscillation of the cable, forfeiting any explanation of how the oscillation is initiated.

As RWIVs tend to occur for wind velocities that are generally lower than the maximum velocity used for the structural design of the cables and the bridge, the determination of the force coefficients of bridge cables in wet conditions has commonly been neglected. Nevertheless, these may vary significantly from those of dry cables. Furthermore, they may prove useful in the evaluation of the significance of the aforementioned additional effects in the mechanisms leading to RWIVs.

In the current work, the static forces and force coefficients of yawed full-scale bridge cable section models are determined from wind-tunnel tests, in both dry and wet surface conditions. From these tests, it is found that the measured forces on a wet cable differ from those of a dry cable. In particular, the drag coefficient is noticeably reduced, whilst the lift coefficient is near zero throughout the tested Re range – making the static cable model incapable of predicting negative aerodynamic damping. Furthermore, the fluctuating lift components are analysed and it is found that cable Strouhal numbers increase in wet conditions. Based on the measured drag and lift coefficients, as well as the observed Strouhal number, it is conjectured that the running water rivulets plays a similar role on the flow structure around the cable as a stationary tripping wire at a critical angular position from the flow stagnation line. Finally, the rain rivulet seems to generate a form of enhanced vortex shedding, which may contribute in some way to the initiation of the RWIV vibrations.

2 WIND TUNNEL TESTS

2.1 *Test setup*

Static wind tunnel tests were performed at the closed-circuit DTU/Force Climatic Wind Tunnel in Lyngby, Denmark. The wind tunnel features a test section of L×W×H =5m×2m×2m. Technical specifications of the wind tunnel are reported by Georgakis et al. [6]. The model (see Fig. 1) is a section of a prototype HDPE tube, with a nominal outer diameter of 160 mm, placed on an inner aluminium tube for increased stiffness. The measured roughness average of the cable model is R_a~1.8 μm. Aerodynamic forces at both cable ends were measured using 6-DOF force transducers, covered by HDPE dummy pieces of the same cable. For the tests performed in dry surface conditions, two configurations were tested, namely with and without end plates. When tested with end plates, the model was provided with circular end plates of diameter equal to 5 times the cable diameter, placed at a distance of approximately 90 mm from the walls, in order to minimize end effects. Wet tests were performed using the same model as in the dry state, but without end plates. At the upper end of the cable model, just above the measuring portion, two small diameter tubes were attached and connected to a water source placed outside the wind tunnel test chamber. In this way, a formed upper and lower water rivulet was simulated and allowed for a uniform rivulet along the full length of the cable model. Fig. 2 shows the test set-up in wet conditions. All tests were undertaken in smooth flow, i.e. for an along-wind turbulence intensity of I_u=0.5%, and for selected relative cable-wind angles Φ, defined as:

$$\Phi = \arctan\left(\frac{\sqrt{\tan^2\theta + \sin^2\beta}}{\cos\beta}\right) \qquad (1)$$

where θ is the vertical inclination and β is the horizontal yaw. In dry conditions, Φ=90º, 60º, and 55º were tested. In wet conditions, only Φ=60º and Φ=55º were investigated, as flow normal to the cable in wet conditions does not allow for the formation of a rain rivulet outside the wake. In dry conditions, the full wind tunnel velocity range up to 31 m/s was investigated. In wet conditions, the velocity range was restricted to the velocities at which rain rivulets could be formed, i.e. 8-18 m/s.

Figure 1. Full-scale, yawed cable model (dry tests).

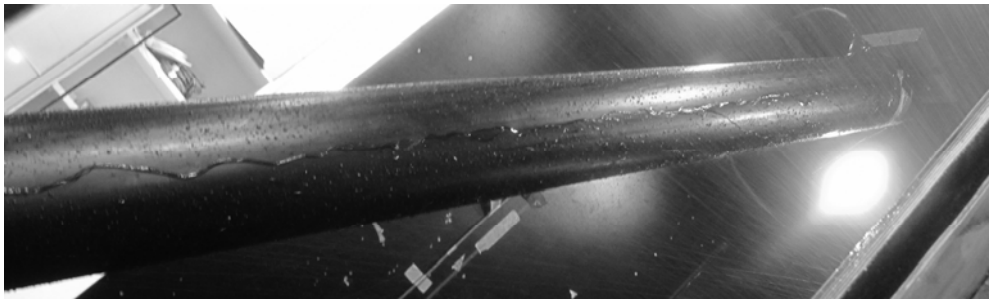

Figure 2. Full-scale yawed cable model (wet tests).

3 RESULTS

3.1 *Dry state*

The drag and lift coefficient components of dry inclined cables for the two selected relative cable-wind angles (Φ=60º and Φ=55º), together with cross-flow coefficients, are presented in Fig. 3. In cross flow, the blockage ratio was 8%, thus leading to the need for a drag coefficient correction following the Maskell III Method [7]. For the yawed cable tests, the wind tunnel blockage was lower than 2% and therefore no correction was needed.

The cable's aerodynamic damping is determined according to the general expression derived by Macdonald and Larose [8] for small (1-DOF) vibrations of a cylinder in a given plane. For

across-flow vibration (α=90°) and along-flow vibration (α=0°) the aerodynamic damping reduces to equations (2) and (3) respectively:

$$\xi_a = \frac{\mu \mathrm{Re}}{4m\omega_n} \frac{1}{\sin\phi}(C_D + \frac{\partial C_L}{\partial \alpha}) \qquad (2)$$

$$\xi_a = \frac{\mu \mathrm{Re}}{4m\omega_n}(2C_D \sin\phi + \frac{\partial C_D}{\partial \mathrm{Re}} \mathrm{Re} \sin\phi + \frac{\partial C_D}{\partial \phi}\cos\phi) \qquad (3)$$

where C_D, C_L are the cable's drag and lift coefficients, respectively, α is the wind angle-of-attack, Φ is the relative cable-wind angle, μ is the dynamic viscosity, m is the cable's mass and ω_n is the cable's circular frequency.

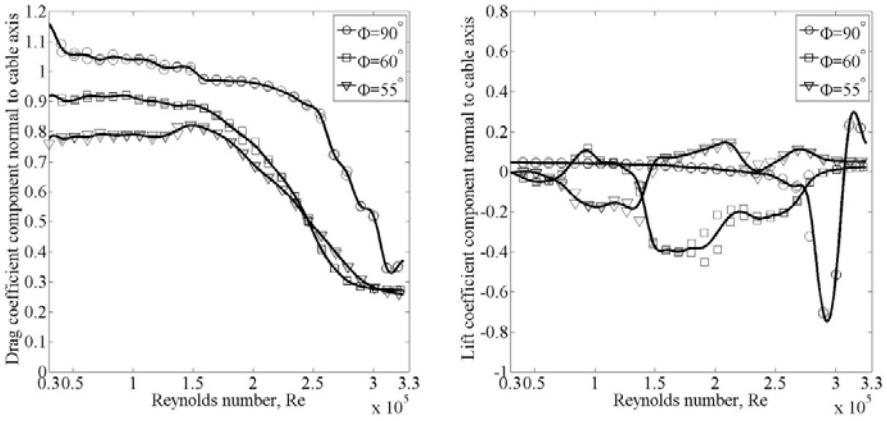

Figure 3. Drag and lift coefficient components for full-scale yawed cable model in dry conditions with end plates.

The across-flow (left) and along-flow (right) aerodynamic damping, normalized by the factor ($\mu/(4m\omega_n)$) and based on the drag and lift coefficient components in Fig. 3, are shown in Fig. 4. By neglecting the variation of the lift coefficient with angle-of-attack, the predicted across-flow aerodynamic damping is positive through the tested range of Reynolds number for all tested geometries. Similarly, neglecting the variation of the drag coefficient component with relative cable wind angle, leads to negative aerodynamic damping for Re=2.55×10^5-3.18×10^5 (Φ=90º), Re=2.27×10^5-2.83×10^5 (Φ=60º), Re=2.35×10^5-3.01×10^5 (Φ=55º).

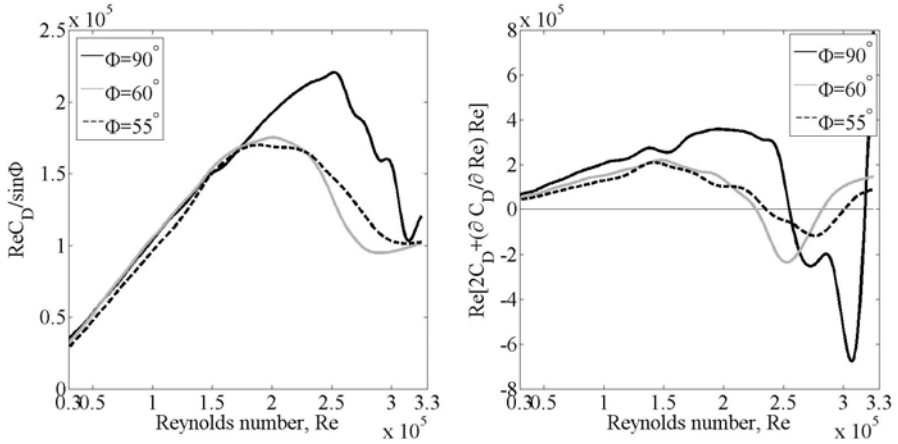

Figure 4. Across-flow and along-flow normalized aerodynamic damping for yawed cable model (dry conditions).

In Fig. 5, the drag and lift coefficient components for yawed cable models in dry conditions and in the absence of end plates are presented, for relative cable wind angles of Φ=90°, 60º and 55°. For all tested relative cable-wind angles, Φ, the drag and lift coefficient components are significantly changed in the absence of end plates. It is believed that varied three dimensional flow conditions must thus be responsible for the change in the aerodynamic behavior of the cable models, particularly when yawed. From Fig. 5 it is in fact observed that for flow normal to the cable axis, i.e. Φ=90º, the drag coefficient decreases through the full tested range of Reynolds numbers. For the yawed cases, the drag coefficient component normal to cable is continuously decreasing for Reynolds numbers higher than Re=1.61×10^5 (Φ=60º) and Re=1.06×10^5 (Φ=55º).

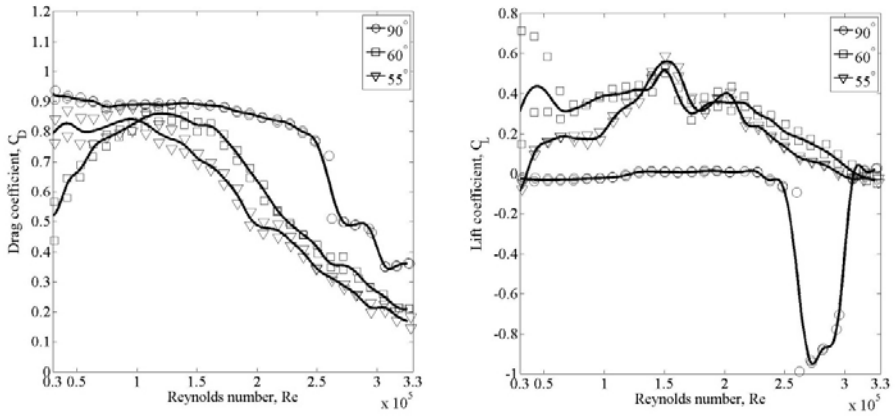

Figure 5. Drag and lift coefficient components for yawed cable model (dry conditions, no end plates).

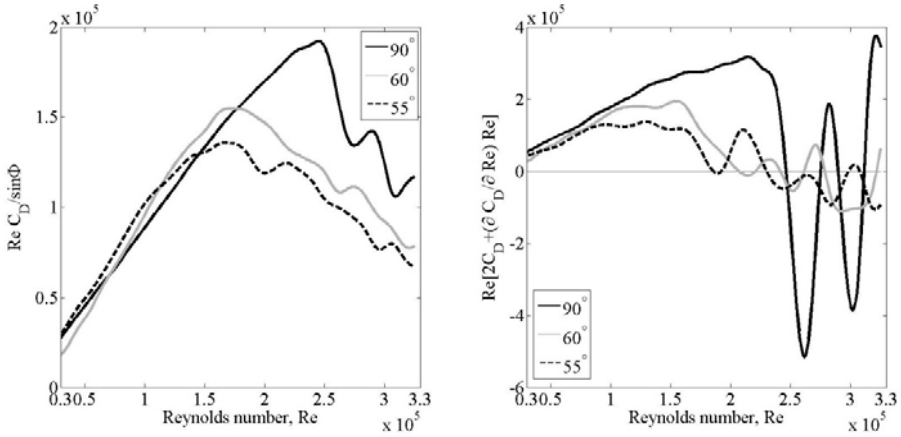

Figure 6. Across-flow and along-flow normalized aerodynamic damping for yawed cable model (dry conditions, no end plates).

Fig.6 is similar to Fig. 4, except that the results are for the dry tests with no end plates. Due to discontinuities in the slope of the drag coefficient components in the critical Re range, a change in the sign of the normalized aerodynamic damping is experienced. Negative aerodynamic damping is predicted for Re=2.46×10^5-2.75×10^5 and Re=2.90×10^5-3.11×10^5 (Φ=90º), Re=2.06×10^5-2.21×10^5 and Re=2.41×10^5-2.61×10^5 (Φ=60º), Re=1.86×10^5-1.92×10^5 and Re=2.30×10^5-2.98×10^5 (Φ=60º).

3.2 *Wet state*

In wet conditions, upper and lower water rivulets form when the wind velocity reaches the value of U=8 m/s (Re=0.80×10^5). This can be understood as the velocity at which there is a balance between the gravitational and the aerodynamic forces acting on the rivulet. At this stage the rivulets follow a slightly sinusoidal trajectory along the cable length. As the wind velocity is increased, the rivulets trajectory changes to a straight line. When the wind velocity overcomes the value of U=18 m/s (Re=1.8×10^5) the rivulets are disrupted, as all water is blown off of the cable.

Due to the presence of the water rivulets, the total force measured on the cable section at any time is comprised of an aerodynamic component and a gravitational component, as a result of the added weight of the water on the cable surface. The latter contribution was estimated based on the visually observed width and thickness of the upper and lower water rivulets along the cable length, which were equal to approximately 20 mm by 2 mm. This is in agreement with previous accounts, where the water rivulet base carpet width and hump height were estimated, depending on the rain intensity, to be in the range of 8-38 mm and 0.5-2mm, respectively, [9]. Thus, by assuming as observed that the weight of the water rivulets remains constant throughout the range of wind velocities - from their formation up to their disruption - the total added weight of water is 1 N/m. The drag and lift force components normal to the cable for relative cable-wind angle Φ=60° are presented in Fig. 7.

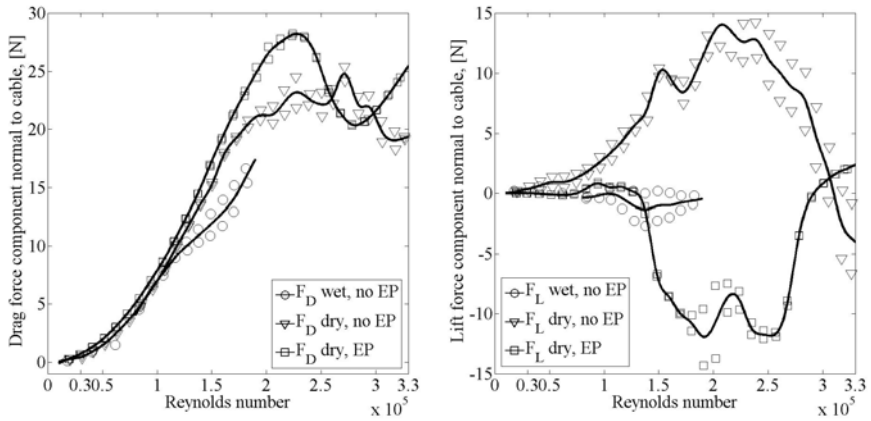

Figure 7. Drag (left) and lift (right) force component normal to cable (Φ=60º). EP refers to 'end plates'

For the dry tests with varying end conditions, it can be observed that the drag force components normal to cable generally follow each other in the subcritical Re range. Major deviations are observed though for Reynolds numbers higher than Re~1.6×10^5, i.e. in the critical Reynolds number range. In wet conditions, the drag force component normal to cable is generally equal to or lower than the respective force component in dry conditions, whilst the lift force component is near zero.

The drag and lift forces normal to the cable for relative cable-wind angle Φ=55° are reported in Fig. 8. Note that in wet conditions, for both Φ=60° and 55°, the total and purely aerodynamic force components do not differ significantly from each other, as the contribution of the projection of the added gravitation water weight along the two force components is lower than 0.52 N/m. Moreover, for Φ=55°, the angle between the gravitational force and the lift force component is 90°, thus making the total and the lift force components equal. The aerodynamic force components in wet conditions have been converted into aerodynamic force coefficients and presented in Figs. 9-10. In these figures, the drag and lift coefficient components normal to the cable axis obtained in wet surface conditions (with end plates) are compared with the respective force

components in dry surface conditions (with and without end plates) for the two yawed cable models.

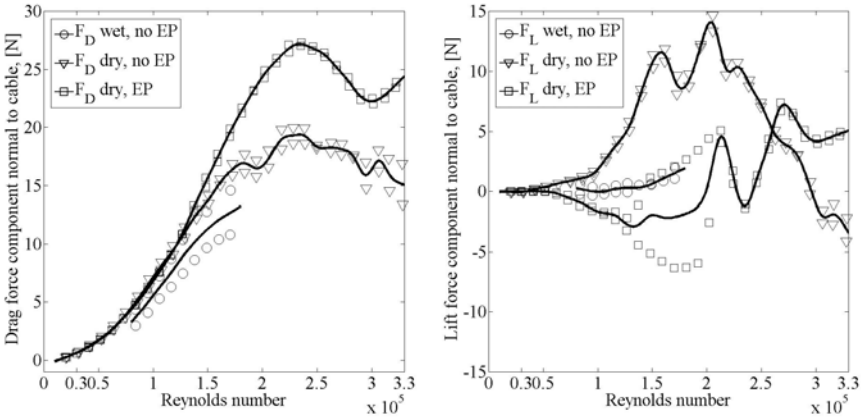

Figure 8. Drag (left) and lift (right) force component normal to cable (Φ=55º). EP refers to 'end plates'.

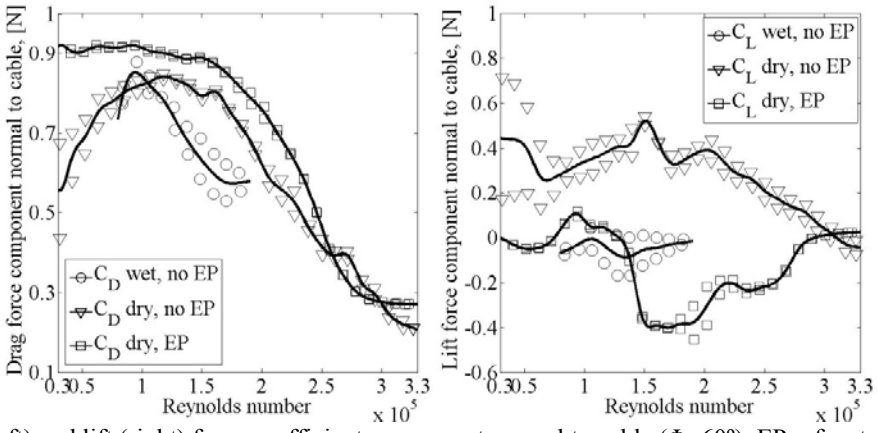

Figure 9. Drag (left) and lift (right) force coefficient component normal to cable (Φ=60º). EP refers to 'end plates'.

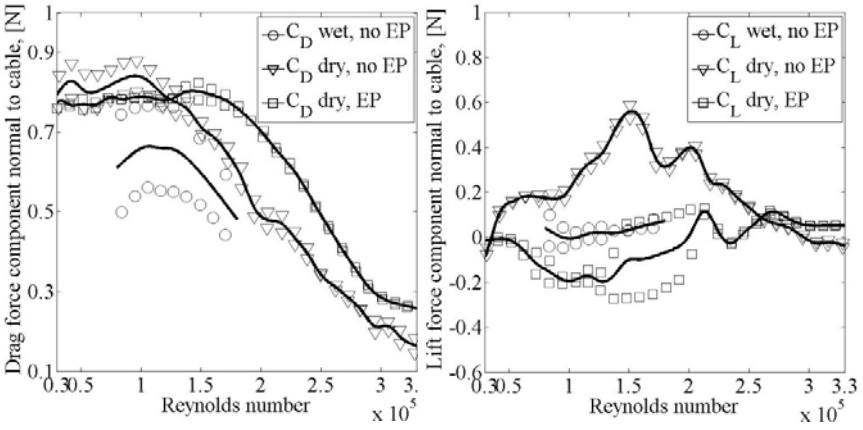

Figure 10. Drag (left) and lift (right) force coefficient component normal to cable (Φ=55º). EP refers to 'end plates'

In Figs. 11 and 12, the along-wind and across-wind normalized aerodynamic damping obtained in wet conditions (with end plates) and dry conditions (with and without end plates) for the two yawed cable models, is shown. For the case of Φ=60°, the across-wind and along-wind aerodynamic damping follows the same tendency as for the dry state, but it exhibits lower values. For

the case of Φ=55°, even if positive, the aerodynamic damping in wet conditions doesn't follow the same tendency as for the other tested cases in dry conditions.

It is apparent that the presence of water rivulets on a static yawed cable leads to a change in the flow structure around the cable (and thus in the drag and lift coefficient components), but it is not sufficient in itself to predict negative aerodynamic damping.

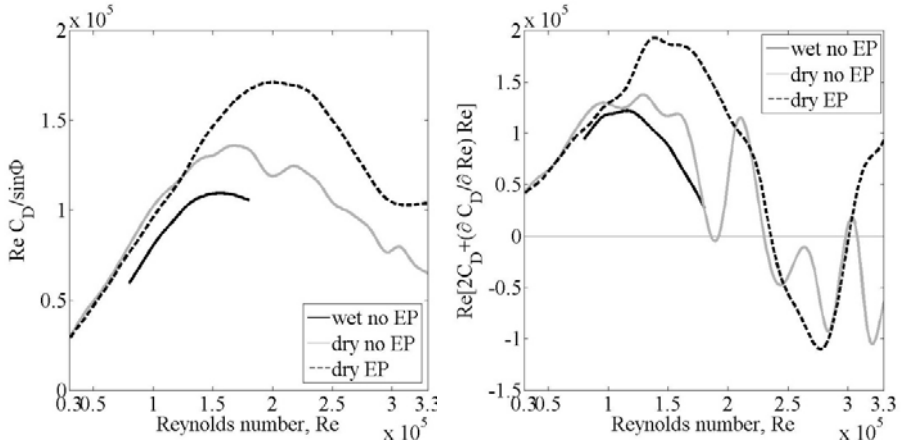

Figure 11. Across-wind (left) and along-wind (right) normalized aerodynamic damping for yawed cable model (Φ=60°). EP refers to 'end plates'

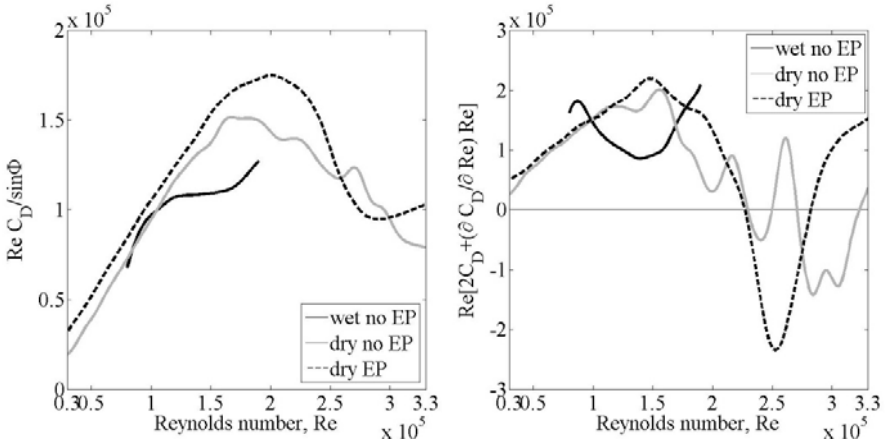

Figure 12. Across-wind (left) and along-wind (right) normalized aerodynamic damping for yawed cable model (Φ=55°). EP refers to 'end plates'

3.3 *Vortex shedding*

The RMS (Root Mean Square) values of the lift component normal to the cable (i.e. fluctuating lift) for varying Re values are reported in Fig. 13. For Φ=60° it is observed that in dry conditions the fluctuating lift coefficient exhibits an increase for Re~1.0-3.0×10^5, in both the presence and absence of end plates. In wet conditions, the fluctuating lift component peaks at between Re=1.3-1.4×10^5, whilst for Φ=60°, the fluctuating lift is considerably higher than in dry conditions, represented a form of enhanced vortex shedding. The same phenomenon, i.e. increase of the fluctuating lift for wet cylinders in comparison to the dry state, has been previously reported for the range of Reynolds numbers where the upper water rivulet reaches a critical angular position from

the flow stagnation line, but albeit for much lower Re numbers that examined here [10]. The increased RMS of the fluctuating lift for Φ=60° also qualitatively resembles the increased RMS response observed in certain cases when a cylinder is fitted with a flow tripping wire [11]. As it is unclear what initiates the RWIV, it is conjectured that the observed enhanced vortex shedding may trigger a response in higher cable harmonics or sub-harmonics. The driving mechanism may then migrate from vortex shedding to an aeroelastic mechanism.

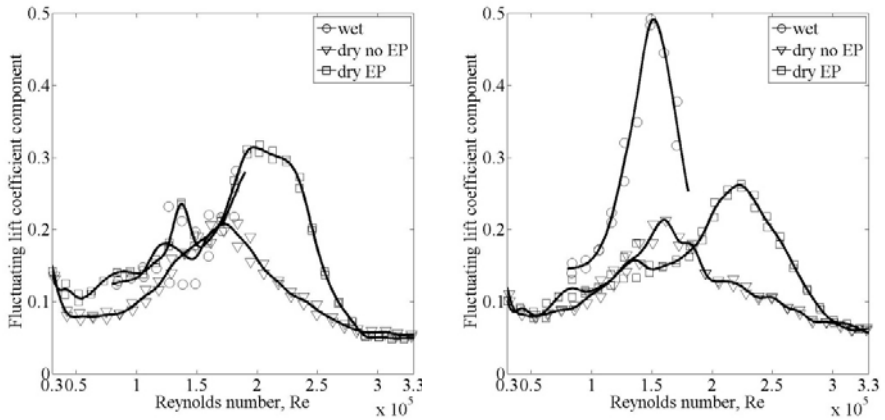

Figure 13. RMS fluctuating lift coefficient component normal to cable for Φ=60° (left) and Φ=55° (right).

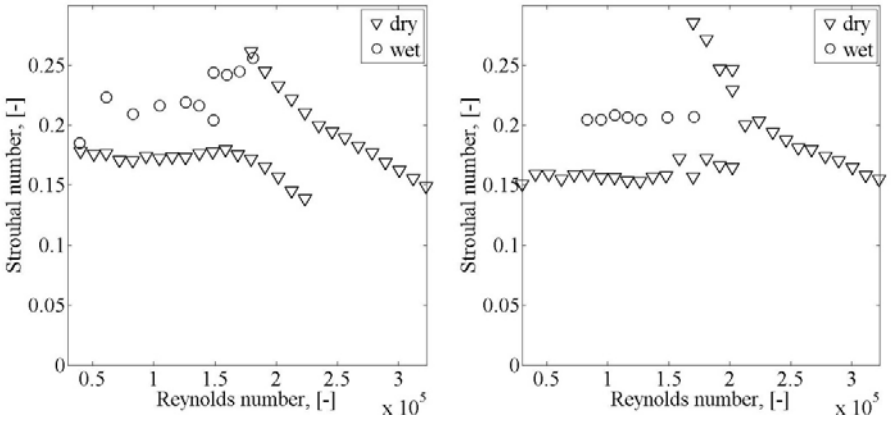

Figure 14. Strouhal number versus Reynolds number, Φ=60° (left) and Φ=55° (right), dry and wet conditions.

The Strouhal number versus Reynolds number is plotted for all of the tests in Figure 14. A linear trend is observed between the Strouhal frequency and Reynolds number in the PSD (power spectral density) of the lift coefficient component normal to cable for Φ=60° and Φ=55° in dry conditions, which disappears for Re~1.6×10^5 for both Φ=60° and Φ=55°. Additionally, in dry conditions and in the critical Reynolds number range, the lift's PSD exhibits local peaks at two separate Strouhal frequencies. In wet conditions, the same linearity is evident only for the test case Φ=55° throughout the full tested Re range. Moreover, in dry conditions, for both Φ=60° and Φ=55°, and for Reynolds numbers marking the start of the critical range (i.e. Re~1.6×10^5), local peaks in the PSD are observed for frequencies near zero. These may be associated with the occurrence of an alternating single separation bubble on one side of the cylinder, as reported by Nikitas et al. [12]. Finally, for both Φ=60° and Φ=55°, the Strouhal numbers measured in wet conditions are higher than in dry conditions and between 0.2 and 0.25. Again, this might be ex-

pected of a stationary cylinder with tripping wire fitted at a critical angular position from the stagnation line [11], [13].

4 CONCLUSION

Static forces and force coefficients of yawed full-scale bridge cable section models are determined from wind-tunnel tests, in both dry and wet surface conditions. In dry conditions, tests are performed for wind velocities between 2 and 31 m/s, while in wet conditions they are performed for wind velocities between 8 and 18 m/s. For the tested relative cable-wind angles, it is found that the drag coefficient of cables in wet conditions is reduced compared to a dry cable and the lift coefficient is near zero throughout the tested Re range. The changes in the aerodynamic coefficients in the range of Reynolds numbers in which the water rivulet can form cannot predict the generation of negative aerodynamic damping. Moreover, in wet conditions, the cable's Strouhal numbers are increased when compared to a dry cable. Based on the trend on the drag and lift coefficient, as well as of the Strouhal number, it is suggested that the running water rivulets plays a similar role on the flow structure around the cable as a stationary tripping wire fitted on the cable's surface. Finally, it is conjectured that an observed enhanced vortex shedding may contribute to the initiation of RWIV.

Comparison of several innovative bridge cable surface modifications

Kenneth Kleissl, Christos T. Georgakis

Department of Civil Engineering, Technical University of Denmark, Kgs. Lyngby, Denmark,
kenk@byg.dtu.dk, cg@byg.dtu.dk

INTRODUCTION

Over the last two decades, several bridge cable manufacturers have introduced surface modifications on the high-density polyethylene (HDPE) sheathing that is installed for the protection of inner cable strands or wires. The modifications are based on research undertaken predominantly in Europe and Japan, with two different prevailing systems: HDPE tubing fitted with helical fillets and tubing with pattern-indented surfaces. In the US and Europe, helical fillets dominate, whilst pattern indented surfaces are more common in Asia, particularly for long-span cable-stayed bridges.

Research into the effectiveness of helical fillets and pattern-indented surfaces has shown that, besides their purported ability to suppress rain-wind induced vibrations, they also modestly reduce drag forces at design wind velocities. This is of particular interest to bridge designers, as wind on stay planes of long-span bridges can now produce more than 50% of the overall horizontal load on the bridge (Gimsing and Georgakis, 2012). Recently, the authors presented a comprehensive comparative study of the aerodynamic performance of these existing cable surface modifications (Kleissl and Georgakis, 2011, 2012). The comparison helped to eliminate uncertainties in previous studies, due to the fact that several researchers, in different facilities, with varying wind-tunnel flow characteristics and performance, have developed each separately. During the study, the authors were able to document the performance advantages of each of the modifications, but often not to the levels that have been commonly reported.

Therefore, similarly to Yagi et al. (2011), several new surface modifications are proposed herewith, in an attempt to combine and enhance the performance advantages of each of the existing modifications. Each of the proposed modifications was investigated through wind tunnel testing. The resulting mean static force coefficients were obtained from wind tunnel tests, with the cables positioned normal to the wind, and were used as “gateway” criteria for the subsequent investigation of rain rivulet suppression.

SURFACE MODIFICATIONS

Several variations of the surface modifications tested are shown in Table 1. The code given to each modification is a combination of a letter assignment to a type of modification and a running index number, specifying an increase in the number of add-ons and/or roughness. Therefore, letters A and B relate to the application of discrete sharp-edged cylindrical protrusions or Cylindrical Vortex Generators (CVGs) in various patterned distributions. The smaller CVGs (models A1-A8) have a height of 2 mm (D/80) and a diameter of 8 mm (D/20), whilst the larger ones (models B1-B4) have a diameter of 14 mm (D/11). The CVGs were selected so as to generate a localised increase in streamwise vorticity in the form of a pair of counter-rotating vortices. Trough flow mixing, these enhance the near-wall streamwise momentum and thus delay the point of flow separation. The helical pattern with a 30-

degree pitch was adopted, thus introducing waviness into the separation line along the cable axis and a wavy wake structure, which is known to disturb vortex shedding, whilst increasing base pressure.

As the CVGs were not expected to sufficiently suppress rain rivulets, other modifications with the potential for drag-reduction were developed, primarily with rivulet suppression in mind. This first of these modifications involves elongated channels (models C1-C2). Here, a thermal procedure was employed in the generation of the modification, which resulted in protruding lips on each side of the channels. This was intentionally done, so as to increase the localised streamwise vorticity and introduce a wavy wake structure, whilst forming a barrier for rain rivulets running along the cable.

The next three modifications (models D-F) all involve the application of protruding strakes. The strake cross-section has a triangular shape with concave sides and a height of 6 mm, corresponding to 3.75% of the cable diameter. The concave sides have two intended functions. Firstly, they work as a ramp for rain rivulets, forcing water to leave the surface of the cable. Secondly, the concave sides and the sharp tip lead to stronger directional guidance of the remaining water along the strake. In models D1-D2 the strakes were arranged laterally in a staggered helical pattern with a 30-degree pitch. On model E the strakes were positioned circumferentially all around the cable at 1.25 D spacing along the cable. Model F replicates the typical fillet arrangement on current stay cables with helical fillets, leading to a double helix at a 45-degree pitch angle.

Model G was originally proposed and tested by Yagi et al. (2011) and involves 12 rectangular protrusions (7.5 x 5 mm) that are placed in a helical pattern, so as to hinder the formation of water rivulets, whilst reducing the drag through the disruption of vortex shedding.

Finally and for comparison, the most prevalent cable surfaces were also tested. These include plain, pattern-indented and twin helically filleted.

WIND TUNNEL TESTS

The comparative wind tunnel tests were performed at the $2x2m^2$ cross-section closed-circuit DTU/Force Climatic Wind Tunnel, located at Force Technology, Lyngby, Denmark. The flow conditions were measured with a cobra probe and turbulence intensities of 0.41-0.64% were found for 33/66/100% of the tunnel maximum flow velocity at the quarter point positions, both vertically and horizontally. When examining the yawed cable for rain rivulet suppression, the reported flow conditions are correct for the upwind end of the cable. The surface modified sectional cable models were all based on 160mm diameter original plain full-scale HDPE samples, supplied by bridge cable manufacturers. For the determination of the force coefficients, the models were placed horizontally, resulting in a near 2-D flow normal to the models. The force coefficients were measured with 6-DOF force transducers at each end of the cable. The force transducers were installed in between the cable model and supporting cardan joints fixed to the walls. End plates with a diameter of approximately five cylinder diameters were fitted close to the model ends to eliminate undesirable flow disturbances from the cable ends and cardan joints. Dummy tube pieces were mounted around the force transducers, leaving approximately a 2 mm gap to the cable model and extending beyond the end plates. During the tests, the wind velocity was increased by regular increments of approximately 1 m/s, up to the maximum wind-tunnel velocity of 32 m/s, allowing for supercritical Reynolds numbers to be reached for all test models. With an effective model length of 1.53 m, the aspect ratio was 9.6:1. The blockage ratios for all section models are 8% and the drag coefficients have been corrected with the Maskell III method, according to Cooper et al. (1999). The force coefficients are found according to $C_i=2F_i/\rho U^2DL$ where, F_d and F_l are the drag and lift forces, respectively. ρ is the air density, D is model diameter, L the model length and U the upstream undisturbed wind velocity.

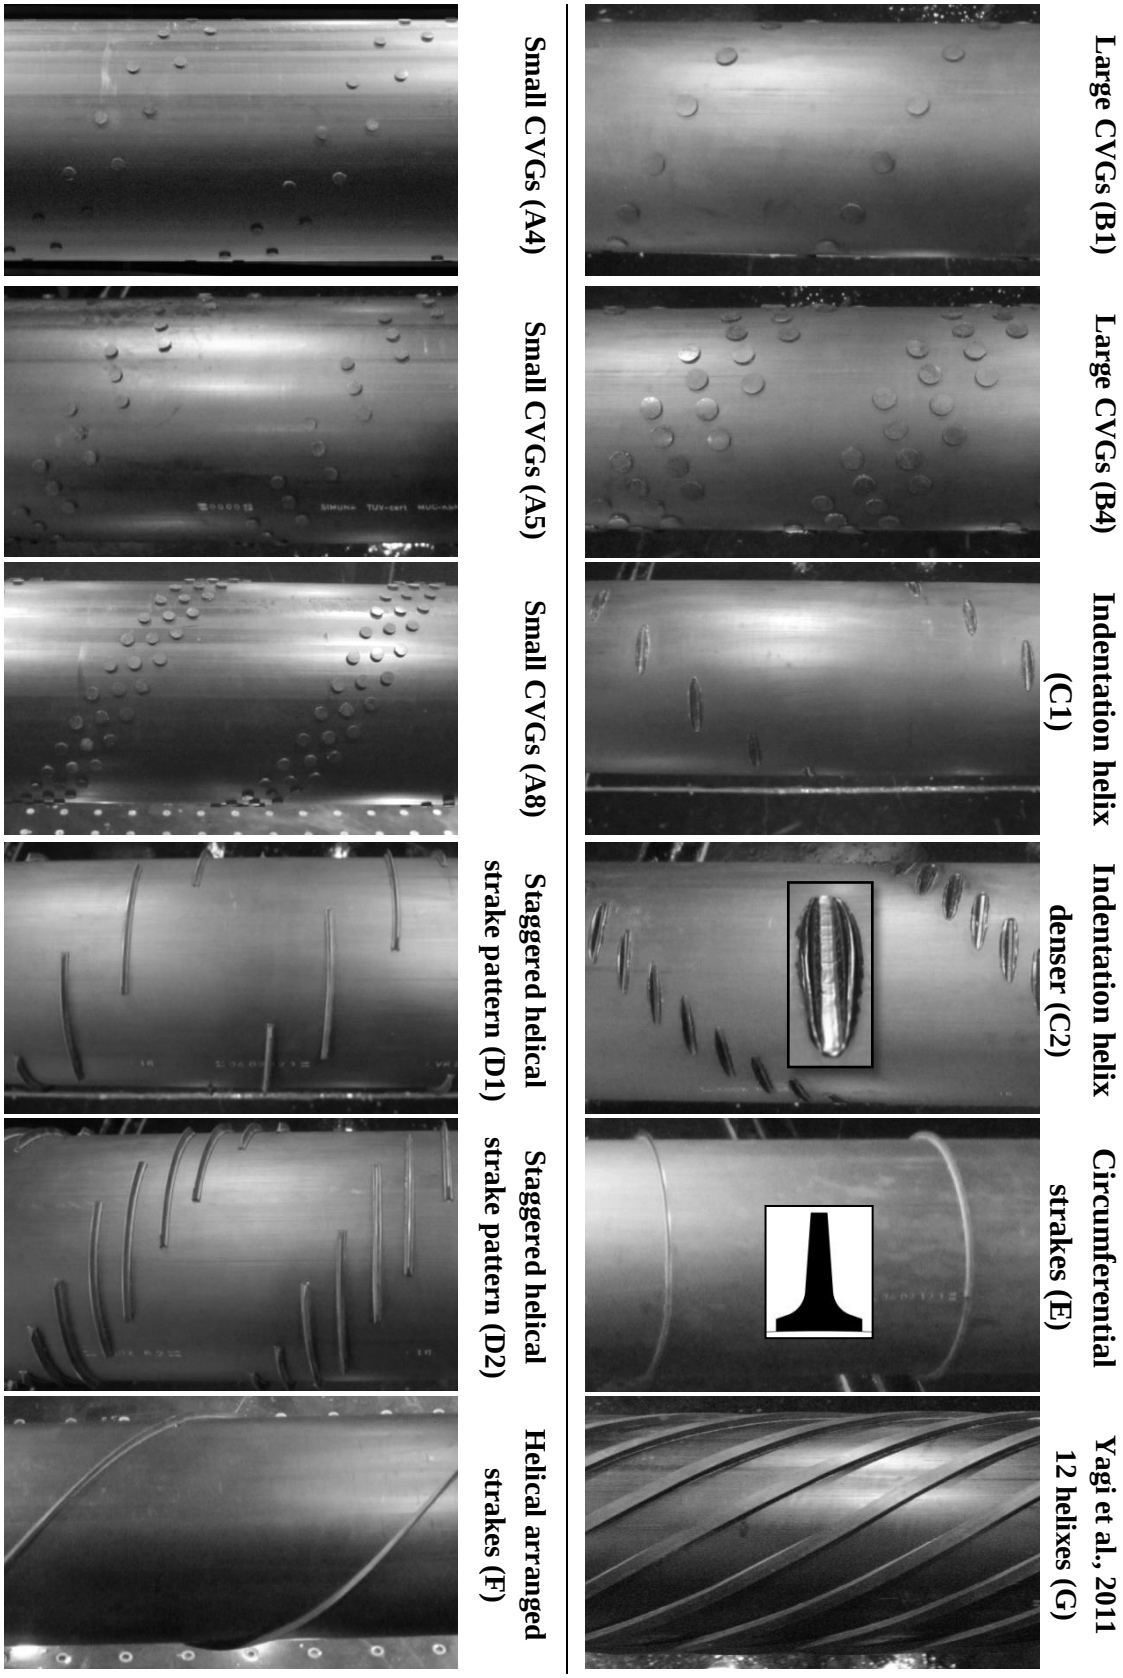

Table 1: Illustration of the different types of surface modifications tested.

RESULTS AND DISCUSSION

FORCE COEFFICIENTS

The average drag and lift coefficients obtained for all the tested models with CVGs applied are shown in Figure 1. For brevity only the results for the modifications shown in Table 1 are presented. Compared with the plain tubing, all of the models with CVGs experienced an earlier flow transition and a tendency for a near-constant drag coefficient in the supercritical region. With the appropriate number of CVGs, the flow transition occurs very gradually and with a minimum of lift force appearing. At the same time some of the tested modifications lead to a rather low supercritical drag coefficient. The best performance is obtained with test model A5, shown in Table 1. This model exhibits a near constant drag coefficient slope, resulting in a lift coefficient smaller than any of the currently applied surfaces. Throughout the tested supercritical Reynolds number range the drag coefficient remained below 0.59.

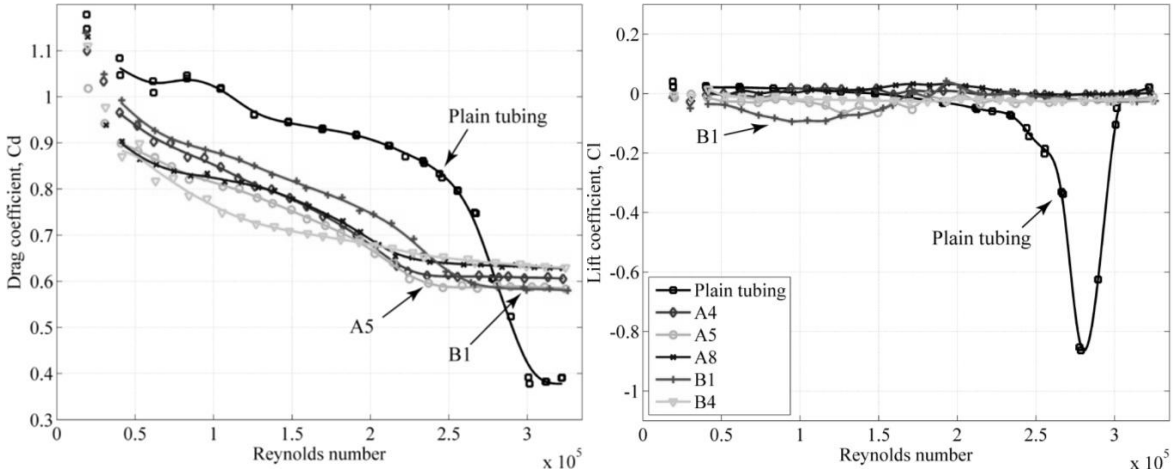

Figure 1. Drag (left) and lift (right) coefficients for the test models with CVG's.

The corresponding drag and lift coefficients for the remaining surface modified cable models, including the currently applied cables, are shown in Figure 2. Among these, model D2 and F appear successful in generating a gradual flow transition and sustaining near-zero lift coefficients. The drag optimised staggered strake arrangement of model D2 reaches a supercritical drag coefficient of 0.65, which is very similar to that of the pattern-indented cable surface. While the drag performance of the helical strake arrangement of model F is very similar to that of the currently applied cable with helical fillets. The reproduced cable surface with 12 rectangular helixes (G) proposed by in Yagi et al. (2011) resulted in a much larger drag coefficient than previously reported and was thus not further considered.

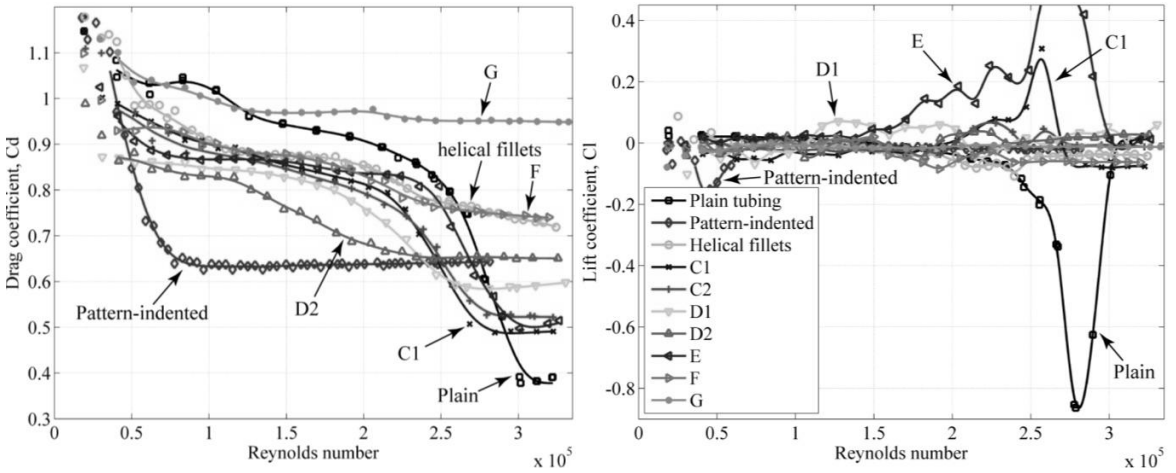

Figure 2. Drag (left) and lift (right) coefficients for the test models with indentations and strakes, compared with the currently applied cables having plain, pattern-indented, and helical fillets.

LIFT FORCE FLUCTUATIONS

A comparison of the fluctuating lift force between models was also made. With the test rig employed, only the total RMS lift fluctuations could be estimated. These are shown in Figure 3. Several of the tested models appear successful in generating small-scale vorticity, whilst avoiding any significant increase in lift force fluctuations. Among the models with CVGs, the smaller CVGs seem to perform best in this respect, with A5 having the best combination of low drag and lift. Model F exhibited the lowest level of lift fluctuations, whilst model D2 and the traditional helical fillets also performed well. The largest fluctuations were observed with the pattern-indented surface, with the lift experiencing a significant peak around Re~1.76×10^5.

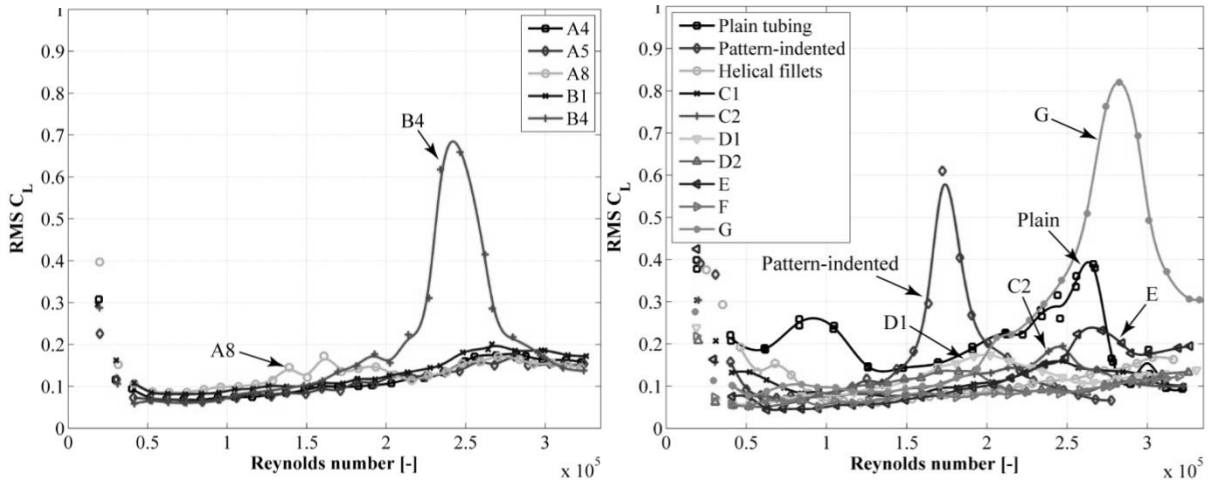

Figure 3. RMS values for the static lift force coefficients. Surface modified models with CVGs (left) and remaining surface modified models including currently applied cables (right).

RIVULET SUPPRESSION

Preliminary static tests on a plain cable showed that a lower rain rivulet formed for all tested wind velocities, while an upper rivulet only formed within the range of approximately 7-15m/s. Outside this range, the upper rivulet did not form as either gravity or the wind loading became dominant. As RWIVs typically occur within this velocity range, the presence of the upper rivulet is often considered critical for the generation of vibrations. The upper rain rivulet on a plain cable can be seen in Figure 4, whilst the lower rivulet is shown in Figure 5. All of the rivulet suppression tests were performed with the cable declining along the wind direction at a cable inclination angle of 40 degrees and with a yaw angle of +/- 22.5 degrees (relative to the along wind direction). In both situations the relative cable-wind angle is 45 degrees. See Kleissl and Georgakis (2012) for definition of angles.

The appearance and position of the rivulets were initially identified during simulation of uniform rain. Afterwards it was confirmed that by adding water only at the upper end of the cable, the same rivulets still formed along the full length of the cable. Based on this, it was decided that the inclined cable should consist of plain tubing at the upper part, where water was added, and then changed into the modified surface, in the central part of the section model, where the rivulets had been fully established. This allowed for a more conservative evaluation of the rivulet suppression ability of the modified cable surfaces.

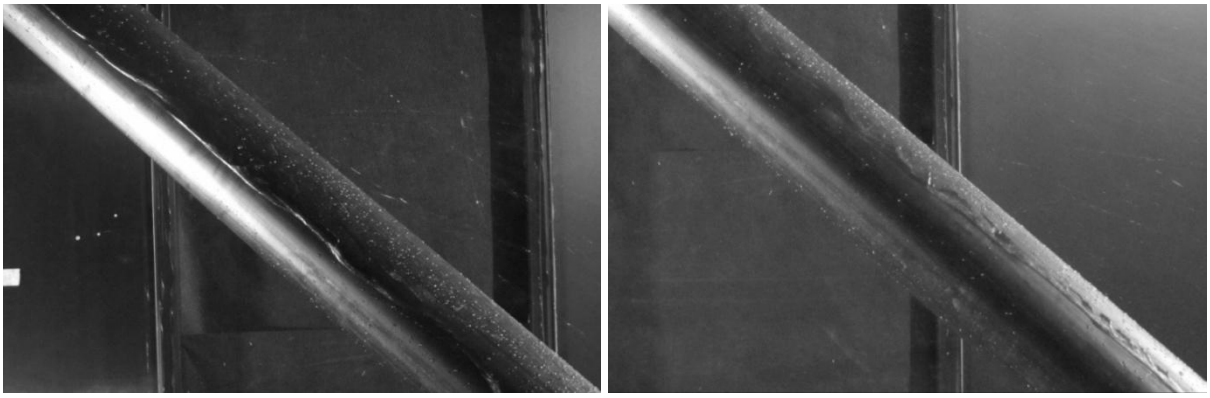

Figure 4. Plain tubing – strong presence of the upper rivulet. 8 m/s (left) and 14 m/s (right).

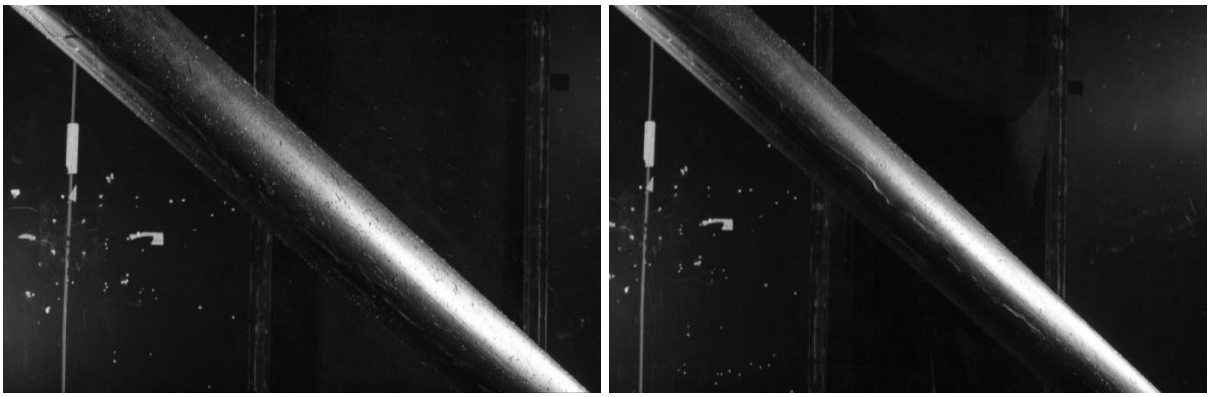

Figure 5. Plain tubing – strong presence of the lower rivulet. 8 m/s (left) and 14 m/s (right).

Figure 6 shows the upper rivulets forming on cable models A8 and B4. Neither of the two CVG sizes was capable of hindering the rivulets. Only minor rivulet disturbances were observed.

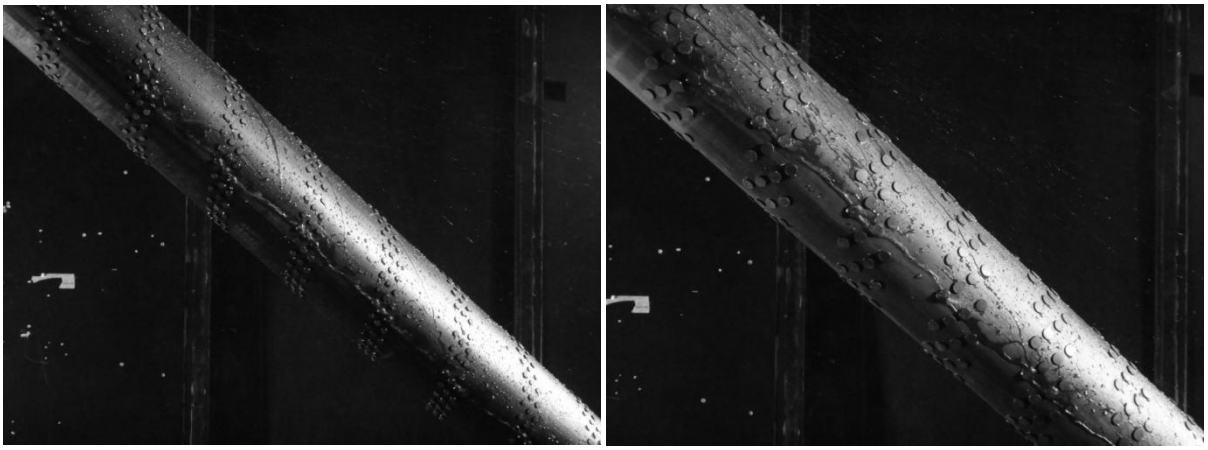

Figure 6. Strong presence of the lower rivulet at 14 m/s. Model A8 with small CVGs (left) and model B4 with larger CVGs (right).

Modified cable models C2 and model E are shown in Figure 7. Whilst neither of them completely suppressed the rivulets, the model with circumferentially arranged strakes (E) only experienced a weak upper rivulet. Although some of the water was knocked off of the surface, the strake arrangement failed to guide the remaining drops away from the point of balance, were the upper rivulet is stable.

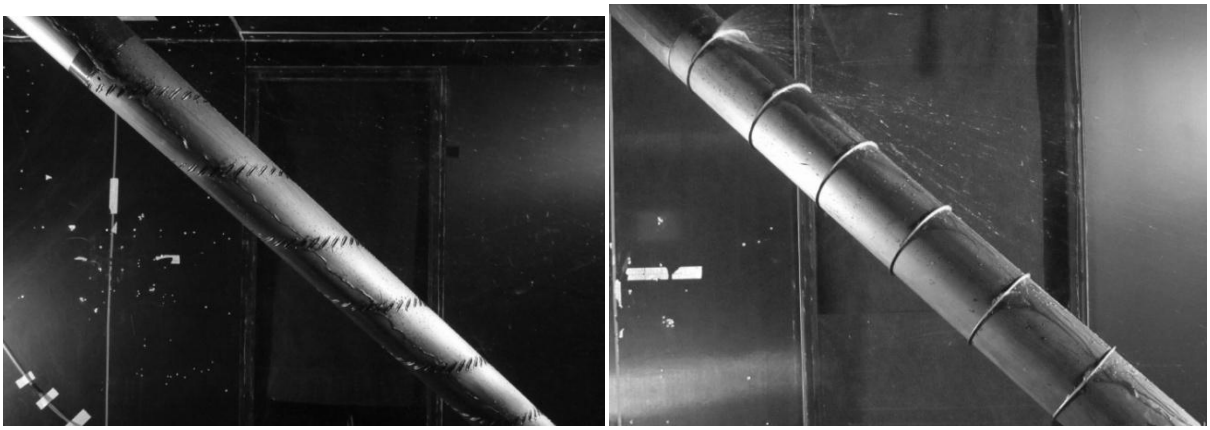

Figure 7. Lower rivulet forming on model C2 at 14 m/s (left) and model E with a weak upper rivulet at 14 m/s (right).

Figures 8-9 show how model D2, with the staggered arrangement of strakes, and model F, with helical strakes, both completely suppress the rivulets. In both cases the strakes work as ramps, which knock off the water rivulet from the surface of the cable.

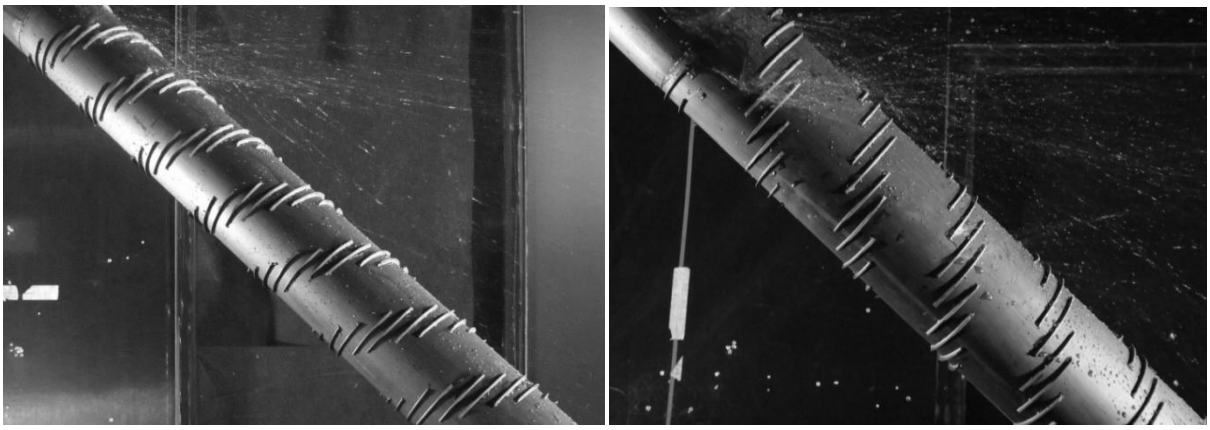

Figure 8. Model D2 completely suppressing the rivulets at all tested angles. Upper rivulet at 14 m/s (left) and lower rivulet at 14 m/s (right).

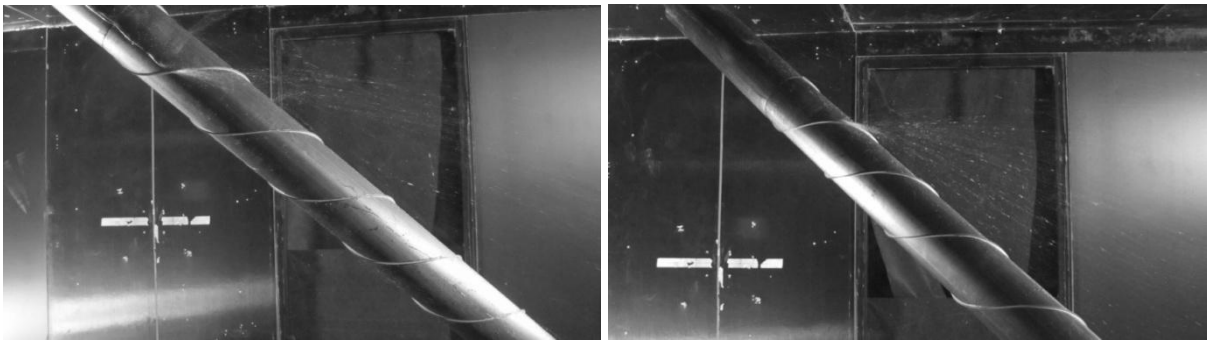

Figure 9. Model F with helical strakes completely suppressing the rivulets. Lower rivulet at 14 m/s (left) and upper rivulet at 14 m/s (right).

The cable with the currently applied helical fillets was found to be partly effective. Figure 10 shows how both a lower and upper rivulet could form despite the fillets' presence.

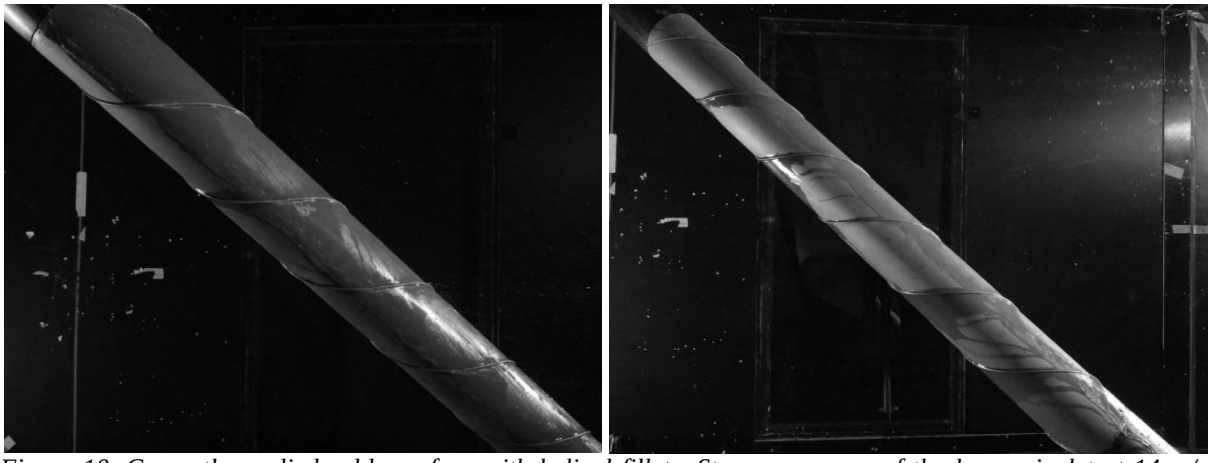

Figure 10. Currently applied cable surface with helical fillets. Strong presence of the lower rivulet at 14 m/s (left) and the upper rivulet at 14 m/s (right).

BRIEF CONCLUSION

Several novel and one previously proposed cable surface modification have been wind tunnel tested for the determination of aerodynamic force coefficients and rain rivulet suppression. Two of the proposed surface modifications outperform or match the current cables with helical fillets, both in drag reduction and rivulet suppression, whilst most of the other proposed modifications were unable to do both. While one of these newly proposed surfaces have similar drag coefficient to that of the current helically filleted cables, the other outperforms it and reaches a drag coefficient of only 0.65; at a level similar to that of the pattern-indented surface.

ABSTRACT: Wind tunnel tests and buffeting analyses were conducted to investigate wind induced responses of a catwalk structure of a suspension bridge. It was found from the wind tunnel tests that the Reynolds number effects on the aerostatic coefficients were negligible for the catwalk floor systems. Design formulae were proposed to estimate the aerostatic coefficients of catwalks with various solidity ratio and angle of attack. The buffeting analysis results revealed that tying the catwalk on an erecting main cable may be an effective structural countermeasure to reduce the lateral displacements of the catwalk.

KEYWORDS: Catwalk; Suspension bridge; Wind force; Wind tunnel test; Reynolds number.

1 INTRODUCTION

1.1 *Catwalk system*

Catwalk structures are temporary walkways that allow the erection of main cables in suspension bridges. As shown in Figs. 1 and 2, catwalk structures consist of a few ropes, wooden beams, wooden steps, and porous wire meshes at the bottom and sides. The ropes support a worker's weight, equipment for cable erection, and some wires forming main cable. The other components of catwalk are used for pedestrian comfort and safety. A pair of catwalk structures is generally installed along the main cables and linked at regular intervals by cross bridges.

Figure 1. Catwalk structure of Kwangyang Bridge.

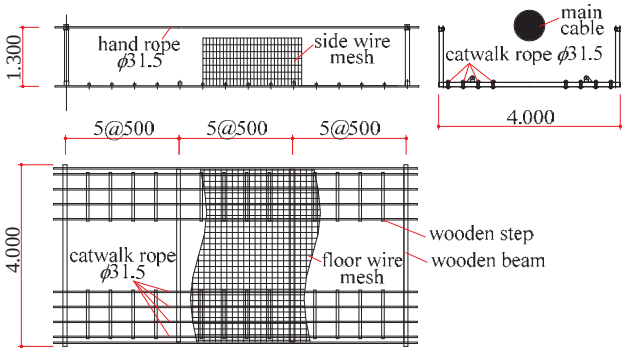

Figure 2. Details of the catwalk system.

The target model used in the present study was a catwalk structure derived from a design alternative of the Kwangyang Bridge, which has a main span length of 1,430 m (Fig. 1). The data used in this paper are not the actual properties of the Kwangyang Bridge catwalk but those of an alternative submitted to a design competition by DM Engineering Company.

As shown in Fig. 2, the width and height of the single side catwalk were 4.0 m and 1.3 m, re-

spectively. Each catwalk consists of 10 ropes with a diameter of 31.5 mm and a safety apparatus consisting of wire mesh, a wooden step, and a hand post. The solidity ratios of the side and bottom were 7% and 16%, respectively.

1.2 *Previous research and research objective*

The effects of wind on catwalk systems have not been well defined although many suspension bridges have recently been completed or are under construction worldwide (Tanaka 1998). Kawaguchi and Fukunaga (1995), Takeno et al. (1997), and Kitagawa (2004) suggested an erection plan for the catwalk structure in the Akashi Bridge. They assessed possible technical problems arising from the erection of the main cable such as the hauling system, erection sequence, static deformation, aerodynamic stability, arrangement of cross bridges, and vibration control measures. Matsuzaki et al. (1990) introduced the fabrication and erection of the prefabricated parallel wire strand used for most of the Honshu-Shikoku Bridges in Japan.

Shinichi et al. (1997) provided information for the design and construction of the catwalks for the Kurushima Bridges. They tested the effectiveness of stay ropes and guy ropes to mitigate vibrations of the catwalk using a 1/10 scaled structural model. Recently, Zheng et al. (2007) performed wind tunnel tests for the catwalks of the Runyang Bridges. Although they measured aerostatic force coefficients for various angles of attack and yaw angles, their tests were limited to a specific catwalk and did not provide general information for the aerodynamic forces acting on catwalk structures.

As a countermeasure to mitigate the lateral vibration of catwalks, additional storm ropes have been used to stabilize catwalk structures, which are sensitive to wind action due to their flexibility. The use of storm ropes, however, is associated with some disadvantages such as a protracted construction period, inconvenient navigation, and anchorage problems (Akiyama et al. 1999). Recently, additional guy ropes parallel to catwalk ropes or horizontal ropes connecting each catwalk have been adopted to reduce the horizontal vibrations caused by wind as well as by catwalk use (Hojo et al. 1995).

As summarized above, limited research has been conducted concerning the aerodynamic characteristics of catwalk structures. In particular, Reynolds number effects of porous catwalk structures have not been investigated. In this study, wind tunnel tests of two different scale models were performed in order to investigate the effects of the Reynolds number, main cable, and solidity ratio. Parameter studies of structural properties of catwalks and countermeasures to vibration were performed to examine the wind induced responses of catwalks by applying buffeting analysis in the time domain. This paper summarizes the technical results obtained from wind tunnel tests and buffeting analyses of catwalks.

2 EXPERIMENTAL SETUP

The parallel catwalks along the bridge axis are assumed to be aerodynamically independent of each other, because the porous catwalks were separated by more than 20 m. Consequently, wind tunnel tests were only conducted for a single catwalk.

Two rigid models with scale of 1/14 and 1/4 were fabricated and tested in wind tunnels to obtain the aerostatic force coefficients of the catwalk floor system. The solidity ratios of the model were varied by replacing porous wire mesh tied at steel frame. In order to investigate the Reynolds number effects, the aerostatic force coefficients of two different scaled models were measured at various wind velocities ranging from 5 to 30 m/s, which correspond to 1/84 to 1/4 of the Reynolds number of the actual catwalk.

(b) 1/4 scale model in the large wind tunnel

Figure 3. Catwalk models in the wind tunnels.

Fig. 3 shows the catwalk models installed on external force balances in the wind tunnels. The wind tunnel tests were carried out in two wind tunnels at the KOCED Wind Tunnel Center at Chonbuk National University in Korea. The 1/4 scale model tests were performed at the high speed test section of a closed return type wind tunnel. The size of the test section was 5.0 m wide × 2.5 m high × 20 m long, and the maximum wind speed was 31 m/s. The 1/14 scaled model was tested at the small wind tunnel with a test section of 1.0 m wide × 1.5 m high × 5 m long. The turbulent intensities of the large and small wind tunnels are less than 1% and 0.5% respectively.

The aerostatic forces acting on the models were measured using a pair of JR3 force balances that were capable of reading three forces and the associated three moments. The mean wind speed was measured using a pitot tube and a pressure transducer. The angle of attack was varied from -10 degree to +10 degree at 1 degree intervals. The correction for blockage effect was not done because blockage ratio of the models was less than 1%. The forces and moments were transformed into non-dimensional aerostatic coefficients using the following equations.

$$C_D = \frac{D}{\frac{1}{2}\rho V^2 H}, \quad C_L = \frac{L}{\frac{1}{2}\rho V^2 H}, \quad C_M = \frac{M}{\frac{1}{2}\rho V^2 H^2} \tag{1}$$

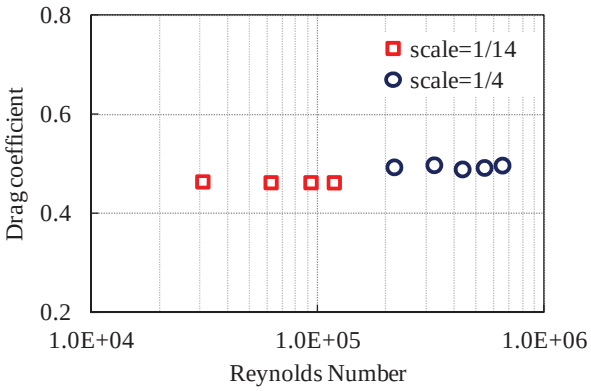
where, D is the drag force, L is the lift force, M is the pitching moment, V is the free stream wind speed, ρ is the air density and H is the height of the catwalk.

3 EXPERIMENTAL RESUTLS

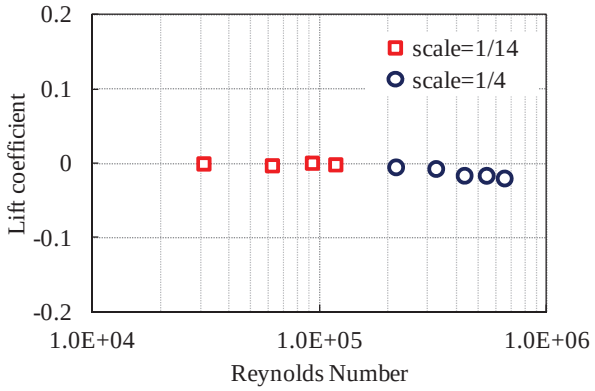
3.1 *Effects of the Reynolds number*

The Reynolds number effects on the aerostatic coefficients were investigated using the two different scale models under uniform wind flow. The Reynolds numbers of the actual catwalk range from 4.3×10^5 to 2.6×10^6, while those of the scale models ranged from 3.1×10^4 to 6.5×10^5. The height of catwalk models was used for reference length evaluating the Reynolds numbers.

Fig. 4 shows that the Reynolds number effects on the aerostatic force coefficients were not significant for the catwalk floor systems. Lift coefficient and pitching moment coefficient were also found to be independent to the Reynolds number. In summary, the Reynolds number effect on aerostatic force coefficients of the catwalk system is negligible.

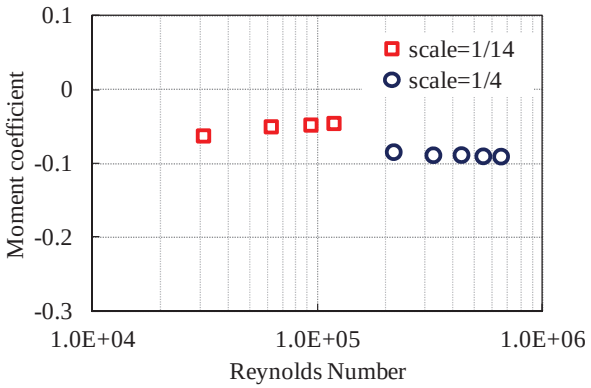


(a) Drag coefficient



(b) Lift coefficient

Figure 4. Aerostatic force coefficient as a function of Reynolds number.



(c) Moment coefficient

Figure 4.

Figure 5. Catwalk with the main cable at its center.

3.2 *Effects of the main cable*

As the main cable erection work nears completion through air spinning, a strand bundle is placed inside of the catwalk, as shown in Fig. 5. Differences in the displacements between the main cable and the catwalk structure can occur under high winds because of discrepancy in stiffness. Consequently, the location of the main cable within the cross section of the catwalk shifts from the center point to the quarter point of the catwalk. These conditions were simulated in the wind tunnel tests, and the effects of the main cable presence on the aerostatic coefficients of the catwalk structure were investigated.

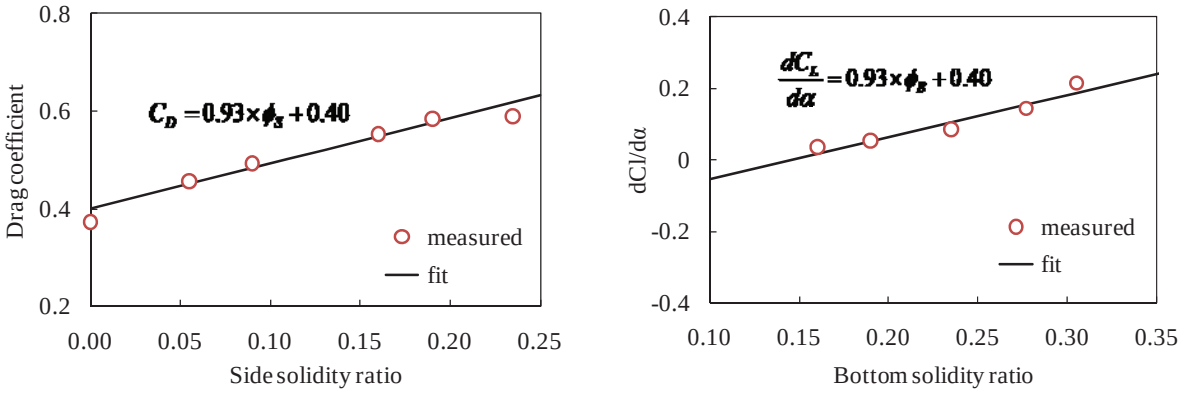
Fig. 6 shows the aerostatic coefficients of the catwalk without and with the main cable at the center point and quarter point. Although the aerostatic coefficients were slightly reduced in the presence of the main cable, the effects of the main cable on the aerostatic coefficients of the catwalk are negligible from a practical point of view.

3.3 *Effects of the solidity ratio*

The solidity ratios of a catwalk vary over a wide range depending on suspension bridges. The bottom solidity is generally higher than the side solidity. In order to investigate the effects of the solidity ratios on the aerostatic coefficients, wind tunnel tests were performed for solidity ratios

of the floor system ranging from 9% to 23.5% at the side and from 16% to 30.5% at the bottom. Most of the catwalk floor systems surveyed in this study was within the above ranges. The solidity ratios of the test model were changed by tying a proper porous wire mesh to frame of model.

The test results are shown in Fig. 6. It is clear from the figures that the side solidity ratio strongly affects the drag and moment coefficients but not the lift coefficient. In addition, the lift coefficient is only influenced slightly by the bottom solidity ratio but the drag and moment coefficients are not. From the above results, it is found that the drag and moment coefficients are a function of side solidity ratios, yet the lift coefficients are a function of bottom solidity ratio.



(a) Drag coefficient (b) Lift coefficient slope

Figure 6. Aerostatic Best fit lines of the aerostatic coefficients at attack angle of 0°.

3.4 *Design formulae for aerostatic coefficients*

From the results of wind tunnels tests for various solidity ratios of the catwalk, it is clear that the aerostatic coefficients are affected mostly by the solidity ratio of the floor system. As shown in Fig. 6, the drag coefficient and moment coefficient are almost linearly proportional to the side solidity ratio. Therefore, the following linear fit equations are proposed to estimate the aerostatic coefficients of a catwalk at attack angle of 0 degree as functions of the solidity ratios.

$$C_D = 0.93 \times \phi_S + 0.40 \tag{2a}$$

$$C_M = -0.32 \times \phi_S - 0.06 \tag{2b}$$

$$\frac{dC_L}{d\alpha} = 0.93 \times \phi_B + 0.40 \tag{2c}$$

$$C_L \approx \frac{dC_M}{d\alpha} \approx 0 \tag{2d}$$

where α is angle of attack, ϕ_S is the side solidity ratio, and ϕ_B is the bottom solidity ratio. In addition, the best fit equations for drag coefficients as a function of angle of attack and solidity ratio are given as follows.

$$C_D(\alpha, \phi_S) = 1.674 \times 10^{-3}\alpha^2 + 2.862 \times 10^{-4}\phi_S^2 + 0.470, \quad \phi_B = 16\% \tag{3a}$$

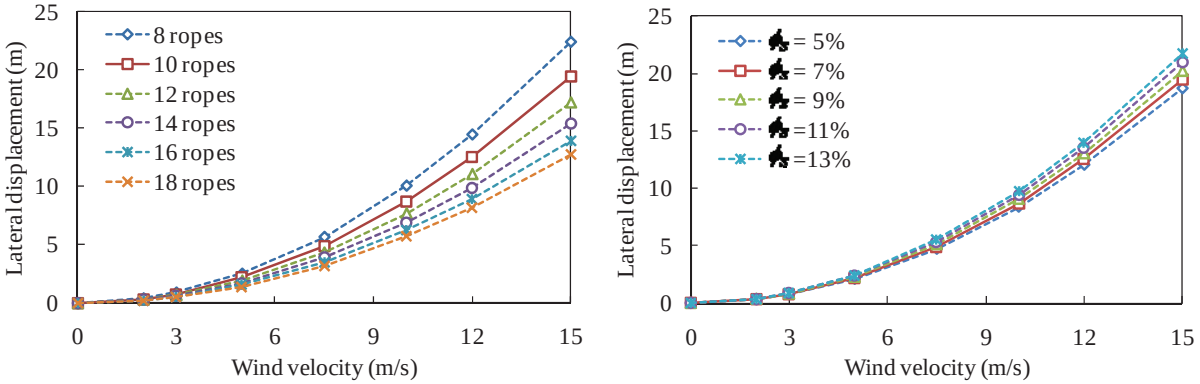
$$C_D(\alpha, \phi_B) = 1.977 \times 10^{-3}\alpha^2 + 1.597 \times 10^{-5}\phi_B^2 + 0.493, \quad \phi_S = 9\% \tag{3b}$$

4 WIND INDUCED RESPONSES

4.1 *Structural modeling and buffeting analysis*

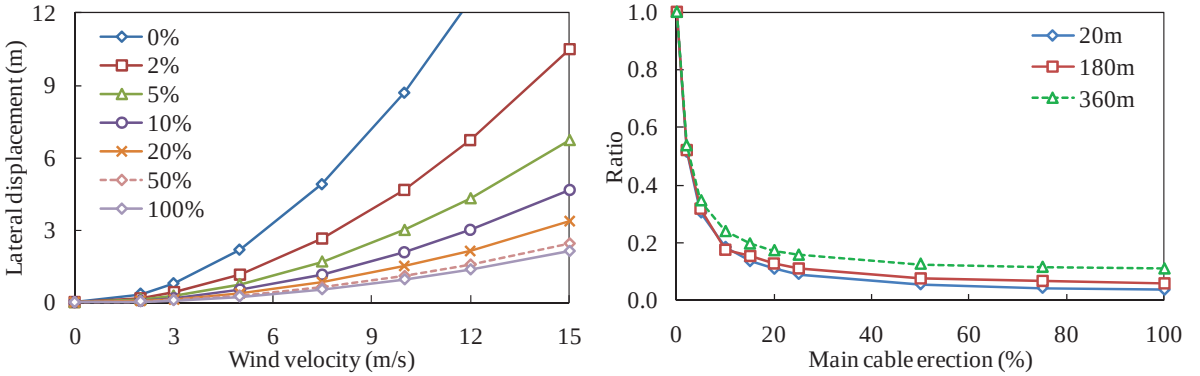
The catwalk structural system was modeled using finite element based structural analysis software developed by DM Engineering Co. Isolated catwalk system neglecting the flexibility of the supporting towers was adopted at the analysis. The catwalk ropes were modeled by an elastic catenary element and cross bridges were modeled by a frame element. A total of 10 ropes at each side of the catwalk were considered to behave coincidently and were modeled as a single equivalent rope. The inertial effects of the wood steps, hand posts, and wire meshes were considered and their stiffness were neglected in the analysis.

To find the unstrained length and initial tension of ropes for the initial equilibrium configuration, present study used the TCUD (target configuration under dead loads) method that was an iterative numerical approach based on the Newton-Raphson method. Detail description of the TCUD method can be found in the reference (Kim and Lee 2001). By using the computed unstrained length and initial tension, the initial nonlinear static analysis was firstly conducted in order to include the influence of self weight on the deformations and internal forces of the catwalk structure, and then the free vibration analysis was done at next. The natural frequencies of the lowest four lateral modes were found to be 0.049 Hz, 0.097 Hz, 0.146 Hz, and 0.195 Hz. The lowest four vertical modes were 0.137 Hz, 0.194 Hz, 0.231 Hz, and 0.275 Hz.



(a) Effect of the number of ropes (b) Effect of the side solidity ratio

Figure 7. Static lateral displacements of the catwalk under wind loads.



(a) Displacements as a function of the main cable erection ratio (b) Reduction ratio of displacements as a function of the tying interval

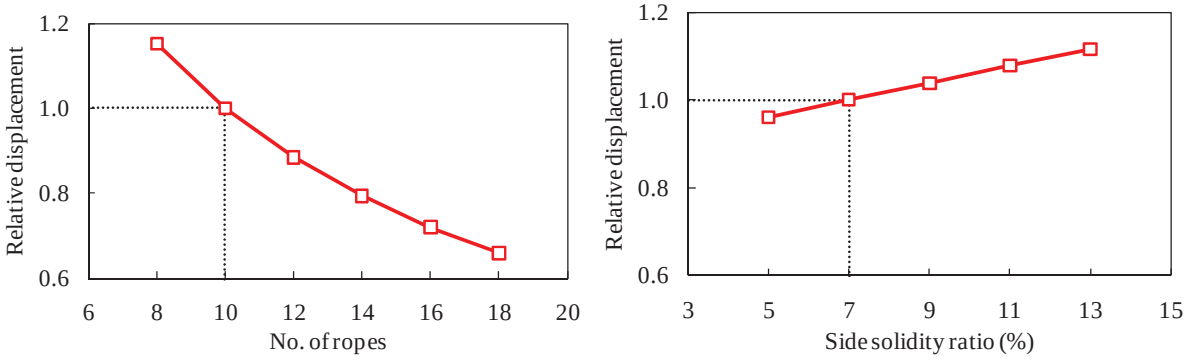
Figure 8. Static lateral displacements of the catwalk tied to the erecting main cable.

The horizontal and vertical components of turbulent wind velocities were generated by the ARMA technique considering special correlations along the bridge axis (Cao et al. 2000). Wind velocities were generated every 50 m along the bridge axis. A modal analysis combining the free vibration data and buffeting forces was performed to compute the catwalk displacements under turbulent winds. In the quasi-steady theory, the instantaneous forces acting on the moving catwalk structure are almost identical to the static forces at the same effective attack angle, and the phase lag between wind and moving body velocity is not considered. Aerodynamic damping was evaluated from the forced vibration tests (Kwon and Lee 2009).

4.2 *Static responses*

Fig. 7 shows the static lateral displacements of the catwalk under wind loads. The displacements gradually decrease as the number of ropes increases. However, the cross bridge intervals had a minor effect on the static lateral displacements. Static displacements slightly increased as the side solidity ratio was increased. This is because the drag coefficient increased by only 20% as the side solidity ratios increased from 5% to 13%.

Fig. 8(a) shows the static lateral displacements of the catwalk as a function of main cable erection completion. As the main cable erection was close to completion, the significantly increased stiffness of the main cable contributed to reduce the lateral displacement of the tied catwalk. Fig. 8(b) shows the effect of the tying interval between the catwalk and main cable on the lateral displacement. The lateral displacement can be effectively reduced by tying down the catwalk and main cable, regardless of the tying interval if the stress level of tying material is acceptable.



(a) Effect of the number of ropes (b) Effect of the side solidity ratio

Figure 9. Relative dynamic lateral displacements of the catwalk under turbulent winds.

4.3 *Dynamic responses*

Relative dynamic lateral displacements of the catwalk are given in Fig. 9. To allow a relative comparison of each structural type, the lateral displacements of the catwalks were normalized by dividing by the lateral displacement of the generic catwalk shown in Fig. 2. The dynamic displacements were significantly reduced as the number of ropes was increased. The cross bridge slightly contributed to reduce the lateral displacements. However, increasing the number of cross bridges may not be an effective way to reduce the lateral vibrations. The dynamic displacements also slightly increased as the side solidity ratio increased, as in the static evaluation results. In conclusion, the reduction of dynamic displacements can be effectively accomplished by increasing the number of ropes, that is, stiffening. However, the effect of the cross bridge interval on the vibration reduction is not significant.

5 CONCLUSIONS

Wind tunnel tests and buffeting analysis were performed in order to investigate wind induced responses of catwalk structures of a suspension bridge. The main findings of the present study are as follows.

The wind tunnel tests revealed that the Reynolds number effects on the aerostatic coefficients were negligible for the catwalk floor systems. The aerostatic coefficients of the catwalk were found to be consistent for practical purposes, regardless of the presence of the main cable inside the catwalk. Simple design formulae that are functions of the solidity ratios were proposed to estimate the aerostatic coefficients of the catwalk. It was found from the buffeting analysis that static and dynamic lateral displacements of the catwalk significantly decreased as the number of ropes increased. Lateral displacements were effectively reduced by tying down the catwalk and erecting a main cable.

Wind tunnel tests for simulating large-amplitude, low-frequency galloping on overhead transmission lines

Hisato Matsumiya [a*], Takashi Nishihara [a]

[a] *Central Research Institute of Electric Power Industry, 1646 Abiko, Abiko-shi, Chiba-ken 270-1194, Japan * E-mail: hisato-m@criepi.denken.or.jp*

ABSTRACT: In order to carry out a complete investigation of the galloping phenomenon of overhead transmission lines under ice and snow accretion, the authors develop a modeling technique that enables physical simulation of the galloping motion of actual transmission lines in a wind tunnel. The test apparatus proposed here is composed of a transmission wire sector model supported in the wire axis direction by multiple elastic cords. This unique support allows the sector model to vibrate with large amplitudes at low frequencies in the vertical, horizontal, and torsional directions. Dynamic equations were derived for the large-amplitude motions of the model, and the frequency characteristics were examined theoretically and numerically. Free vibration tests in a wind tunnel were performed using a sector model of four-bundled conductors with dimensions identical to ACSR 410 mm^2 conductors. Observation of large amplitude galloping at low frequencies in these tests verifies the validity of this experimental technique and indicates that it is possible to fully discuss the galloping oscillation characteristics and unsteady aerodynamic forces during the vibration by using this technique.

KEYWORDS: Galloping, Overhead transmission lines, Sector model, Elastic rope

1 INTRODUCTION

The galloping phenomenon of overhead transmission lines is sometimes observed when they are subject to ice and snow accretion, which causes significant vertical oscillation with horizontal and torsional oscillation at low frequency. A considerable amount of research effort has been focused on this phenomenon [1] through studies such as field observation of full-scale transmission lines to investigate the actual characteristics of ice and snow accretion and analysis of the dynamic response of the lines caused by galloping [2-5]. While galloping of full-scale lines can be observed, it is difficult to identify in detail the conditions that induce galloping, e.g., accreted shape distribution and wind speed distribution. Furthermore, systematic clarification of the occurrence conditions and response characteristics is also difficult, because the structural conditions are difficult to alter and climate conditions in the observation period is limited. Thus, numerical analysis methods have been developed to simulate the dynamic response of lines under various conditions (structural characteristics, accreted shape, angle of attack, wind speed, etc.) [6-8]. Generally, aerodynamic forces are taken into account as quasi-steady forces [9] by using steady-state aerodynamic coefficients obtained from a wind tunnel test [10-12] and numerical fluid analysis [13,14]. However, it has been pointed out that the unsteady aerodynamic forces differ from the quasi-steady aerodynamic forces for large-amplitude motion: there is a significant difference in the aerodynamic moment [15,16]. Therefore, it is necessary to clarify the degree to which the simulation results are affected by this discrepancy.

Free vibration tests in a wind tunnel under definite input conditions offer an effective method for clarifying the occurrence conditions and response characteristics of conductor galloping. Furthermore, the influence of each individual condition can be clearly identified in the experiment, and the validity of the quasi-steady theory can be checked against the wind tunnel tests. Although some researchers have previously conducted free vibration tests in a wind tunnel [17-19], the oscillation amplitude has typically been limited to a comparatively small range because of experimental restrictions.

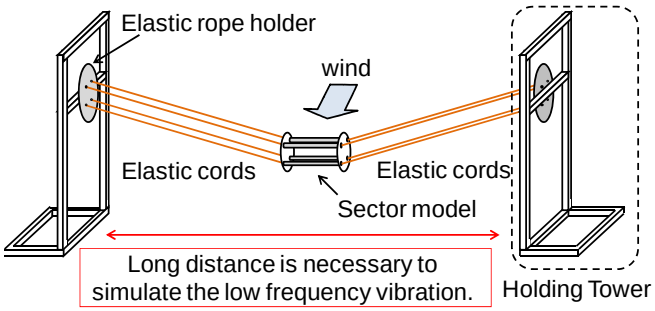

Figure 1 Elastic support technique of the sector model

Accordingly, the authors have developed a modeling technique that allows physical simulation of the galloping motion in actual overhead transmission lines. The sector model in the technique can oscillate in the vertical, horizontal, and torsional directions with large amplitude at low frequency, and the frequency of each motion can be selected arbitrarily and individually. This paper presents the details of this technique and the governing equations of motion of the sector model. The results of free vibration tests in a wind tunnel using this technique verify its applicability.

2 PROPOSED MODEL SUPPORT TECHNIQUE USING ELASTIC CORDS

2.1 *Model support technique*

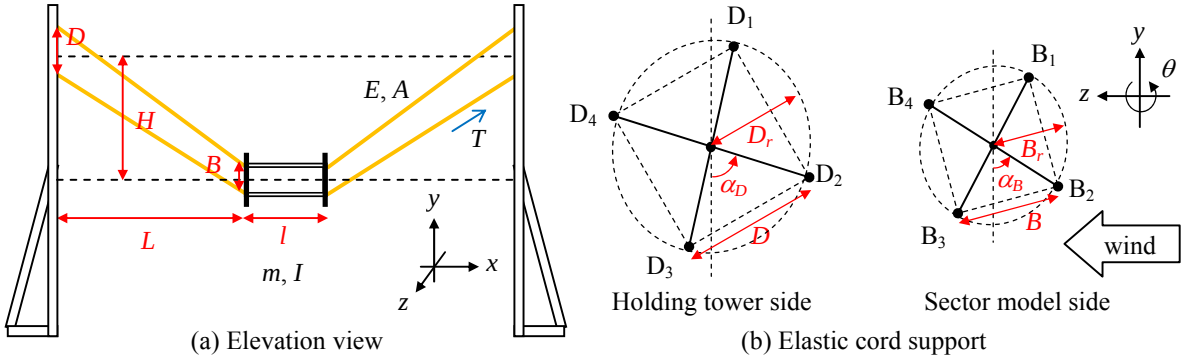
The experimental technique proposed here is shown in Figure 1. This system is composed of a transmission wire sector model that is supported by multiple elastic cords extending in the direction of the wire axis. The technique described here is characterized via support from "long" elastic cords with "low" rigidity. This unique support method allows the sector model to vibrate with significant amplitude at low frequencies in the vertical, horizontal, and torsional directions. Furthermore, in this experimental system, the elastic cord holder on the holding tower can be rotated to adjust the angle of attack of the sector model.

2.2 *Governing equations of motion*

The equations of motion of the sector model can be derived using Lagrange's equation. The relevant parameters in this experiment are listed here and shown in Figure 2.

m	mass of the sector model [kg]
I	mass moment of inertia of the sector model [kgm^2]
B_r	radius of the elastic cord support on the sector model side [m]
D_r	radius of the elastic cord support on the holding tower side [m]
α_B	inclined angle of the elastic cord support on the sector model side [rad]
α_D	inclined angle of the elastic cord support on the holding tower side [rad]
L	horizontal length of the elastic cords [m]
H	sag (depth) of the sector model from the support point [m]
T	tension in the elastic cords [N]
EA	axial rigidity of the elastic cords [N]

The sector model is supported by eight elastic cords from the right and left sides, i.e., four elastic cords on each side. The distance between each elastic cord is B ($B=\sqrt{2}B_r$) on the sector



(a) Elevation view (b) Elastic cord support

Figure 2 Definition of each parameter

model side and D ($D=\sqrt{2}D_r$) on the holding tower side. It is assumed that all elastic cords are uniform and are set with same tension, and the weight of the elastic cords is ignored.

As shown in Figure 2 (b), the elastic cord support points on the holding tower side are defined as D_1 to D_4, and those on sector model side are defined as B_1 to B_4. When the sector model is in the stationary condition, the cord lengths $L^*_{i0}(i=1,2,3,4)$ (i.e., the distance from D_i to B_i) are described as follows.

$$L^*_{10}=\left\{L^2+\left(-H+B_r\sin\alpha_B-D_r\sin\alpha_D\right)^2+\left(-B_r\cos\alpha_B+D_r\cos\alpha_D\right)^2\right\}^{1/2} \tag{1}$$

$$L^*_{20}=\left\{L^2+\left(-H-B_r\cos\alpha_B+D_r\cos\alpha_D\right)^2+\left(-B_r\sin\alpha_B+D_r\sin\alpha_D\right)^2\right\}^{1/2} \tag{2}$$

$$L^*_{30}=\left\{L^2+\left(-H-B_r\sin\alpha_B+D_r\sin\alpha_D\right)^2+\left(+B_r\cos\alpha_B-D_r\cos\alpha_D\right)^2\right\}^{1/2} \tag{3}$$

$$L^*_{40}=\left\{L^2+\left(-H+B_r\cos\alpha_B-D_r\cos\alpha_D\right)^2+\left(+B_r\sin\alpha_B-D_r\sin\alpha_D\right)^2\right\}^{1/2}. \tag{4}$$

When the axial rigidity of the elastic cords is constant regardless of the rate of elongation, the initial lengths are

$$L_{i0}=\frac{EA}{T+EA}L^*_{i0}. \tag{5}$$

The vertical, horizontal, and torsional displacements from the stationary position during vibration of the sector model are y, z, and θ, respectively, and thus the lengths "L^*_i" at this time are described as follows:

$$L_1=\left\{L^2+\left(-H+y+B_r\sin(\alpha_B+\theta)-D_r\sin\alpha_D\right)^2+\left(z-B_r\cos(\alpha_B+\theta)+D_r\cos\alpha_D\right)^2\right\}^{1/2} \tag{6}$$

$$L_2=\left\{L^2+\left(-H+y-B_r\cos(\alpha_B+\theta)+D_r\cos\alpha_D\right)^2+\left(z-B_r\sin(\alpha_B+\theta)+D_r\sin\alpha_D\right)^2\right\}^{1/2} \tag{7}$$

$$L_3=\left\{L^2+\left(-H+y-B_r\sin(\alpha_B+\theta)+D_r\sin\alpha_D\right)^2+\left(z+B_r\cos(\alpha_B+\theta)-D_r\cos\alpha_D\right)^2\right\}^{1/2} \tag{8}$$

$$L_4=\left\{L^2+\left(-H+y+B_r\cos(\alpha_B+\theta)-D_r\cos\alpha_D\right)^2+\left(z+B_r\sin(\alpha_B+\theta)-D_r\sin\alpha_D\right)^2\right\}^{1/2}. \tag{9}$$

These lengths can then be used to derive the equations of motion. Lagrange's equation without a damping term is given by

$$\frac{d}{dt}\left(\frac{\partial T_v}{\partial\dot{q}}\right)-\frac{\partial T_v}{\partial q}+\frac{\partial(U_k+U_g)}{\partial q}=0. \tag{10}$$

Here, T_v is the kinetic energy of the sector model, U_k is the gravitational potential energy of the sector model, U_k is the elastic potential energy of the cords, and q is the displacement (y, z, and θ). Each energy term is described as follows:

$$T_v=\frac{1}{2}m(\dot{y}^2+\dot{z}^2)+\frac{1}{2}I\dot{\theta}^2,\ U_k=2\sum_{i=1}^{4}\frac{1}{2}\frac{EA}{L_0}\left\{L_i-L_0\right\}^2,\ U_g=mgy. \tag{11}$$

Here, g is gravitational acceleration. By substituting these equations into Equation (10), the differential equations for the vertical, horizontal, and torsional motion are

$$
\begin{aligned}
&m\ddot{y} + 2EA\{-H + y + B_r \sin(\alpha_B + \theta) - D_r \sin\alpha_D\}\left(L_{10}^{-1} - L_1^{-1}\right) \\
&\quad + 2EA\{-H + y - B_r \cos(\alpha_B + \theta) + D_r \cos\alpha_D\}\left(L_{20}^{-1} - L_2^{-1}\right) \\
&\quad + 2EA\{-H + y - B_r \sin(\alpha_B + \theta) + D_r \sin\alpha_D\}\left(L_{30}^{-1} - L_3^{-1}\right) \\
&\quad + 2EA\{-H + y + B_r \cos(\alpha_B + \theta) - D_r \cos\alpha_D\}\left(L_{40}^{-1} - L_4^{-1}\right) + mg = 0,
\end{aligned} \tag{12}
$$

$$
\begin{aligned}
&m\ddot{z} + 2EA\{z - B_r \cos(\alpha_B + \theta) + D_r \cos\alpha_D\}\left(L_{10}^{-1} - L_1^{-1}\right) \\
&\quad + 2EA\{z - B_r \sin(\alpha_B + \theta) + D_r \sin\alpha_D\}\left(L_{20}^{-1} - L_2^{-1}\right) \\
&\quad + 2EA\{z + B_r \cos(\alpha_B + \theta) - D_r \cos\alpha_D\}\left(L_{30}^{-1} - L_3^{-1}\right) \\
&\quad + 2EA\{z + B_r \sin(\alpha_B + \theta) - D_r \sin\alpha_D\}\left(L_{40}^{-1} - L_4^{-1}\right) = 0,
\end{aligned} \tag{13}
$$

$$
\begin{aligned}
&I\ddot{\theta} + 2EAB_r\{+(-H + y)\cos(\alpha_B + \theta) + z\sin(\alpha_B + \theta) + D_r \sin(\alpha_B - \alpha_D + \theta)\}\left(L_{10}^{-1} - L_1^{-1}\right) \\
&\quad + 2EAB_r\{+(-H + y)\sin(\alpha_B + \theta) - z\cos(\alpha_B + \theta) + D_r \sin(\alpha_B - \alpha_D + \theta)\}\left(L_{20}^{-1} - L_2^{-1}\right) \\
&\quad + 2EAB_r\{-(-H + y)\cos(\alpha_B + \theta) - z\sin(\alpha_B + \theta) + D_r \sin(\alpha_B - \alpha_D + \theta)\}\left(L_{30}^{-1} - L_3^{-1}\right) \\
&\quad + 2EAB_r\{-(-H + y)\sin(\alpha_B + \theta) + z\cos(\alpha_B + \theta) + D_r \sin(\alpha_B - \alpha_D + \theta)\}\left(L_{40}^{-1} - L_4^{-1}\right) = 0.
\end{aligned} \tag{14}
$$

2.3 *Adjustment technique of each frequency*

If $B_r = D_r$, $\alpha_B = \alpha_D$, and the motion is assumed to be infinitesimal, the frequencies are given by

$$
f_z = \frac{1}{2\pi}\sqrt{\frac{g}{H}},\ f_y = \frac{1}{2\pi}\sqrt{\frac{g}{H}}\sqrt{1 + \frac{EAH^2}{TL_g^2}},\ f_\theta = \frac{1}{2\pi}\sqrt{\frac{g}{H}}\frac{B_r}{R}\sqrt{1 + \frac{EAH^2}{2TL_g^2}}\ . \tag{15}
$$

Here, f_z, f_y, and f_θ are the frequencies of the horizontal, vertical, and torsional motion, respectively, L_g is the cord length ($=\sqrt{L^2 + H^2}$), and R is the radius of gyration of the sector model around the x axis ($=\sqrt{I/m}$). Then, the tension in the elastic cords T is

$$
T = \frac{mg}{8}\frac{L_0^*}{H}. \tag{16}
$$

The relationship between the frequencies and the parameters in Equations (15) and (16) show that each frequency, f_z, f_y, and f_θ, can be arbitrarily chosen by calibrating T, EA, and B_r, respectively. This adjustment technique is also applicable when $B_r \neq D_r$, $\alpha_B \neq \alpha_D$, and the motion is large. In that case, the torsional frequency can be adjusted through the choice of B_r or D_r. However, when $B_r \neq D_r$, the torsional motion is coupled structurally to the horizontal motion.

3 FREE VIBRATION TESTS IN A WIND TUNNEL

To verify the applicability of this experimental technique, free vibration tests in a wind tunnel were performed using a sector model of four-bundled conductors. The test conditions and free vibration test results are presented in this section.

3.1 *Test conditions*

3.1.1 *Wind tunnel facilities*

The tests were performed in an Eiffel-type wind tunnel with an axial fan at the Central Research Institute of Electric Power Industry (Figure 3). The outlet area of the wind tunnel is 1.6 m × 2.5 m (width × height), and the maximum wind speed is 17 m/s. The sector model was set up in the center of the wide open test space, 1.0 m in front of the outlet as shown in Figure 4. The variation of the wind speed was ±1.0%, and the turbulence intensity was less than 0.5% in a 1.2 m ×

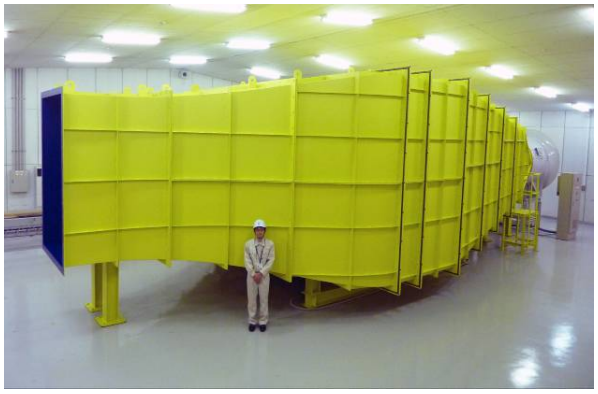


Figure 3 Overall view of wind tunnel

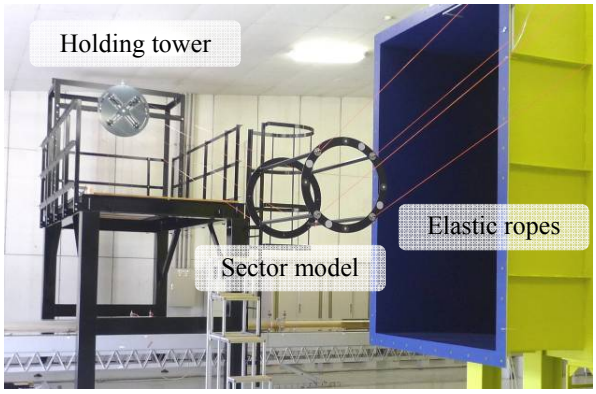

Figure 4 Experiment system

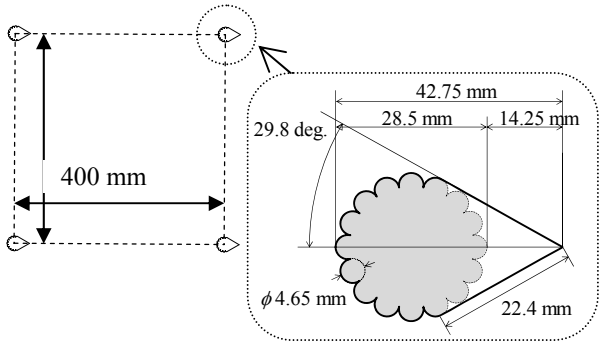

Figure 5 Cross-section of the sector model

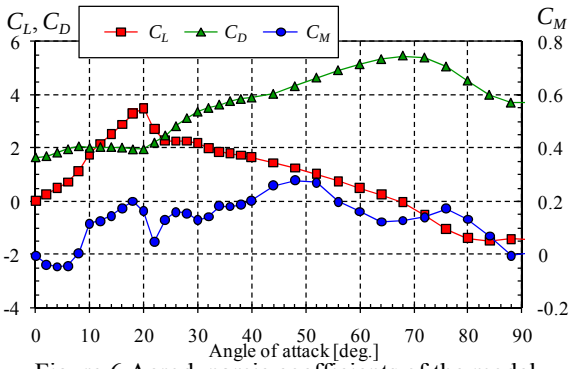

Figure 6 Aerodynamic coefficients of the model

2.0 m (width × height) area 0.5 m downstream of the outlet. The variation of the wind speed was ±1.0% in a 1.0 m × 1.5 m (width × height) area 2.5 m downstream of the outlet.

3.1.2 *Sector model shape and aerodynamic characteristics*

The four-bundled-conductor sector model had imitated snow accretion with a sharp triangular tip, the height of which was half the conductor diameter, as shown in Figure 5. The dimensions and weights of the model are identical to ACSR 410 mm^2 conductors with a span length l of 1.0 m. The angle of attack α was the same as α_B. The end plate was not installed this sector model because aerodynamic instability in the yaw rotation or spanwise directions may occur through the aerodynamic force on the end plate. The effect of the absence of the end plate should be discussed in future work.

The aerodynamic coefficients of the model in a wind speed of 10 m/s are shown in Figure 6 [12], and the aerodynamic coefficients fulfill the conditions of the Den Hartog criterion [10] in that the angle range is 20 to 24 degrees, which is just larger than the stalling angle. The definitions of the aerodynamic coefficients in this study are expressed as follows:

$$D_F = \frac{1}{2}\rho U^2 2D_l l C_D, L_F = \frac{1}{2}\rho U^2 2D_l l C_L, M_F = \frac{1}{2}\rho U^2 2D_l B_l l C_M. \quad (17)$$

Here, ρ and U are the air density [kg/m^3] and wind velocity [m/s], respectively. The mean value of the drag D_F [N], lift L_F [N], and pitching M_F [Nm] moments depend on the coefficients of the drag C_D, lift C_L, and moment C_M, respectively. The diameter of the conductor D_l is 0.0285 m, and the conductor center interval B_l is 0.40 m.

3.1.3 *Experimental set up and test cases*

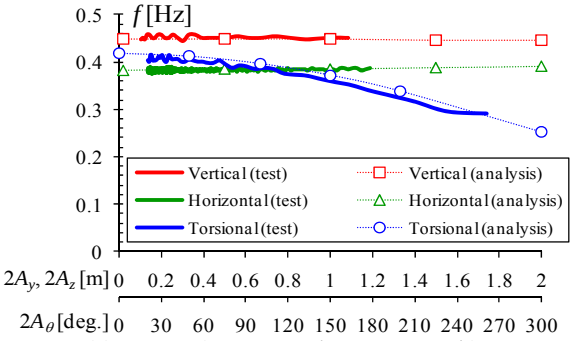
Each of the eight elastic cords supporting the sector model was a two-bundled urethane rubber rope with a diameter of 3 mm. To discuss the vibration characteristics of a certain structural con-

dition (frequency and damping), free vibration tests should be performed by changing both the angle of attack and wind speed simultaneously. However, in this study, the purpose of the tests is mainly to verify the applicability of this experimental technique, free vibration tests were performed by changing the angle of attack and wind speed individually. In case 1, the angle of attack was set to about 20 degrees to fulfill the conditions of the Den Hartog criterion [9], and free vibration tests were conducted at various wind speeds. In case 2, the wind speed remained constant at U = 11.9 m/s, and tests were conducted at varying angles of attack. The other conditions for each case are shown in Table 1, along with the frequencies calculated by Equation (15).

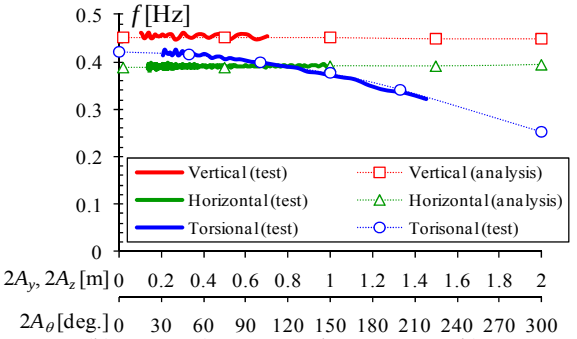
Since the oscillation amplitude caused by galloping might have hysteresis characteristics, the dynamic response was measured in two ways for each wind speed (or angle of attack): after disengaging from the stationary position and after applying a large initial vibration. The vertical, horizontal, and torsional oscillating displacements were measured by a video tracking system with a frame rate of 60 Hz.

Table 1 Test conditions

Parameters	Case 1	Case 2
m	6.692 kg	6.692 kg
I	0.535 kg m^2	0.535 kg m^2
$B = D$	0.400 m	0.400 m
$\alpha_B = \alpha_D$	19.2 deg.	−0.8 to 29.4 deg.
L	6.293 m	6.255 m
H	1.696 m	1.657 m
T	31.5 N	32.0 N
EA	176.4 N	176.4 N
U	1.6–14.6 m/s	11.9 m/s
f_{y0}	0.449 Hz	0.452 Hz
f_{z0}	0.383 Hz	0.387 Hz
$f_{\theta 0}$	0.417 Hz	0.421 Hz



(a) Case 1 (α_B = 19.8 deg., U = 0 m/s)



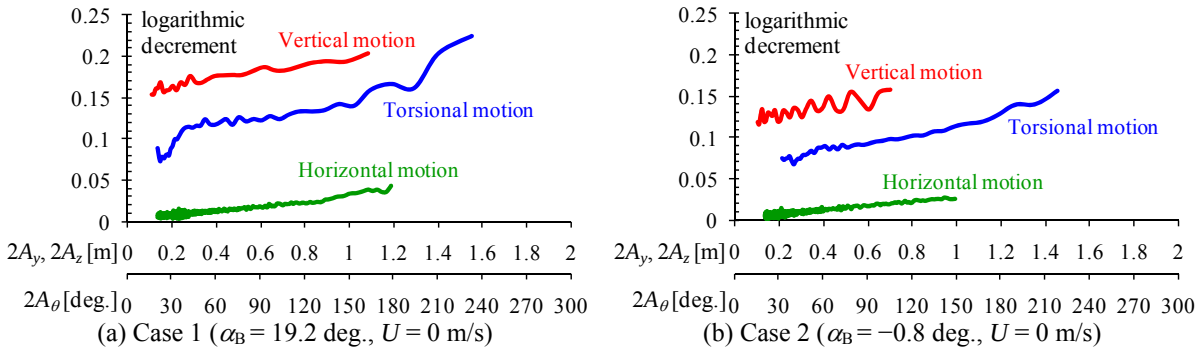
(b) Case 2 (α_B = −0.8 deg., U = 0 m/s)

Figure 7 Natural frequency characteristics

3.2 *Shift of natural frequency and structural damping with an increase in oscillation amplitude*

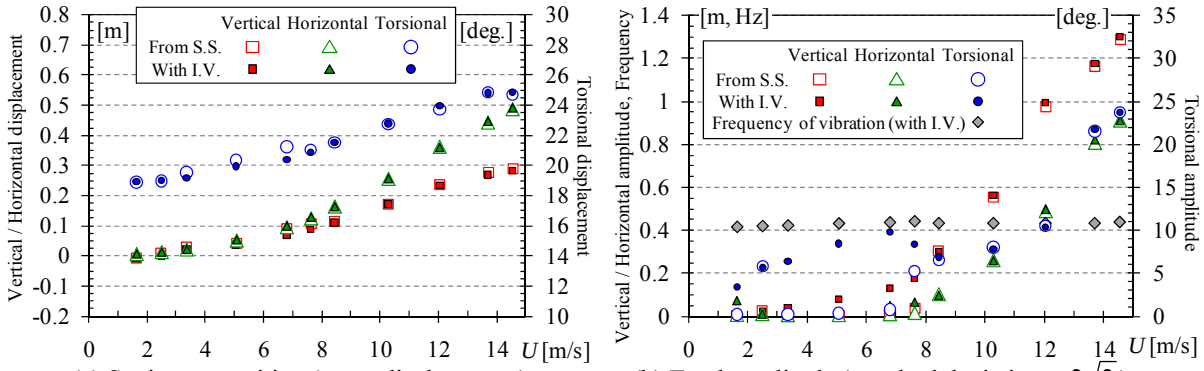
To investigate the natural frequency characteristics and structural damping, free vibration tests were conducted in a wind speed of 0 m/s. In these tests, the response was measured after applying an initial displacement in one direction only; a total of three measurement test were performed, one for each direction. The amplitude of the vertical, horizontal, and torsional displacements are defined as A_y, A_z, and A_θ, respectively. Figure 7 shows the natural frequency characteristics as a function of the total (peak-to-peak) oscillation amplitude of each degree of freedom. The results show a shift in the natural frequency with an increase in oscillation amplitude, and the torsional displacement frequency, in particular, decreases with an increase in the oscillation amplitude.

The relationship between the frequency and amplitude was also calculated analytically, and the results are plotted in Figure 7. Here, by using the Runge-Kutta method, the time-series behavior after the initial vibration, which has a specific amplitude for each degree of freedom, is calculated by Equations (12) to (14), which are non-damping equations of motion. A power spectrum analysis of the displacement data then shows the predominant frequency of each vibration for each amplitude. The analytically calculated frequency is in good agreement with the test results and therefore verifies the validity of the governing equations of motion in Section 2.2.



(a) Case 1 (α_B = 19.2 deg., U = 0 m/s) (b) Case 2 (α_B = −0.8 deg., U = 0 m/s)

Figure 8 Structural damping characteristics



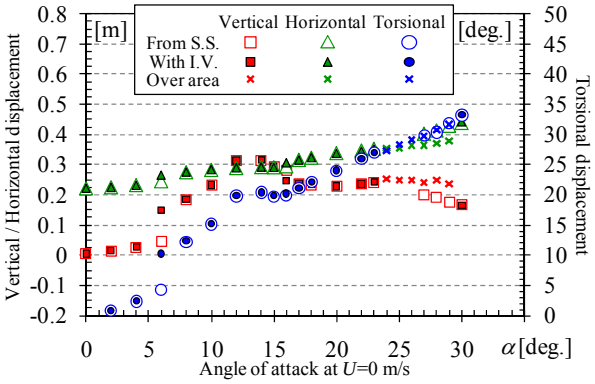
(a) Stationary position (mean displacement) (b) Total amplitude (standard deviation $\times 2\sqrt{2}$) and frequency of galloping oscillation

Figure 9 Test results at each wind speed in Case 1 (α = 19.2 deg.)

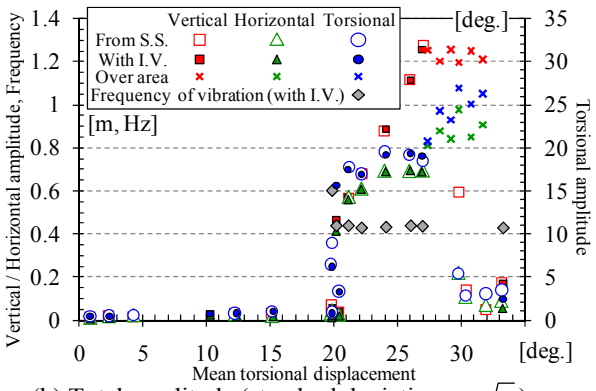
Figure 8 shows the structural damping characteristics, which also display a change with increasing oscillation amplitude. The structural damping of the vertical motion is the largest of the three directions because the elongation of the elastic cords is the longest. It was not possible to adjust the structural damping in the currently system, and thus, an adjustment technique will be developed in future work.

3.3 *Results of free vibration tests*

The results of the free vibration tests at each wind speed in Case 1 are shown in Figure 9. In these tests, "from S.S." indicates measurements of the response disengaged from the stationary state, and "with I.V." indicates measurements of the response after applying a large initial vibration. Figure 9(a) shows the stationary position at each wind speed that corresponds to the mean displacement from the stationary position in a wind speed of 0 m/s. The galloping oscillation observed in this tests had a steady amplitude and only one predominant frequency. Figure 9(b) shows the $2\sqrt{2}$ standard deviation, which corresponds to the total (peak-to-peak) amplitude, and also shows the frequency of the galloping oscillation. For some wind speeds in the range 1.6–7.6 m/s, galloping occurred when applying an initial vibration, although it did not occur from the stationary state. At wind speeds exceeding 7.6 m/s, the oscillation amplitude increased with increasing wind speed, with the vertical amplitude peaking at about 1.3 m and accompanied by horizontal and torsional oscillation. The vibration frequency was about 0.40–0.45 Hz. These results validate that the large-amplitude, low-frequency galloping observed in actual overhead transmission lines can be reproduced by using this experimental technique.

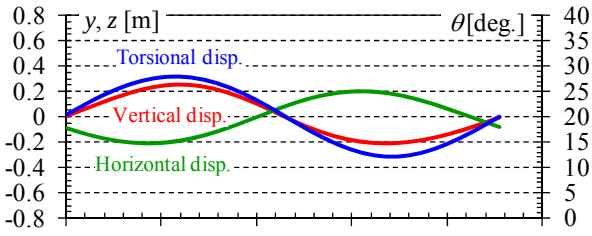


(a) Stationary position (mean displacement)

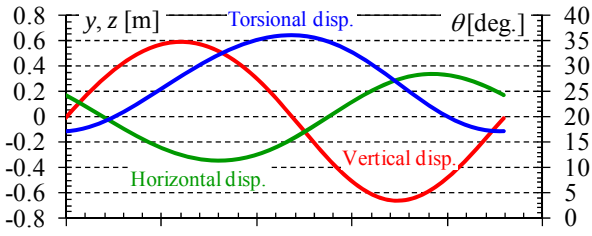


(b) Total amplitude (standard deviation $\times 2\sqrt{2}$) and frequency of galloping oscillation

Figure 10 Test results at each angle of attack in Case 2 (U = 11.9 m/s)



(a) Initial angle of attack α = 16 deg.



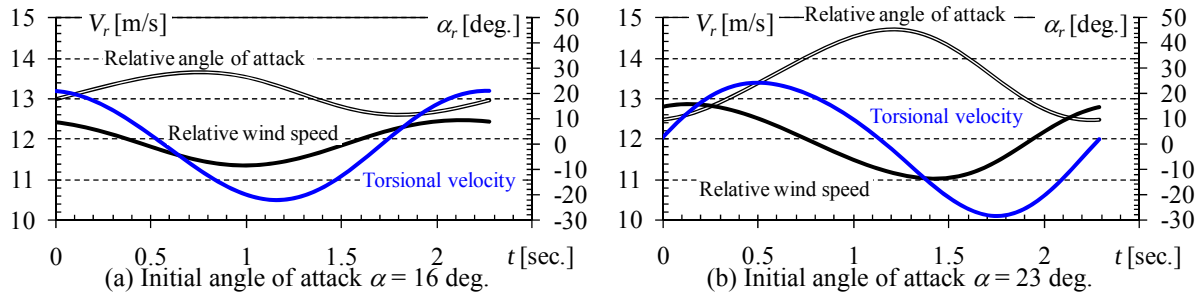
(b) Initial angle of attack α = 23 deg.

Figure 11 Time series of phase averaged displacement in Case 2

The results of the free vibration tests at each angle of attack in Case 2 are shown in Figure 10. The horizontal axis of Figure 10(a) represents the initial angle of attack at U = 0 m/s, which is the same value as the elastic cord support angle, and the horizontal axis of Figure 10(b) represents the mean torsional displacement. In some cases, the oscillation amplitude was larger than the area in which the wind speed distribution is approximately uniform. These cases are indicated as "over area" in Figure 10, and the actual value may differ from the represented value. As shown in Figure 10(a), the stationary angle to the wind is different from the initial angle of attack, especially in the case when the initial angle of attack is slightly less than the stalling angle (20 degrees). In contrast, as shown in Figure 10(b), when the stationary angle is larger than the stalling angle, galloping occurs. Figure 11 shows the phase averaged data of the galloping displacement in one period when the initial angle of attack α is 16 and 23 degrees in Case 2. The phase difference of each displacement varies with the initial angle of attack. In both cases, the torsional displacement range fulfills the Den Hartog criterion, and the mechanism of oscillation onset is thought to be essentially the same as "Den Hartog galloping" [1], which is the aeroelastic instability in a one-degree-of-freedom (vertical motion) only system. As above, a detailed discussion of the oscillation characteristics and onset conditions of galloping can be conducted by this experimental technique.

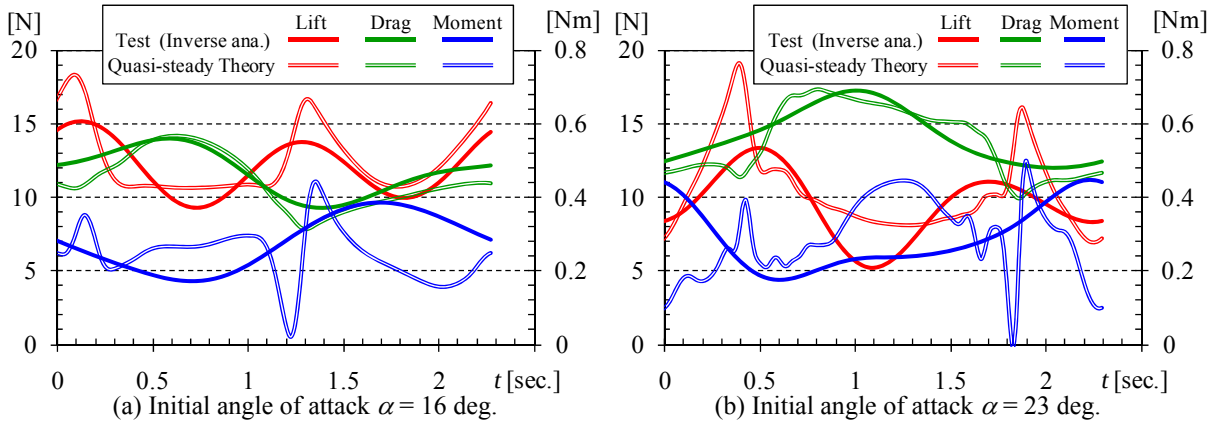
4 DISCUSSION ON UNSTEADY AERODYNAMIC FORCES

The quasi-steady aerodynamic forces can be calculated using the relative wind speed V_r and the relative angle of attack α_r as



(a) Initial angle of attack $\alpha = 16$ deg. (b) Initial angle of attack $\alpha = 23$ deg.

Figure 12 Time series of relative wind speed, relative angle of attack, and torsional velocity in Case 2



(a) Initial angle of attack $\alpha = 16$ deg. (b) Initial angle of attack $\alpha = 23$ deg.

Figure 13 Comparison of the aerodynamic forces obtained by inverse analysis of the free vibration tests and those calculated by quasi-steady theory in Case 2

$$V_r = \sqrt{(V - \dot{z})^2 + \dot{y}^2}, \alpha_r = \theta + \tan^{-1}\left(\frac{-\dot{y}}{V - \dot{z}}\right). \tag{18}$$

Furthermore, when the four-bundled conductor has a torsional velocity, each sub-conductor has a velocity in a circumferential direction. Thus, by using the aerodynamic coefficients [12], relative wind speed, and relative angle of attack of each sub-conductor, the quasi-steady aerodynamic force theory can calculate some effects of torsional velocity. Figure 12 shows a time series of the relative wind speed, relative angle of attack, and torsional velocity for Case 2.

In contrast, the unsteady aerodynamic forces acting on the sector model can be derived from an inverse analysis of the time-series displacements shown in Figure 11. In the inverse analysis, the structural characteristics are assumed to be expressed by Equations (12) to (14). Furthermore, the structural damping force is taken into account as an internal force. The total oscillation amplitude of each case is calculated by time-series displacements, and the value of the logarithmic decrement corresponding to the amplitude is derived from Figure 8. Figure 13 shows a comparison of the aerodynamic forces obtained by an inverse analysis of the free vibration tests and the quasi-steady aerodynamic forces that take into consideration the quasi-steady aero dynamic forces of each sub-conductor.

As shown in Figure 13, the drag data for both methods is in good agreement. The trend in the lift data is similar but the drastic changes seen in the quasi-steady forces are not present in the unsteady force calculation. Furthermore, there is a large discrepancy in the moment data. Although the reason for this discrepancy will be clarified in future work, the characteristics of the unsteady aerodynamic forces during large amplitude vibrations caused by galloping can be identified by the developed experimental technique.

5 CONCLUSION

The authors have developed and successfully implemented a modeling technique to physically simulate the galloping motion of actual overhead transmission lines in a wind tunnel at low frequency with a large amplitude. Furthermore, the technique allows the possibility of an in-detail discussion of the galloping oscillation characteristics and unsteady aerodynamic forces during the vibration. Future work will involve systematically determining the occurrence conditions and response characteristic of conductor galloping under definite input conditions: accretion shape, angle of attack, frequencies ratios, and wind speed. The results will then permit discussion of a model of the unsteady aerodynamic forces.

ABSTRACT: As a part of Messina Strait Bridge independent checking, numerical analysis was carried out to evaluate the bridge aerodynamic response and associated wind loads. The topic of this paper is a comparative presentation of the results obtained by RWDI and Politecnico di Milano (POLIMI) through independent theoretical and numerical methods, on the basis of an identical scheme of the structure and the same aerodynamic and wind turbulence properties.

KEYWORDS: Suspended bridge, Flutter, Stability analysis, Buffeting analysis, Wind Loads, Messina Strait Bridge

1 INTRODUCTION

The framework of the analysis consists in drawings provided by the bridge contractor Eurolink designers COWI, and mass distribution and structural model (eigenvalues and eigenvectors) as provided by Parsons Transportation Group (PTG), the Project Management Consultants for the Stretto di Messina Project. The behavior of the bridge under strong winds was predicted numerically based on experimental data from sectional model wind tunnel tests, carried out on a 1:45 scaled deck sectional model by Politecnico di Milano (POLIMI)and on a 1:100 scaled sectional and aeroelastic models of the tower by RWDI. Aerodynamic static coefficients of the twin main cables were supplied by the high Reynolds number sectional model tests performed on behalf of the bridge contractor Eurolink [Scheweand Jacobs, 2010].

The generalized coordinate numerical approach was applied allowing comparative verifications through independent analysis by RWDI and POLIMI on stability, buffeting and wind loads using similar, yet completely independent, numerical approaches and procedures.

2 THEORETICAL FRAMEWORK OF STABILITY AND RESPONSE ANALYSIS

Analyses were performed using modal approach, solving the bridge dynamics equations of equilibrium in generalized coordinates through the state space matrix of the first 100modes.
The aerodynamic stability of the structure was investigated using a numerical recursive method for taking into account the dependence of the reduced velocity in both the mean wind speed and the frequency of each mode. The aeroelastic terms were introduced by experimental coefficients (Flutter Derivatives).

The adopted numerical method allows for obtaining system eigenvalues as a function of the actual mean wind speed and the actual angle of attack (depending on the bridge average static configuration that is a non-linear function of the mean wind speed itself). Finally, the method

applies an innovative stability criterion focusing on the residual damping parameter, instead the traditional "flutter speed limit" criterion.

To describe the bridge response to turbulent winds, a time domain analysis was performed, based on time-space wind distributions in agreement with the local wind statistical parameters. Aeroelasticity effects were introduced with experimental Flutter Derivatives and buffeting loads were generated based on the quasi-static theory corrected with experimental aerodynamic admittances.

Based on the above theoretical background, independent solution methods were developed and implemented by POLIMI and RWDI producing two sets of “wind loads” that would cover fully the envelope of the expected time domain responses of the bridge to turbulent winds at the required limit states for structural design.

2.1 *Stability Analysis*

Using the described above theoretical framework, the stability analysis has been performed and its results compared to S.d.M. specifications. The stability of all important modes under wind action was verified.

The eigenvalues analysis takes into account the wind-structure aeroelastic effects using the Flutter Derivatives in order to simulate the state dependent forces and moments, accounting for the dependence of the local angle of attack and the frequency of every mode being analyzed. This procedure allows examining the evolution of the total modal damping (structural plus aerodynamic) as a function of the mean wind speed.

An innovative aspect of this independent check is that for the first time, according to S.d.M. specifications, in order to evaluate the stability performances of a suspended bridge, the key-factor of the analysis is the residual damping of each modes instead of the usual value of critical flutter velocity, corresponding to the lowest value of mean wind speed that causes the vanishing of the residual damping. The residual or total damping, also called “stability index”, is defined as $\alpha_i/\omega_i = f(V^*)$ where α_i and ω_i are the real and imaginary part of eigenvalues related to the i^{th} mode with frequency f_i being a function of the reduced velocity $V^*=V/(f_iB)$ (B is the deck width). It comprises structural and aerodynamic damping at given wind speed. Due to the relatively low level of the damping of each mode, this residual damping is the linearization of the theoretical modal damping without losing accuracy.

The residual damping is obtained solving the “Eigenvalues problem” of the coupled mechanic-aerodynamic system:

$$[m_s^*]\ddot{\underline{q}} + [r_s^*]\dot{\underline{q}} + [k_s^*]\underline{q} = \underline{F}_{Aero} = [\Phi]^T \underline{F}_{Aero}(V, V^*, \eta) \tag{1}$$

where $[m_s^*]$, $[r_s^*]$ and $[k_s^*]$ are the structural mass, damping and stiffness generalized matrixes. Structural damping ζ_s is set equal to 0.3% of critical for all deck and towers modes while for the main cables pure modes without deck motions, ζ_s = 0.03% representing the expected values for this structure and modes under consideration. The vector $\underline{q}$ and the matrix [Φ] contain respectively the modal coordinates and the modal vectors; $\underline{F}_{aero}(V,V^*,\eta)$ expresses the aeroelastic forces as a function of mean wind speed V(equal for each mode) and of the reduced velocity V^* that changes for each modes and the angle of attach η (due to mean wind static loads on the structure obtained by a non-linear iterative static procedure) that changes for each section.

The aerodynamic loads of each section were expressed using the Flutter Derivatives in the POLIMI convention[Zasso, 1996]. POLIMI used a modified formulation which includes the definition of an aerodynamic inertial matrix:

$$\begin{Bmatrix} F_y/qBL \\ F_z/qBL \\ F_\theta/qB^2L \end{Bmatrix}_{\substack{Deck\,section \\ Local}} = \left[M^*_{aero}\right] \begin{Bmatrix} \ddot{y} \\ \ddot{z} \\ \ddot{\vartheta} \end{Bmatrix}_{\substack{Deck\,section \\ Local}} + \left[R^*_{aero}\right] \begin{Bmatrix} \dot{y} \\ \dot{z} \\ \dot{\vartheta} \end{Bmatrix}_{\substack{Deck\,section \\ Local}} + \left[K^*_{aero}\right] \begin{Bmatrix} y \\ z \\ \vartheta \end{Bmatrix}_{\substack{Deck\,section \\ Local}} \tag{2}$$

where the aerodynamic matrixes are:

$$\left[M^*_{aero}\right] = -\begin{bmatrix} p_6^* \frac{\pi B}{2V^2} & p_4^* \frac{\pi B}{2V^2} & 0 \\ h_6^* \frac{\pi B}{2V^2} & h_4^* \frac{\pi B}{2V^2} & 0 \\ a_6^* \frac{\pi B}{2V^2} & a_4^* \frac{\pi B}{2V^2} & 0 \end{bmatrix} \quad \left[R^*_{aero}\right] = -\begin{bmatrix} -p_5^* \frac{1}{V} & -p_1^* \frac{1}{V} & -p_2^* \frac{B}{V} \\ -h_5^* \frac{1}{V} & -h_1^* \frac{1}{V} & -h_2^* \frac{B}{V} \\ -a_5^* \frac{B}{V} & -a_1^* \frac{B}{V} & -a_2^* \frac{B^2}{V} \end{bmatrix}$$

$$\left[K^*_{aero}\right] = -\begin{bmatrix} 0 & 0 & p_3^* \\ 0 & 0 & h_3^* \\ 0 & 0 & a_3^* B \end{bmatrix} \tag{3}$$

To consider the Flutter Derivatives not identified through Wind Tunnel tests ($a_{5,6}^*$; $h_{5,6}^*$;$p_{5,6}^*$) the quasi-static approximation using the static aerodynamic coefficients was adopted:

$$\begin{cases} \left\{a^*, h^*, p^*\right\}_6 = 0 \\ p_5^* = 2C_D \\ h_5^* = 2C_L \\ a_5^* = 2C_M \end{cases} \tag{4}$$

where C_D, C_L and C_M are respectively the drag, lift and moment aerostatic coefficients of the bridge deck section.

The same procedure is adopted for the main cables using the static coefficients provided by the dedicated wind tunnel tests [Schewe and Jacobs, 2010],and for the hangers considering only the drag contribution adopting a C_D derived from literature [Zdravkovich, 1997].

	C_{D0}	K_{D0}	C_{L0}	K_{L0}
Main Cables	0,52	0	0	-2.6767
Hangers	0,6	0	0	0

Table 2-1 Main Cables and hanger aerodynamic coefficients

The quasi-static approximation was also used for the two towers. Since their influence was judged small on stability estimation, the towers were included only for buffeting analysis in the POLIMI model. Given the same numerical model and solver was applied by RWDI, towers were included both into flutter stability and buffeting analyses.

Stability assessment was done using a modal approach on the basis of modal properties of the bridge provided by Parsons. The first mode becoming unstable is the first torsional anti-symmetric one (#4 - f = 0.080 Hz); Table 2-2reports a summary of the evolution of the residual damping at different angle of attach and at different mean wind speed value. Figure 2-1 shows the behavior of the first torsional anti-symmetric mode and the corresponding vertical and lateral modes those are directly involved in flutter. Results are presented considering or disregarding the main cables effect.

η[deg]	V_{fl}[m/s]		Wind speed[m/s]

Table 2-2 Stability limit and residual damping of the 1st torsional mode with and without (gray cells) the main cables

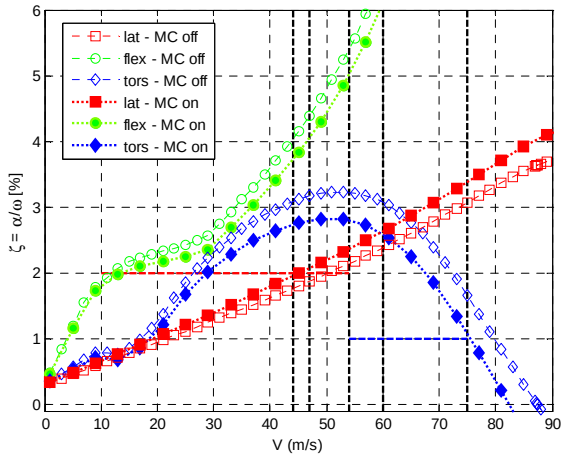

Figure 2-1 Residual damping of 1st lateral, vertical and torsional modes as functions of mean wind speed. Results of simulation with and without main cables. Assumed angle of wind attack 0°.

The project requests for aerodynamic specifications stability were satisfied for all fundamental modes controlling the deck stability at angle of attack η=0° as showed in Figure 2-2 that collects the evolution of all modes as requested by the project specification (modes: from 1 to 4 torsional asymmetric).The torsional instability is overcome at higher wind speed due to the regular positive aerodynamic damping shown by the asymptotic trend of the a^*_2 Flutter Derivatives at higher reduced velocity.

Due to negative lift coefficient of the Main Cables in twin configuration (as reported in Table 2-1) some higher cable modes show quite low damping. This problem must be addressed in the "Esecutivo" phase but it is easily resolvable.

Based on the same set of full data and theoretical framework, RWDI applied its procedure called "3D Flutter Analysis" [Stoyanoff, 1993] modified to include POLIMI's derivatives formulation. On the selected trial case at zero degree, mean angle of wind attack, almost identical residual damping traces (Figure 2-1) were predicted and critical flutter speeds within 2.5 m/sec.

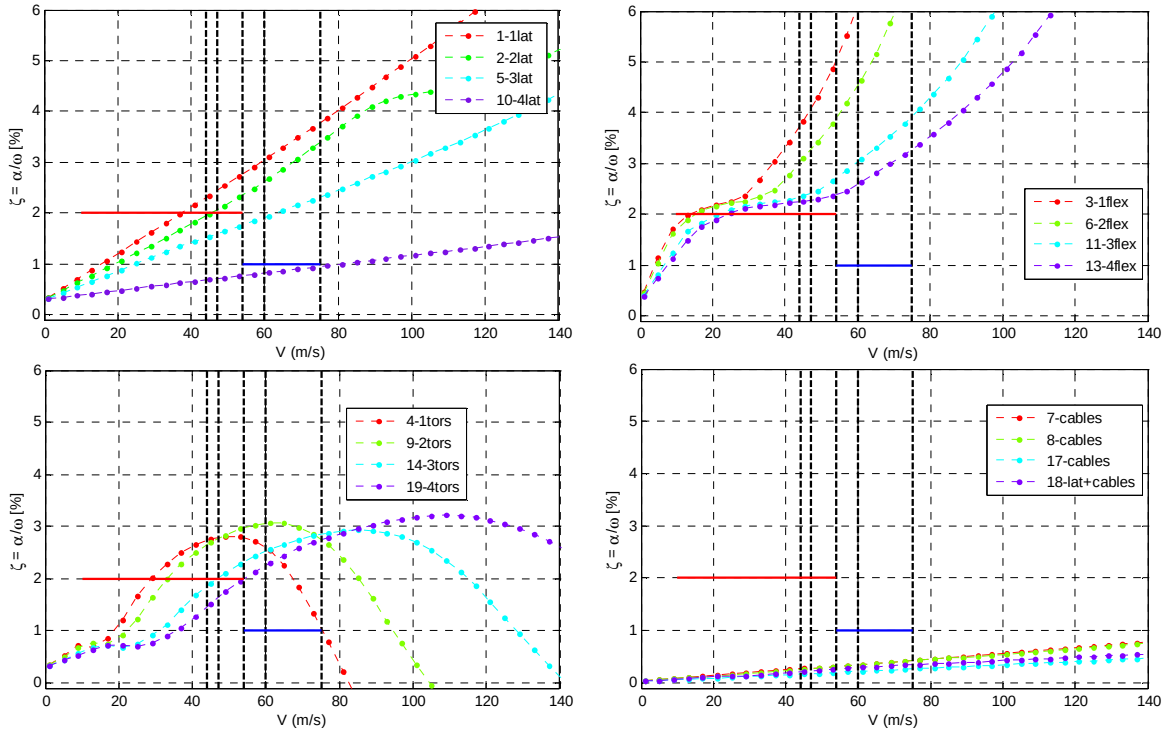

Figure 2-2.Instability coefficient vs. mean wind speed – Main cables + hangers ON – Modes by category.

2.2 *BUFFETING ANALYSIS*

Buffeting analysis has been performed with evaluation of displacements and accelerations distribution of the structure. The time histories of the bridge displacements and accelerations, together with the mean and turbulent wind components actions allow evaluation of the overall reference wind loads on the structure due to combined static and dynamic effects. The analysis has been performed using a linear integration analysis in time domain. RWDI's response solver uses a highly efficient "exact" integration method (Stoyanoff, 2001).

The buffeting analysis procedure entails the following steps:

- Choose a "wind grid" which covers the structure.
- Interpolate the bridge structure and the wind grid to locate the wind loads points of application.
- Generate wind time histories at all nodes get at previous step according with S.d.M. target turbulence properties
- Using these wind time histories, the Drag, Lift and Moment loads are expressed in the local frame of reference through the aerodynamic admittance functions define for each section and time step. As done for the Flutter Derivatives, the quasi-static approximation was used to extrapolate the aerodynamic admittance functions coefficients and cover for drag which was not experimentally identified. This simplification conserves the dependence from the angle of attach but obviously disregards the one to the reduced velocity.
- Integrate the equations of motion with buffeting loads obtained in the previous step.

Static force and moment coefficients on the towers were included based on the 1:100 sectional model test undertaken by RWDI (Stoyanoff et al, 2012).

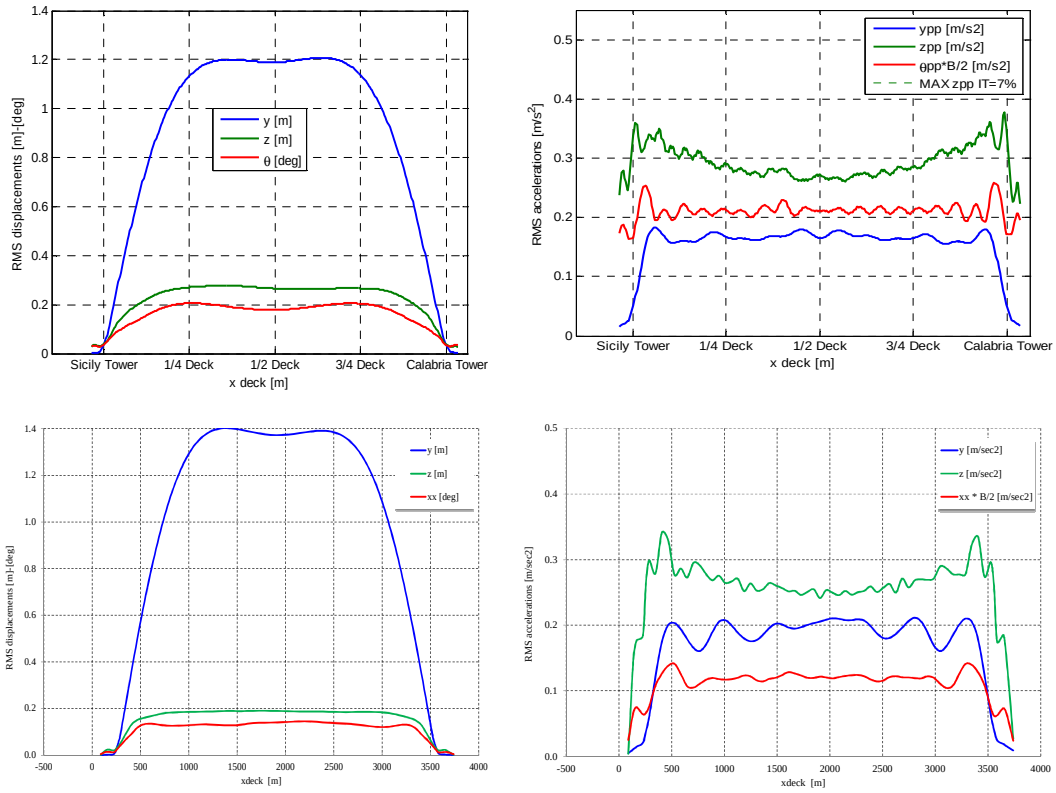

Table 2-3 Comparison between POLIMI (up)/RWDI (down) - rms displacements (left) and acceleration (right) of the deck in physical coordinates.

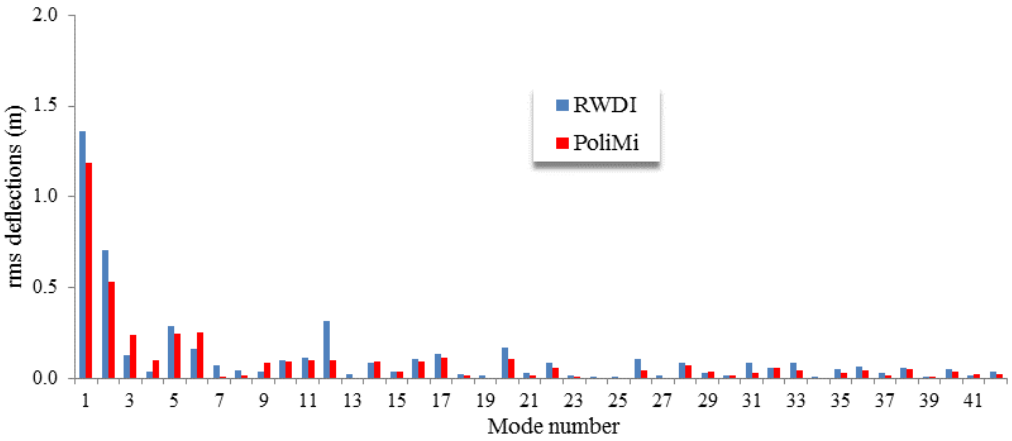

Table 2-4 Comparison between POLIMI /RWDI –modal rms. displacements for the first 50 modes

Figures 2-3 and 2-4 compare bridge response predicted by Polimi and RWDI at wind speed of 44 m/sec based on the same dynamic model and set of aerodynamic data. The observed differences were attributed to the different interpretations and simulations of the wind turbulence model and response analyses. These should outline the boundary of predictions for possible bridge responses.

3 WIND LOADS

3.1 *Time domain approach (POLIMI)*

The total loads on the bridge include stationary ones, due to the mean wind speed and time-averaged structure configuration and non-steady loads, caused by time dependent aeroelastic forces and by incoming turbulence fluctuations (buffeting forces). In response to these loads, the structure accelerations generate additional time dependent inertial forces. Performing the buffeting analysis, as describe in the previous paragraph, it is possible to calculate these loads at each simulation time step and for each section of the structure.

A common design practice is to express the effect of both steady and non-steady wind loads as equivalent wind loads (EWL), statically applied to the structure and taking into account also the dynamic effects of wind interaction. Different criterions were adopted in order to select these equivalent "scenarios" representative of critical loading.

A possible straightforward strategy is to select the loads combination determining the peak curvature values along the deck, main cable or tower sections, considering the direct link among structural curvatures and corresponding stresses in the structural components.

In order to calculate the structure time-space curvature distribution it's possible to take advantage of the modal approach due to the intrinsic separation of time and space domain functions, and writing the space partial derivative in terms of derivative of the eigenvectors as functions of the running space coordinate along the structure as follows:

$$\underline{x}(\zeta,t)=\left[\Phi(\zeta)\right]\underline{q}(t) \quad \rightarrow \quad \frac{\partial^2 \underline{x}}{\partial \zeta^2}=\left[\frac{\partial^2 \Phi}{\partial \zeta^2}\right]\underline{q}(t) \tag{5}$$

where $\underline{x}(\zeta,t)$ represent the time-space vector of the displacements, $[\Phi(\zeta)]$ the modal matrix of the eigenvectors and $\underline{q}(t)$ the vector of generalized coordinates. This vector of is a known function calculated from the buffeting response. It is possible now to select among the time-space curvature distributions, extreme values causing extreme stress conditions along the structure and to select those instantaneous configurations (and their associated equivalent static loads) as components of the relevant scenario of wind loading as required for structural design.

For instance, Figure 3-1shows,for the mean wind speed V=44m/s, one of the selected scenario in which the deck curvature in the horizontal plane reached extreme values (close to the north-west tower). The figure shows also the other curvatures (vertical and torsional) and the associated displacements simultaneously reached by the structure. The same figure shows finally the corresponding distribution of equivalent wind loads determining the over described extreme configuration described(external, inertial and total loads). It is important noting that wind loads causing maximum curvature are not caused by loads local extremes on a section, rather to overall load distributions along the deck, main cables and towers.

Proposed method supplies the "true" instantaneous distributions of external and inertial forces and moments determining the extreme bending or torsion curvatures which represent the loading condition at a selected limit state. They are derived straightforward from the time domain response analysis. Further work is ongoing to establish a probabilistic interpretation of these results.

Figure 3-1 Snapshot of the scenario that represents the maximum curvature reached by the deck in the along wind direction. Also the other components (deflections, curvatures and loads in the crosswind direction and along the deck) are quoted. (a): curvature (blue), displacement (green). (b): total loads (black), inertial loads (red), buffeting loads (green), static loads (blue), max/min envelope loads on the total simulated time history(magenta/cyan).

3.2 *Wind Loads: modal participation approach based on top-bin sorting (RWDI)*

Wind loads were also developed by RWDI's independent procedure. The dynamic loads due to wind buffeting at various time instances tend to stress critically different bridge parts. They occur simultaneously with other static loads. It has been most convenient to designers to present wind loads as equivalent static loads. The dynamic wind loads are decomposed into various "snap-shot" equivalent-static load cases in order to cover likely critical conditions. Various combinations are developed with the load patterns being distributed lateral, vertical, longitudinal, and torsional loads.

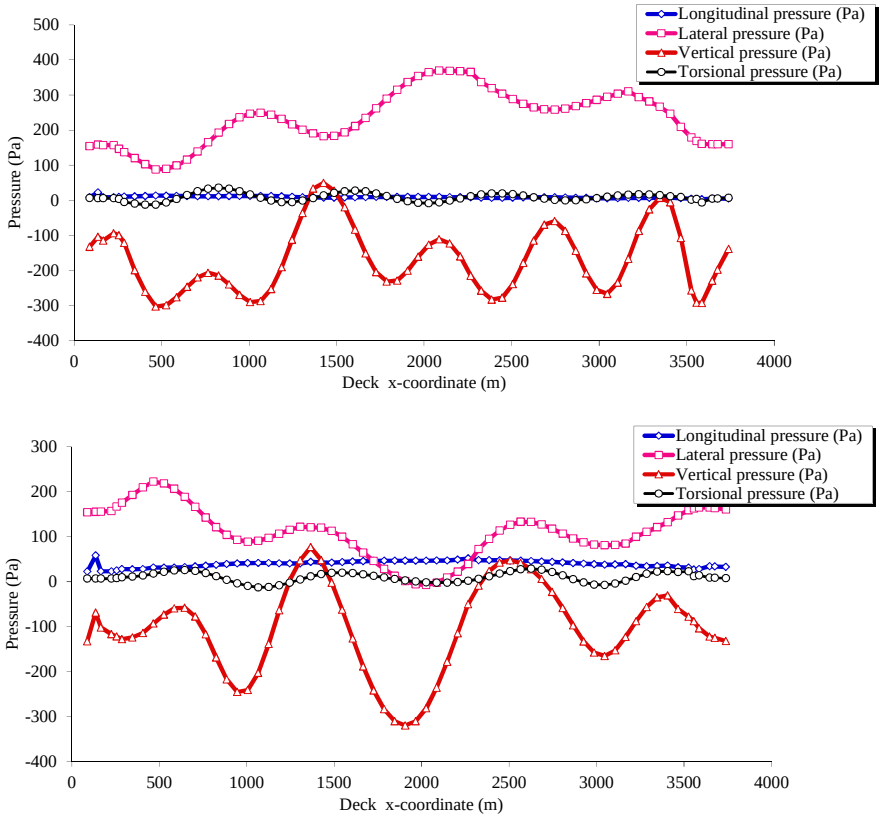

Figure 3.2 Equivalent static load distributions derived for the deck based on the modal participation factors identified from the top-bin sorting method. Longitudinal pressure (blue), lateral pressure (purple), vertical pressure (red) and torsional pressure (black) are given for the deck physical coordinates. UP: load distribution causing maximum lateral deflection. BOTTOM: load distribution causing maximum vertical negative deflection.

Whereas combining mean and direct wind gusts, and inertial loads is a straightforward procedure, the challenge is in defining the modal participation factors. One new technique can be applied where the time series of known responses at selected locations, e.g. on the deck near by the towers, are normalized and sorted. After normalization, the time histories of modal vectors will take values in the range of ±1 (in most cases only one of the boundaries will reach unity).The response then is divided into bins where the top-bin (for example from 0.99 to 1.0) will provide several sets of participation factors for simultaneously occurring lateral, vertical and torsional responses. Since RWDI's method for the response integration is in fact an exact solution in generalized coordinates, the modal participation factors are then directly obtained as required for load combinations.

Considering deflection only, on a long-span bridge typically are selected ¼, ½, and ¾ of the main span locations and time series of the overall response vectors produced. To examine differential responses, the cross-response vectors of (¼+½+¾)/3 and (¼-¾) span locations are also produced. Accepting then as a sorting objective to identify time instances of maximum and minimum deflections in along, lateral, vertical, and torsion direction would lead to about 50 load cases. Examples of load distributions on the deck causing maximum lateral and vertical deflections are given in Figure 3.2.

4 CONCLUSIONS

Considering stability in strong winds, reasonably similar results were predicted by the two independent analyses, confirming a high reliability of the applied experimental-numerical methodology. Based on the same structural and aerodynamic parameters, comparing the response predictions to turbulent winds, however larger scatters were found between the two independent solutions. This confirms the expectation of wider uncertainties depending on the actual implementation of the established methodological framework of increased complexity.

Concerning the wind loads, there is an ongoing development in both methodologies including the implementation of probabilistic interpretations with a reference to structural fatigue.

ABSTRACT: This paper presents the unsteady buffeting response prediction of bridges in the time domain using the proper orthogonal decomposition. Digital simulation of the turbulence wind fields is carried out at the bridge nodes using the spectral representation techniques via Cholesky decomposition and modal factorization. Covariance matrix-based proper orthogonal decomposition is used to decompose the unsteady buffeting forces via the impulse response functions, then formulate the buffeting response prediction of bridges in the time domain. The impulse response functions of unsteady buffeting forces are identified via aerostatic force coefficients and aerodynamic admittance functions. The Newton-beta integration method is also applied to obtain the buffeting response solution in the time domain. Numerical example of full-scale bridge is taken into account for illustration and discussions.

1 INTRODUCTION

Buffeting response prediction of long-span bridges subjected to the turbulent-induced forces (the buffeting forces) requires essential concern among wind-induced vibrations and their aerodynamic responses. General formulation and framework of the buffeting response prediction of bridges has been proposed by A.G. Davenport in the frequency domain (Davenport 1962). Recently, the state-of-the-art buffeting response analysis of bridges in coupling with the aeroelastic forces in the time domain has been carried out by some authors (ex., Boonyapinyo et al. 1999, Chen at al. 2000). Computational difficulties are to decompose spatially-correlated full-scale buffeting forces into the structurally generalized coordinates which are decomposed thanks to the structural modal transformation in order to estimate the generalized responses in the generalized coordinates and then the global responses of structures. In conventional methods in both the frequency-domain and the time-domain, the so-called joint acceptance function (JAF) has been used to decompose the full-scale buffeting forces into the structurally generalized coordinates.

Proper orthogonal decomposition (POD) (Lumley 1970), has been applied in many engineering fields (Liang et al. 2002). In the wind engineering topics, the proper orthogonal decomposition has been applied for analysis and order-reduced synthesis of the random pressure fields (Tamura et al. 1999), representation and simulation of the random fields (Tubino and Solari 2005), stochastic dynamic response (Carassale et al. 1999, Solari and Carassale 2000, Chen and Kareem 2005). Basing on the basic matrix of either the zero-time-lag covariance matrix or cross spectral density matrix of the random field, the proper orthogonal decomposition has been branched by either the covariance proper transformation or the spectral proper transformation. New approach of the gust response analysis of

structures has been proposed recently by Carassale et al. 1999 in which the structural modes decomposed by the structural modal transformation are associated with either the covariance turbulent loading modes or the spectral turbulent loading modes decomposed from proper transformations in order to determine the generalized responses and the global responses of structures. Combination manner between the structural modes and the turbulent loading modes for predicting the stochastic response of structures is named by Carassale et al. 1999 and Solari and Carassale 2000 as the double modal transformations (DMT). So far, almost literatures on the proper orthogonal decomposition application to the stochastic response of structures are formulated based on the spectral proper transformation in the frequency domain (Carassale et al. 1999, Solari and Carassale 2000, Chen and Kareem 2005). The frequency-domain buffeting response of long-span bridge using the spectral proper transformation has been formulated previously somewhere (ex., Tubino and Solari, 2007). The stochastic response of structures formulated in the time domain using the covariance proper transformation is very promising because of its direct and capable solutions for nonlinear problems and unsteady buffeting aerodynamics. However, digital simulation of the time series of the turbulence wind fields and the direct integration methods of generalized dynamic equations are usually required that are associated with time-consumed and difficult computation. Time-domain buffeting analysis is always promising for advanced treatment of nonlinear problems, unsteady buffeting response and buffeting-induced vibration countermeasures. Moreover, the unsteady buffeting forces in the time domain via the impulse response functions are better approach for the unsteady buffeting response problem due to its advantage for modeling so-called "memory effect" in the unsteady fluid that could capture the past history of response.

In the paper, the unsteady buffeting response prediction of bridges in the time domain using the proper orthogonal decomposition has been formulated. The spectral branched proper orthogonal decomposition has been used to digitally simulated the turbulence wind fields on the bridge, while the covariance branched proper orthogonal decomposition is used to decompose the unsteady buffeting forces via the impulse response functions, then the buffeting response prediction has been formulated in the time domain. The impulse response functions used for the unsteady buffeting forces have been estimated indirectly using the aerostatic force coefficients, the aerodynamic admittance functions and the Roger rational approximation. Buffeting responses of the bridges have been solved directly in the time domain using the Newton-beta integration technique. Numerical example of medium-span cable-stayed bridge has been taken into account for results and discussions.

2 UNSTEADY BUFFETING FORCES

The quasi-steady buffeting forces per unit deck length (lift, drag and moment) are determined due to the quasi-steady theory that is corrected by frequency-dependant aerodynamic admittance functions as follows (see Figure 1):

$$L_b(t)=\frac{1}{2}\rho U^2 B[C_L\chi_{Lu}(n)\frac{2u(t)}{U}+(C_L^{'}+C_D)\chi_{Lw}(n)\frac{w(t)}{U}] \quad (1a)$$

$$D_b(t)=\frac{1}{2}\rho U^2 B[C_D\chi_{Du}(n)\frac{2u(t)}{U}+(C_D^{'}-C_L)\chi_{Dw}(n)\frac{w(t)}{U}] \quad (1b)$$

$$M_b(t)=\frac{1}{2}\rho U^2 B^2[C_M\chi_{Mu}(n)\frac{2u(t)}{U}+C_M^{'}\chi_{Mw}(n)\frac{w(t)}{U}] \quad (1c)$$

where C_L, C_D, C_M: aerodynamic static coefficients (at balanced angle of attack); $C_L^{'}, C_D^{'}, C_M^{'}$: first-order derivatives; $\chi_{Fv}(n)\ (F=L,D,M;\upsilon=u,w)$: aerodynamic transfer functions between turbulent components and turbulent-induced forces (their absolute magnitudes refer as aerodynamic admittance functions).

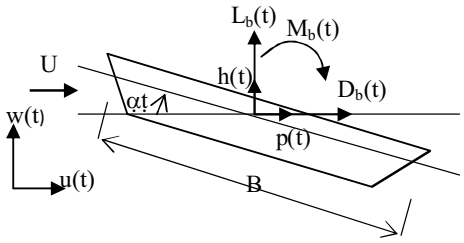

Figure 1. Buffeting forces on bridge deck

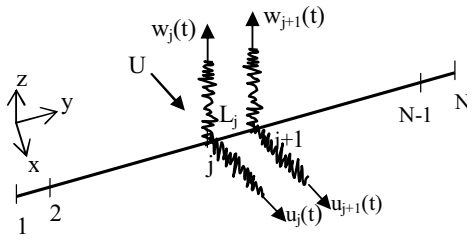

Figure 2. Turbulence wind fields

Quasi-steady buffeting forces, however, do not exactly reflect unsteady characteristics as nature of these random forces, which depend on not only geometric configuration of bridge decks, oncoming wind turbulence, but frequency-dependant parameters due to wind-structure interaction and bluff body flow. Additionally, it is indicated that unsteady fluid dynamics at low, medium flow velocity ranges must account for both past and present motion histories, thus the so-called "memory effect" of the unsteady fluid flow should be included in modeling of unsteady buffeting forces. So far, the unsteady buffeting forces can be determined via either the indicial response functions (Scanlan 1993) or the impulse response functions (Lin 1984, Chen and Kareem 2000) thanks to the convolution integration operation. Recently, the impulse response functions are usually used for modeling the unsteady buffeting forces in the time domain as follows:

$$L_b(t) = \frac{1}{2}\rho U^2 \{ \int_{-\infty}^{t} I_{Lu}(t-\tau)\frac{u(\tau)}{U}d\tau + \int_{-\infty}^{t} I_{Lw}(t-\tau)\frac{w(\tau)}{U}d\tau \} \quad (2a)$$

$$D_b(t) = \frac{1}{2}\rho U^2 \{ \int_{-\infty}^{t} I_{Du}(t-\tau)\frac{u(\tau)}{U}d\tau + \int_{-\infty}^{t} I_{Dw}(t-\tau)\frac{w(\tau)}{U}d\tau \} \quad (2b)$$

$$M_b(t) = \frac{1}{2}\rho U^2 \{ \int_{-\infty}^{t} I_{Mu}(t-\tau)\frac{u(s)}{U}d\tau + \int_{-\infty}^{t} I_{Mw}(t-\tau)\frac{w(\tau)}{U}d\tau \} \quad (2c)$$

where $I_{Lu}, I_{Lw}, I_{Du}, I_{Dw}, I_{Mu}, I_{Mw}$: impulse response functions which are usually obtained thanks to available admittance functions such following formulae as (Chen and Kareem 2002):

$$\bar{I}_{Lu} = 2BC_L\chi_{Lu}(n)\,;\ \bar{I}_{Lw} = B(C_L' + C_D)\chi_{Lw}(n) \quad (3a)$$

$$\bar{I}_{Du} = 2BC_D\chi_{Du}(n)\,;\ \bar{I}_{Dw} = B(C_D' - C_L)\chi_{Dw}(n) \quad (3b)$$

$$\bar{I}_{Mu} = 2B^2C_M\chi_{Mu}(n)\,;\ \bar{I}_{Mw} = B^2C_M'\chi_{Mw}(n) \quad (3c)$$

where $\bar{I}_{F\upsilon}$: Fourier transform of the impulse response functions ($F = L, D, M$ $\upsilon = u, w$) :

$$\bar{I}_{F\upsilon} = \int_0^{\infty} I_{F\upsilon}(t)e^{-i\omega t}dt = \int_0^{\infty} I_{F\upsilon}(s)e^{-iKs}ds$$

.

However, the aerodynamic admittance functions determined by either empirical formula or experimental measurement are expressed at discrete values of reduced frequency. Therefore, it is essential to approximate discrete frequency-dependant function to continuous one. Rational function approximation, known as the Roger's approximation is the mostly utilized for this purpose. Aerodynamic transfer functions can be expanded using rational function approximation:

$$\chi_{F\upsilon}(n) = A_{F\upsilon,1} + (iK)\sum_{j=1}^{m_{F\upsilon}} \frac{A_{F\upsilon,j+1}}{iK + d_{F\upsilon,j}} \quad (4)$$

where $A_{F\upsilon,1}, A_{F\upsilon,j+1}, d_{F\upsilon,j}$ frequency-dependant coefficients ($j = 1,2,\ldots,m_{F\upsilon}$) determined by nonlinear curve-fitting technique.

Then the impulse response functions and the unsteady buffeting forces (here only $I_{Lw}(s)$,

$L_{Lw}(t)$ are expended as example) can be determined as follows (Chen and Kareem, 2002):

$$I_{Lw}(s) = B(C_D + C_L^{'})\left[\left(A_{Lw,1} + \sum_{j=1}^{m_{Lw}} A_{Lw,j+1}\right)\delta(s) - \sum_{j=1}^{m_{Lw}} A_{Lw,j+1} d_{Lw,j} e^{-d_{Lw,j}s}\right] \quad (5a)$$

$$I_{Lw}(s) = \frac{1}{2}\rho U^2 B(C_D + C_L^{'})\left[\left(A_{Lw,1} + \sum_{j=1}^{m_{Lw}} A_{Lw,j+1}\right)\frac{w(t)}{B} - \sum_{j=1}^{m_{Lw}} \frac{d_{Lw,j}U}{B}\phi_{Lw,j}(t)\right] \quad (5b)$$

$$\dot{\phi}_{Lw,j}(t) = -\frac{d_{Lw,j}U}{B}\phi_{Lw,j}(t) + A_{Lw,j+1}\frac{w(t)}{U} \quad (5c)$$

where $\phi_{Fw,j}(t)$: augmented aerodynamic state coefficient.

3 PROPER ORTHOGONAL DECOMPOSITION

The main idea of the covariance matrix-based proper orthogonal decomposition and its covariance proper transformation is to find out a set of orthonormal basic vectors which can expand a multi-variate spatially-correlated random turbulent field into a sum of products of these basic orthogonal vectors (turbulent loading modes) and single-variate uncorrelated random processes (principal coordinates) based on the covariance matrix of this random field. The covariance matrix-based orthogonal vectors are found as the eigenvector solutions of the eigen problem of the zero-time lag covariance matrix $R_\upsilon(0)$ of N-variate random turbulent process $\upsilon(t)$:

$$R_\upsilon \Theta_\upsilon = \Gamma_\upsilon \Theta_\upsilon \quad (6)$$

where $R_\upsilon(0)$: zero-time-lag covariance matrix of $\upsilon(t)$; Γ_υ, Θ: covariance eigenvalue and eigenvector matrices $\Theta_\upsilon = [\theta_{\upsilon_1}, \theta_{\upsilon_2}, \ldots \theta_{\upsilon_N}]$, $\Gamma_\upsilon = diag(\gamma_{\upsilon_1}, \gamma_{\upsilon_2}, \ldots \gamma_{\upsilon_N})$. Because the zero-time lag covariance matrix is positive-definite symmetrical squared one, thus its covariance eigenvalues are real and positive, and covariance eigenvectors are also real, satisfy the orthonormal conditions:

$$\Theta_\upsilon \Theta_\upsilon^T = I; \ \Theta_\upsilon C_\upsilon \Theta_\upsilon^T = \Gamma_\upsilon \quad (7)$$

Then, the random turbulence field and its covariance matrix can be expressed such optimum approximation as follows:

$$\upsilon(t) = \Theta_\upsilon x_\upsilon(t) \approx \sum_{j=1}^{\tilde{N}} \theta_{\upsilon j} x_{\upsilon j}(t) \quad (8a)$$

$$R_\upsilon(0) = \Theta_\upsilon \Gamma_\upsilon \Theta_\upsilon^T(n) = \sum_{j=1}^{\tilde{N}} \theta_{\upsilon j} \gamma_{\upsilon j} \theta_{\upsilon j}^T \quad (8b)$$

where $\hat{x}_\upsilon(t) = \{\hat{x}_{\upsilon_1}(t), \hat{x}_{\upsilon_2}(t), \ldots, \hat{x}_{\upsilon_N}\}^T$: covariance matrix-based principal coordinates (shortly, the covariance principal coordinates) as the N-variate uncorrelated Gaussian random subprocesses that represents as image of the random turbulent field in the covariance-based space; $\tilde{N}$: number of truncated covariance eigenvectors ($\tilde{N} << N$). The covariance principal coordinates can be determined from observed data under following expression:

$$x_\upsilon(t) = \Theta_\upsilon^{-1}\upsilon(t) = \upsilon(t)\Theta_\upsilon = \sum_{i=1}^{N} \upsilon_i(t)\theta_{\upsilon i} \quad (9)$$

These approximations are known as the covariance proper transformation in the time domain. Two N-variate turbulent processes u(t), w(t) acting on the N structural nodes: $u(t) = \{u_1(t), u_2(t), \ldots, u_N(t)\}^T$ and $w(t) = \{w_1(t), w_2(t), \ldots, w_N(t)\}^T$ are represented under the zero-time lag covariance matrices $R_u(0), R_w(0)$.

Two N-variate Gaussian random turbulent processes u(t), w(t) can be transformed and approximated into the covariance principal coordinates due to the covariance proper transformation:

$$u(t) = \Theta_u x_u(t) \approx \sum_{j=1}^{\tilde{N}} \theta_{u_j} x_{u_j}(t) \quad (10a)$$

$$w(t) = \Theta_w x_w(t) \approx \sum_{j=1}^{\tilde{N}} \theta_{w_j} x_{w_j}(t) \quad (10b)$$

where $x_u(t), x_w(t)$: the covariance principal coordinates of u-,w-turbulences, respectively.

As the same way, the covariance matrices can be approximated as follows:

$$R_u(0) = \Theta_u \Gamma_u \Theta_u^{*T} \approx \sum_{j=1}^{\tilde{N}} \theta_{u_j} \gamma_{u_j} \theta_{u_j}^{*T} \quad (11a)$$

$$R_w(0) = \Theta_w \Gamma_w \Theta_w^{*T} \approx \sum_{j=1}^{\tilde{N}} \theta_{w_j} \gamma_{w_j} \theta_{w_j}^{*T} \quad (11b)$$

where $\Gamma_u, \Gamma_w, \Theta_u, \Theta_w$: covariance eigenvalues and corresponding covariance eigenvectors (or covariance turbulent modes) : $\Gamma_u = diag(\gamma_{u_1}, \gamma_{u_2}, ..., \gamma_{u_N})$, $\Gamma_w = diag(\gamma_{w_1}, \gamma_{w_2}, ..., \gamma_{w_N})$, $\Theta_u = \{\theta_{u_1}, \theta_{u_2}, ..., \theta_{u_N}\}^T$; $\Theta_w = \{\theta_{w_1}, \theta_{w_2}, ..., \theta_{w_N}\}^T$ determined from the covariance matrix-based proper orthogonal decomposition of the random turbulent processes u(t), w(t).

4 TURBULENCE WIND SIMULATION

In the unsteady buffeting response prediction of bridges, the turbulence wind fields u(t), w(t) require to be digitally simulated at the bridge nodes. Digital simulation techniques via the spectral representation can be used basing on Cholesky decomposition and modal factorization. The turbulence wind fields can be expressed in the frequency domain using the Cholesky decomposition as follows (Le 2007), see Figure 2:

$$\upsilon_j(t) = \sqrt{2(\Delta f)} \sum_{k=1}^{j} \sum_{l=1}^{\tilde{N}} |\sqrt{S_{\upsilon_j \upsilon_j}(f)} G_{jk}(f_{kl}) \cos(2\pi f_{kl} t + \phi_{kl}) \quad (12)$$

where $\upsilon_j(t)$: simulated turbulence process at node j ($\upsilon(t) = u(t), w(t)$) ; j: index of structural node; k: index of moving node; l: index of moving point in frequency range; $\tilde{N}$: number of frequency intervals; Δf : frequency interval $\Delta f = f_{up}/\tilde{N}$; f_{up} : upper cutoff frequency; f_{kl} : frequency point on frequency range $f_{kl} = (l-1)\Delta f + k\Delta f/N$; $S_{\upsilon_j \upsilon_j}(f)$: auto spectral density function of turbulence processes υ(u(t),w(t)) at bridge node j; $G_{jk_j}(f_{kl})$: coefficient matrix containing coherence values and dimension of bridge decks; N: number of deck nodes; ϕ_{kl} : random phase angles, uniformly distributed over [0,2π] generated randomly by the Monte Carlo technique.

One can use the modal factorization or the spectral matrix-based proper orthogonal decomposition to simulate the turbulence wind fields as following expression (Le 2007), see Figure 2:

$$\upsilon_i(t) = 2\sqrt{\Delta f} \sum_{j=1}^{\hat{N}} \sum_{l=1}^{\bar{N}} \psi_{\upsilon_j}(f_l) \sqrt{\lambda_{\upsilon_j}(f_l)} \cos(2\pi f_l t + \phi_l) \quad (13)$$

where Δf_l: frequency interval at point *l*; Δf : constantly frequency interval $\Delta f = f_{up}/\bar{N}$ and $f_l = (l-1)\Delta f$, f_{up} : upper cut-off frequency; $\psi_{\upsilon_j}(f_l)$: spectral vector of the turbulence process at frequency f_l; $\lambda_{\upsilon_j}(f_l)$: spectral eigenvalue of the turbulence process at frequency f_l; ϕ_l: phase angle considered as random variable uniformly distributed over [0,2π]. The random phase angles can also be digitally generated by the Monte Carlo technique.

Accuracy of simulated turbulence processes must be verified by comparing between power spectral densities of simulated processed and targeted power spectral densities, and between coherence of simulated processes and targeted coherence as well.

5 BUFFETING RESPONSE PREDICTION

Multi-degree-of-freedom motion (MDOF) equations of structures subjected to the full-scale buffeting forces can be expressed thanks to finite element method (FEM):

$$M\ddot{U} + C\dot{U} + KU = F_b(t) \quad (14)$$

where $U = \{h(t)^T, p(t)^T, a(t)^T\}$: displacement vector containing three vertical, lateral and rotational displacements; $\dot{U}, \ddot{U}$: velocity and acceleration vectors; $F_b(t)$: full-scale buffeting forces.

Structurally global responses can be expressed into the mass matrix-normalized generalized coordinates as follows:

$$U(t) = \Phi\xi(t) = \sum_{i=1}^{\overline{M}} \phi_i \xi_i \quad (15)$$

where $\xi(t) = \{\xi_1(t), \xi_2(t), ..., \xi_M(t)\}$: structural generalized coordinates; $\Phi = [\phi_1, \phi_2, ..., \phi_M]^T$: modal matrix; $\overline{M}$: number of truncated structural modes ($\overline{M} << M$);

Therefore, single-degree-of-freedom (SDOF) motion equation of the i-th generalized coordinate is determined:

$$\ddot{\xi}_i(t) + 2\zeta_i\omega_i\dot{\xi}_i(t) + \omega_i^2\xi_i(t) = \frac{1}{2}\phi_i^T \rho UB\left[C_u u(t) + C_w w(t)\right] \quad (16)$$

where ω_i, ζ_i : circular frequency, damping ratio of the i-th generalized coordinate.

Using the covariance proper transformation, the turbulence wind fields u(t), w(t) can be approximated by uncorrelated subprocesses and covariance eigenvectors (or covariance turbulent modes). Thus, the SDOF motion equation is expressed such following forms as:

$$\ddot{\xi}_i(t) + 2\zeta_i\omega_i\dot{\xi}_i(t) + \omega_i^2\xi_i(t) = \frac{1}{2}\rho UB\left[\phi_i^T C_u \sum_{j=1}^{\tilde{M}} \theta_{uj} y_{uj}(t) + \phi_i^T C_w \sum_{j=1}^{\tilde{M}} \theta_{wj} y_{wj}(t)\right] \quad (17a)$$

$$\ddot{\xi}_i(t) + 2\zeta_i\omega_i\dot{\xi}_i(t) + \omega_i^2\xi_i(t) = \frac{1}{2}\rho UB\left[\sum_{j=1}^{\tilde{M}} A_{uij} y_{uj}(t) + \sum_{j=1}^{\tilde{M}} A_{wij} y_{wj}(t)\right] \quad (17b)$$

where $A_{uij} = \phi_i C_u \theta_{uj}$; $A_{wij} = \phi_i C_w \theta_{wj}$: cross modal participation coefficients accounting for interaction between structural modes and covariance turbulent modes; C_u, C_w : full-scale force coefficients relating to wind velocity, aerodynamic force coefficients and deck length; $y_u(t) = \{y_{u_1}(t), y_{u_2}(t), ..., y_{u_N}(t)\}^T$, $y_w(t) = \{y_{w_1}(t), y_{w_2}(t), ..., y_{w_N}(t)\}^T$: covariance principal coordinates, which are determined from original turbulent fields as follows

$$y_u(t) = u(t)\Theta_u; \quad y_{u_j}(t) = u(t)\theta_{u_j} \quad (18a)$$

$$y_w(t) = w(t)\Theta_w; \quad y_{w_j}(t) = w(t)\theta_{w_j} \quad (18b)$$

Therefore, the SDOF motion equations associated with vertical, horizontal and rotation structural principal coordinates can be expressed as follows:

$$\ddot{\xi}_{hi}(t) + 2\zeta_{hi}\omega_{hi}\dot{\xi}_{hi}(t) + \omega_{hi}^2\xi_{hi}(t) = \frac{1}{2}\rho UB\left[\sum_{j=1}^{\tilde{M}} A_{uij}^L y_{uj}(t) + \sum_{j=1}^{\tilde{M}} A_{wij}^L y_{wj}(t)\right] \quad (19a)$$

$$\ddot{\xi}_{pi}(t) + 2\zeta_{pi}\omega_{pi}\dot{\xi}_{pi}(t) + \omega_{pi}^2\xi_{pi}(t) = \frac{1}{2}\rho UB\left[\sum_{j=1}^{\tilde{M}} A_{uij}^D y_{uj}(t) + \sum_{j=1}^{\tilde{M}} A_{wij}^D y_{wj}(t)\right] \quad (19b)$$

$$\ddot{\xi}_{ai}(t) + 2\zeta_{ai}\omega_{ai}\dot{\xi}_{ai}(t) + \omega_{ai}^2\xi_{ai}(t) = \frac{1}{2}\rho UB\left[\sum_{j=1}^{\tilde{M}} A_{uij}^M y_{uj}(t) + \sum_{j=1}^{\tilde{M}} A_{wij}^M y_{wj}(t)\right] \quad (19c)$$

where $A_{uij}^L, A_{wij}^L, A_{uij}^D, A_{wij}^D, A_{uij}^M, A_{wij}^M$: cross modal participation coefficients between structural modes and covariance turbulent modes which are correspondent to u-,w-turbulences and turbulent-induced lift, drag, moment $A_{uij}^L = \phi_{hi} C_u^L \theta_{uj}$; $A_{wij}^L = \phi_{hi} C_w^L \theta_{wj}$; $A_{uij}^D = \phi_{pi} C_u^D \theta_{uj}$; $A_{wij}^D = \phi_{hi} C_w^D \theta_{wj}$; $A_{uij}^M = \phi_{ai} C_u^M \theta_{uj}$; $A_{wij}^M = \phi_{ai} C_w^M \theta_{wj}$

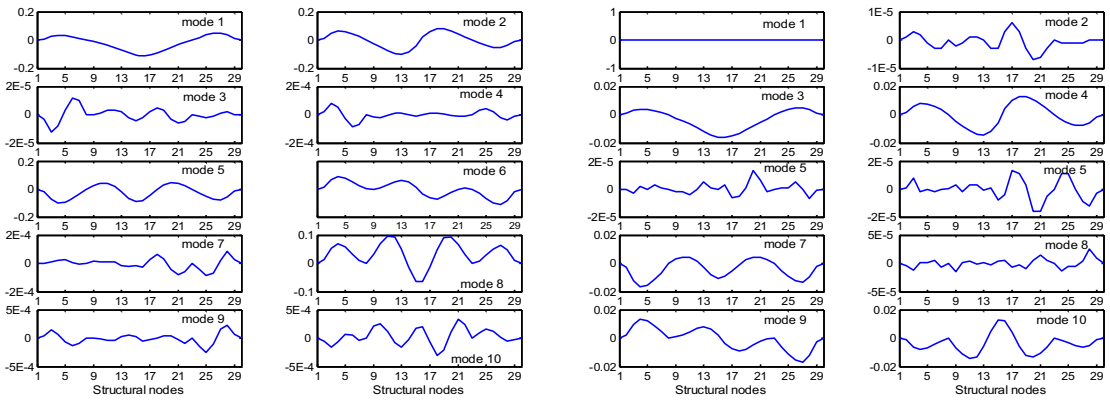
The SDOF motion equations system is formulated in the time domain. Finding out solution of this system can be obtained based on the direct integration methods such as the Newmark-beta method, the fourth-order Runge-Kutta method and so on. Finally, the structural global responses (vertical, lateral and rotational displacements) of bridges can be determined based on the superposition principle as follows:

$$U_h = \sum_{i=1}^{\overline{M}_h} \phi_{hi}\xi_{hi}(t) \quad ; \quad U_p = \sum_{i=1}^{\overline{M}_p} \phi_{pi}\xi_{pi}(t) \quad ; \quad U_a = \sum_{i=1}^{\overline{M}_a} \phi_{ai}\xi_{ai}(t) \tag{20}$$

where U_h, U_p, U_a: global vertical, lateral and rotational displacements, respectively; ϕ_h, ϕ_p, ϕ_a: structural modes corresponding to three responses; $\overline{M}_h, \overline{M}_p, \overline{M}_a$: numbers of component modes in combination of responses.

6 RESULTS AND DISCUSIONS

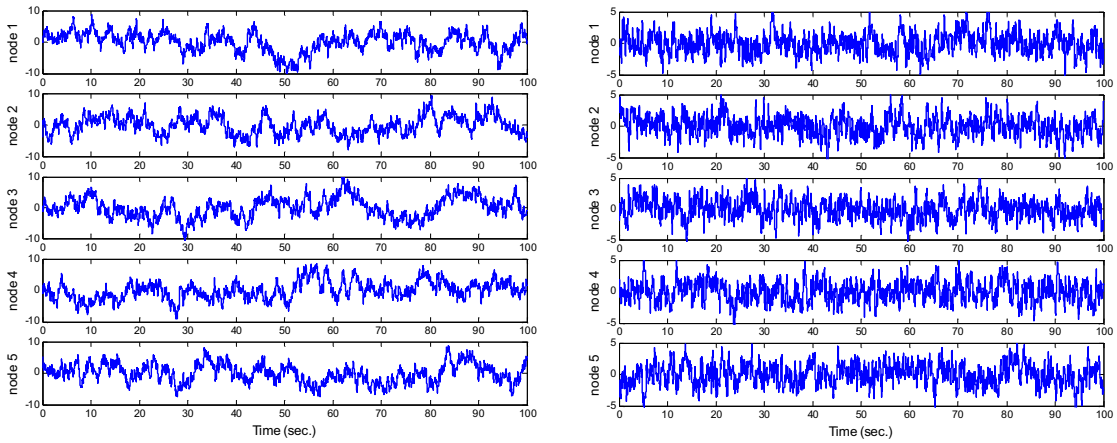
A medium-span cable-stayed bridge has been taken for numerical example using the computational procedures. Span arrangement is 40.5+97+40.5=178m, while there are 30 total nodes in the bridge deck (nodes 8, 23 at pylons). The global responses of bridge are required to predict at the mean velocity range between 5m/s and 40m/s. 3-D frame model has built thanks to the finite element method (FEM), see Figure 3. First ten structural modes have been analyzed. Natural frequencies of the first ten structural modes vary between 0.61Hz and1.86Hz. Structural damping ratios are assumed to be 0.005 for all modes. Aerodynamic static coefficients of cross section at balanced attack angle and their first derivatives have been experimentally determined: $C_L = 0.158$, $C_D = 0.041$, $C_M = 0.174$, $C_L' = 3.73$, $C_D' \approx 0$, $C_M' = 2.06$. One-sided auto spectral density functions of u-, w-turbulent components are obtained due to the Kaimail's and the Panofsky's spectral models, respectively (Simiu and Scanlan 1976). Coherence function is applied the Davenport's empirical exponential function with decay factors with decay factors $c_u = 10,\ c_w = 6.5$ (Davenport 1962). Aerodynamic admittance function is used the Liepmann's empirical function as approximation of the Sears' function (Liepmann 1958), while the mechanical admittance function is determined corresponding to structural generalized coordinates.



(a) Vertical modes (b) Rotational

Figure 3. Normalized bridge mode shapes : a. vertical modal displacement, b. rotational modal displacement

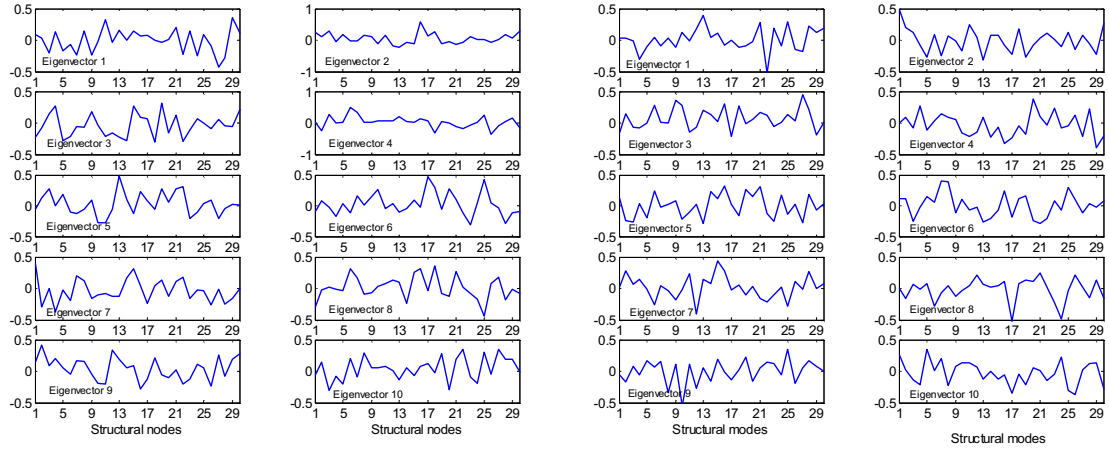
At the beginning, the turbulence wind fields at the 30 deck nodes $u(t) = \{u_1(t), u_2(t), \ldots, u_{30}(t)\}^T$ and $w(t) = \{w_1(t), w_2(t), \ldots, w_{30}(t)\}^T$ have been simulated using the above-mentioned digital simulation procedures. Figure 4 shows simulated turbulence processes at some deck nodes during 100-second interval, at the mean velocity U=20m/s (other simulated turbulence processes at other deck nodes and other wind velocities omitted for a sake of brevity).



(a) u-turbulence (b) w-turbulence

Figure 4. Simulated turbulence processed at some deck nodes at mean velocity U=20m/s

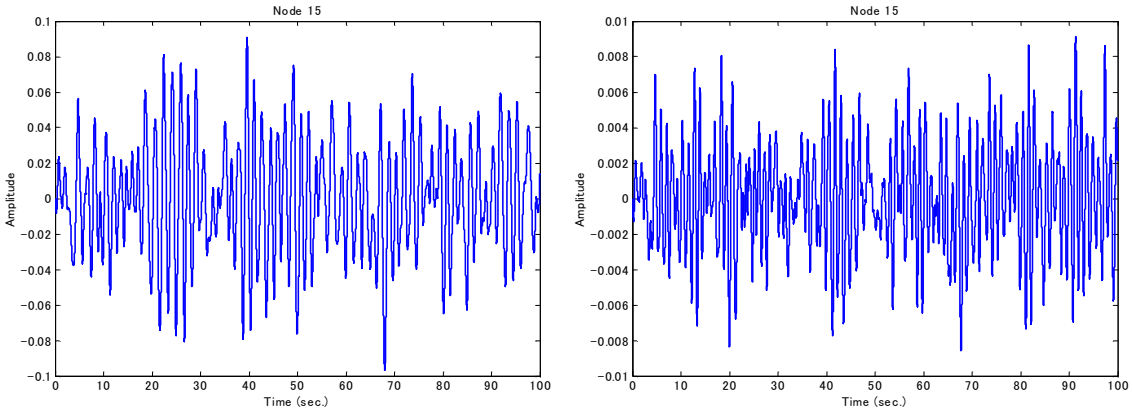
Simulated turbulence fields u(t), w(t) have been used to formulate the zero-time-lag covariance matrix. The covariance eigenvectors (or covariance turbulence modes) and covariance eigenvalues have been found out. From the covariance eigenvalues, eigenvectotrs and the simulated turbulence wind fields, the covariance principal coordinates then can be determined. Figure 5 shows the first ten covariance turbulence modes of u-,w-turbulence wind fields.



(a) u-turbulence (b) w-turbulence

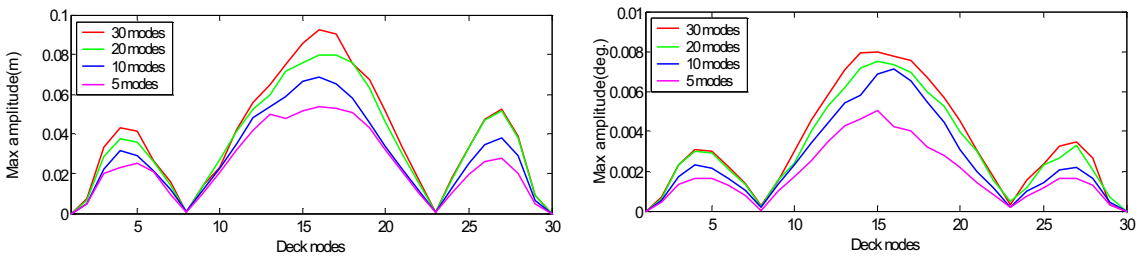
Figure 5. Covariance turbulence modes of u-,w-turbulence wind fields

Time histories of the global buffeting responses of bridge (the vertical, rotational and lateral displacements) can be solved via the direct integration method. Figure 6 indicates the time histories of the vertical and rotational displacements at the main span's middle node No.15 at the wind velocity U=20m/s during the 100-second period. The maximum response values at all bridge deck nodes at all investigated mean wind velocities can be determined from these time histories of the global buffeting responses.



(a) Vertical displacement (b) Rotational displacement

Figure 6. Time histories of global buffeting responses at mid-span node 15 at mean velocity U=20m/s



(a) Vertical displacement (b) Rotational displacement

Figure 7. Effect of number of turbulence modes on global responses at all deck nodes at mean velocity U=20m/s

Effect of number of the covariance turbulence modes on the buffeting responses of bridge has been investigated. Figure 7 indicates the maximum structural responses on the bridge deck at U=20m/s corresponding to number of the turbulence modes ($\tilde{M} = 30;20;10 and 5$, in which 30 modes imply for targeted response). Apparently, maximum buffeting responses reduce with respect to decrease of truncated number of the turbulence modes. Number of turbulence modes in some extent does influence considerably on the buffeting responses of bridge. Concretely, the maximum vertical amplitudes at midspan node 15 are 9.3cm (100%), 8.0cm (86%), 6.9cm (74%) and 5.3cm (57%) and the maximum torsional amplitudes at node 15 are 0.0078^0 (100%), 0.0075^0 (96%), 0.0071^0 (71%) and 0.0049^0 (63%) corresponding to 30, 20, 10 and 5 turbulence modes taken into account. Therefore, higher number of low-order covariance turbulence modes should be used for estimating the buffeting responses of bridge in the time domain.

7 CONCLUSION

New approach for the quasi-steady and unsteady buffeting response prediction of bridges has been formulated in the time domain using the covariance matrix-based proper orthogonal decomposition. Time histories of the turbulence wind fields on the bridge decks have been digitally simulated via the spectral matrix-based proper orthogonal decomposition. Effect of number of the covariance turbulence modes on the simulated turbulence wind fields and

global buffeting responses of bridges also is investigated accordingly. The computational procedure is promising for the both quasi-steady and unsteady buffeting response analysis of bridges in the time domain with its essential advantages to treat with aerodynamic and geometrical nonlinearities, and unsteady buffeting forces as well. Moreover, it seems that many number of the covariance turbulence modes should be required for more accurate estimation of the buffeting response of bridges. In the other words, the first covariance turbulence mode does not play significant role in its contribution for the buffeting response of bridges in the time domain.

Prediction of buffeting response of long span bridges to transient nonstationary winds

Xinzhong Chen

Wind Science and Engineering Research Center, Department of Civil and Environmental Engineering, Texas Tech University, Lubbock, TX, USA

ABSTRACT: This paper presents a general frequency domain framework for predicting buffeting response of long span bridges to transient nonstationary winds. The wind speed field is described in terms of deterministic time-varying mean and evolutionary random fluctuations characterized by their evolutionary spectra. The static, self-excited and buffeting forces on bridges are modeled in static force coefficients, flutter derivatives and admittance functions with consideration of transient nonstationary winds. Formulations are presented for estimating the time-varying mean, evolutionary spectrum, variance and extreme response. The general characteristics of transient buffeting response are discussed using a long span suspension bridge as an example. The effectiveness and accuracy of the proposed framework is also confirmed through time domain Monte Carlo simulations.

KEYWORDS: Buffeting response; Nonstationary response; Bridge aerodynamics; Long span bridges; Wind loading.

1 INTRODUCTION

Current analysis frameworks for estimating wind-induced buffeting response of structures are generally based on the assumption of stationary wind excitations. The mean wind speed within a given time duration, say, 1 hour, is considered as a constant, and the wind fluctuation around its mean is modeled as a stationary random process. The stationarity assumption faces challenges in the cases such as hurricane or typhoon winds and thunderstorm downbursts, where the magnitude and direction of mean wind speed may change with time relatively rapidly, and the random wind turbulence may also show nonstationary characteristics.

Davenport and King (1993) illustrated the influence of storm duration on "build-up" of single torsional modal response of Golden Gate Bridge, and pointed out that the maximum response in a given storm may be greater than it would be in other storm having a higher wind speed but short duration. Chen (2008) developed an analysis framework for quantifying alongwind tall building response under transient nonstationary winds, and investigated the influence of time-varying mean wind speed, mean wind speed profile, and spatial correlation of wind fluctuations on building response. Kwon and Kareem (2009) introduced a general gust-front factor accounting for the extreme response of buildings under transient winds. The theory concerning structural response to nonstationary excitations (e.g., Lin and Cai 1995; Lutes and Sarkani 2004) has been used in earthquake engineering (e.g., Conte and Peng 1997; Michaelov et al. 2001; Barbato and Vasta 2010), but its applications in wind engineering has been very limited.

This paper presents a general frequency domain framework for predicting buffeting response of long span bridges to transient nonstationary winds. Formulations are presented for modeling static, self-excited and buffeting forces and for estimating the time-varying mean, variance and extreme response. The general characteristics of transient buffeting response are discussed using a long span suspension bridge as an example. Time domain Monte Carlo simulations are also performed to confirm the effectiveness and accuracy of the proposed framework.

2 THEORETICAL FRAMEWORK

2.1 *Equations of bridge motion*

A long span bridge subjected to wind excitation with the mean wind direction normal to the bridge deck axis is considered. At the spanwise location x, the deterministic time-varying mean wind speed is denoted by $U(x,t)$ with its random fluctuation components $u'(x,t)$ and $w'(x,t)$ in horizontal and vertical directions, respectively. $u'(x,t)$ and $w'(x,t)$ are regarded as zero mean evolutionary random processes with the underlying zero mean stationary random processes $u(x,t)$ and $w(x,t)$ and complex-valued deterministic modulation functions $g_u(x,\omega,t)$ and $g_w(x,\omega,t)$, respectively. $u'(x,t)$ and $u(x,t)$ are expressed in the general form of a Fourier-Stieltjes integral as

$$u'(x,t)=\int_{-\infty}^{\infty} g_u(x,\omega,t)e^{i\omega t}d\Theta_u(x,\omega)\,;\quad u(x,t)=\int_{-\infty}^{\infty} e^{i\omega t}d\Theta_u(x,\omega) \tag{1}$$

where $d\Theta_u(x,\omega)$ is complex-valued zero mean orthogonal increment random process

$$E[d\Theta_u(x,\omega)]=0;\ E[d\Theta_u(x,\omega)]=E[d\Theta_u^*(x,-\omega)];$$

$$E[d\Theta_u(x_1,\omega_1)d\Theta_u^*(x_2,\omega_2)]=S_u(x_1,x_2,\omega_1)\delta(\omega_1-\omega_2)d\omega_1 \tag{2}$$

$E[...]$ denotes the expectation or ensemble average; $\delta(...)$ represents the Dirac delta function; $S_u(x,\omega)=S_u(x,x,\omega)$ and $S_u(x_1,x_2,\omega)$ are the power spectral density (PSD) of $u(x,t)$ and cross PSD of $u(x_1,t)$ and $u(x_2,t)$; ω is frequency; superscript * denotes complex conjugate operator; and $i=\sqrt{-1}$.

The evolutionary PSD (EPSD) of $u'(x,t)$ and cross EPSD of $u'(x_1,t)$ and $u'(x_2,t)$ are then given as

$$S_{u'}(x,\omega,t)=|g_u(x,\omega,t)|^2\,S_u(x,\omega)\,;\quad S_{u'}(x_1,x_2,\omega,t)=g_u(x_1,\omega,t)g_u^*(x_2,\omega,t)S_u(x_1,x_2,\omega) \tag{3}$$

where $g_u(x,-\omega,t)=g_u^*(x,\omega,t)$. Similar formulations for $w'(x,t)$ and $w(x,t)$ can be given in terms of $d\Theta_w(x,\omega)$, $g_w(x,\omega,t)$, $S_w(x,\omega,t)$ and $S_w(x_1,x_2,\omega,t)$.

The aerodynamic forces on bridge deck, i.e., lift (downward), drag (downwind) and pitching moment (nose-up), can be separated into static (mean), self-excited and buffeting force components. It is assumed that the variation rate of time-varying mean wind speed is low enough such that the effects of transient aerodynamics can be neglected. Accordingly, the aerodynamic forces can be given in the same formulations as traditional time-invariant mean wind speed case, but with consideration of time-varying mean wind speed and evolutionary wind fluctuations. For instance, the static, self-excited and buffeting components of pitching moment per unit length of bridge deck are given as (e.g., Scanlan 1993; Chen and Kareem 2002)

$$M_s(x,t)=\frac{1}{2}\rho U^2(x,t)B^2C_M \tag{4}$$

$$M_{se}(x,t)=\frac{1}{2}\rho U^2(x,t)(2b^2)\left(kA_1^*\frac{\dot{h}}{U}+kA_2^*\frac{b\dot{\alpha}}{U}+k^2A_3^*\alpha+k^2A_4^*\frac{h}{b}+kA_5^*\frac{\dot{p}}{U}+k^2A_6^*\frac{p}{b}\right) \tag{5}$$

$$\begin{aligned}M_b(x,t)=\frac{1}{2}\rho U(x,t)B^2\int_{-\infty}^{\infty}[&2C_M\chi_{Mu}(x,\omega,t)g_u(x,\omega,t)e^{i\omega t}d\Theta_u(x,\omega)\\&+2C_M'\chi_{Mw}(x,\omega,t)g_w(x,\omega,t)e^{i\omega t}d\Theta_w(x,\omega)]\end{aligned} \tag{6}$$

where ρ is air density; $B = 2b$ is bridge deck width; C_M is static pitching moment coefficients; $C_M' = dC_M / d\alpha$; $A_i^*(i = 1-6)$ are flutter derivatives, which are function of reduced frequency $k = \omega b / U(x,t)$; $h(x,t)$, $p(x,t)$ and $\alpha(x,t)$ are bridge deck dynamic displacements around the statically deformed equilibrium at the spanwise location x in acrosswind, alongwind and torsional directions; χ_{Mu} and χ_{Mw} are aerodynamic admittance functions.

It is assumed that the time variation rates of mean wind speed and mean wind loading are low compared to the natural frequencies of the bridge, therefore the resulting bridge response can be calculated through quasi-static analysis. An iterative calculation procedure is need to solve this statically nonlinear problem as the static force coefficients are functions of angle of attack which is influenced by bridge deck rotation. The dynamic buffeting response around the statically deformed equilibrium is expressed in generalized modal responses. Following the finite element procedure, the equations of bridge motion can be expressed as follows in the generalized modal displacement vector $\boldsymbol{q}$ (e.g., Chen et al. 2000a and b)

$$\boldsymbol{M}\ddot{\boldsymbol{q}} + \boldsymbol{C}\dot{\boldsymbol{q}} + \boldsymbol{K}\boldsymbol{q} = \boldsymbol{Q}_{se} + \boldsymbol{Q}_b \tag{7}$$

$$\boldsymbol{M} = diag[m_j]; \quad \boldsymbol{C} = diag[2m_j\xi_{sj}\omega_{sj}]; \quad \boldsymbol{K} = diag[m_j\omega_{sj}^2] \tag{8}$$

$$\boldsymbol{Q}_{se} = \boldsymbol{A}_s(\omega,t)\boldsymbol{q}(t) + \boldsymbol{A}_d(\omega,t)\dot{\boldsymbol{q}}(t) \tag{9}$$

$$\boldsymbol{Q}_b = \int_{-\infty}^{\infty}\left(\boldsymbol{A}_{bu}(\omega,t)e^{i\omega t}d\boldsymbol{\Theta}_u(\omega) + \boldsymbol{A}_{bw}(\omega,t)e^{i\omega t}d\boldsymbol{\Theta}_w(\omega)\right) \tag{10}$$

where $\boldsymbol{M}, \boldsymbol{C}, \boldsymbol{K}$ are generalized mass, damping and stiffness matrices; $m_j, \xi_{sj}, \omega_{sj}$ are j-th generalized mass, damping ratio and frequency; $\boldsymbol{Q}_{se}$ and $\boldsymbol{Q}_b$ are generalized self-excited and buffeting force vectors; $\boldsymbol{A}_s(\omega,t)$ and $\boldsymbol{A}_d(\omega,t)$ are aerodynamic stiffness and damping matrices; $\boldsymbol{A}_{bu}(\omega,t)$ and $\boldsymbol{A}_{bw}(\omega,t)$ are buffeting force matrices; $d\boldsymbol{\Theta}_u(\omega)$ and $d\boldsymbol{\Theta}_w(\omega)$ are orthogonal increment random processes associated with horizontal and vertical wind fluctuation vectors, characterized by the spectral matrices, i.e.,

$$E[d\boldsymbol{\Theta}_u(\omega_1)d\boldsymbol{\Theta}_u^{T*}(\omega_2)] = \boldsymbol{S}_u(\omega_1)\delta(\omega_1-\omega_2)d\omega_1;\ E[d\boldsymbol{\Theta}_w(\omega_1)d\boldsymbol{\Theta}_w^{T*}(\omega_2)] = \boldsymbol{S}_w(\omega_1)\delta(\omega_1-\omega_2)d\omega_1 \tag{11}$$

and T denotes the matrix transpose operator.

The equations of bridge motion can be represented in the state-space format:

$$\dot{\boldsymbol{Y}} = \boldsymbol{A}(\omega,t)\boldsymbol{Y} + \boldsymbol{B}\boldsymbol{Q}_b \tag{12}$$

$$\boldsymbol{Y} = \begin{Bmatrix}\boldsymbol{q}\\ \dot{\boldsymbol{q}}\end{Bmatrix}; \quad \boldsymbol{A}(\omega,t) = \begin{bmatrix}\boldsymbol{0} & \boldsymbol{I}\\ -\boldsymbol{M}^{-1}[\boldsymbol{K}-\boldsymbol{A}_s(\omega,t)] & -\boldsymbol{M}^{-1}[\boldsymbol{C}-\boldsymbol{A}_d(\omega,t)]\end{bmatrix}; \quad \boldsymbol{B} = \begin{bmatrix}0\\ \boldsymbol{M}^{-1}\end{bmatrix} \tag{13}$$

At a given time instant, "frozen time", i.e., a given wind speed, the complex modal properties can be quantified through the solution of following complex eigenvalue problem:

$$\lambda_j\boldsymbol{\Gamma}_j = \boldsymbol{A}(\omega_j,t)\boldsymbol{\Gamma}_j; \quad \lambda_j = -\xi_j\omega_j + i\omega_j\sqrt{1-\xi_j^2}; \quad \boldsymbol{\Gamma}_j = \begin{Bmatrix}\boldsymbol{\Phi}_j\\ \lambda_j\boldsymbol{\Phi}_j\end{Bmatrix} \tag{14}$$

where λ_j and $\boldsymbol{\Phi}_j$ are j-th complex eigenvalue and eigenmode (mode shape) with their complex conjugates $\lambda_{j+N} = \lambda_j^*$ and $\boldsymbol{\Phi}_{j+N} = \boldsymbol{\Phi}_j^*$ (where N is the total number of modes considered); ω_j and ξ_j are j-th complex modal frequency and damping ratio. An iterative calculation is needed for the solution of this eigenvalue problem as $\boldsymbol{A}(\omega,t)$ involves the unknown frequency.

The corresponding eigenmode of $\boldsymbol{A}^T(\omega,t)$ is expressed as

$$\lambda_j \boldsymbol{\Psi}_j = \boldsymbol{A}^T(\omega_j,t)\boldsymbol{\Psi}_j; \quad \boldsymbol{\Psi}_j = \begin{Bmatrix} \boldsymbol{\Psi}_{ju} \\ \boldsymbol{\Psi}_{jd} \end{Bmatrix} \tag{15}$$

It is noted that each of the complex eigenvalues and modal shapes are determined using different system matrix defined at the corresponding modal frequency, i.e., $\boldsymbol{A}(\omega_j,t)$. Therefore, theoretically the orthogonal condition between different modal shapes does not exist, but can be considered to be approximately valid without introducing a noticeable influence on the system behavior. Accordingly, the equations of bridge motion can be represented in an equivalent frequency-independent format with $\boldsymbol{A}_{\text{ef}}(t)$ replacing $\boldsymbol{A}(\omega,t)$ (Chen 2006). This equivalent linear time-variant (LTV) bridge aeroelastic system is uniquely defined by the complex modal properties. Denote

$$\boldsymbol{\Gamma} = \begin{bmatrix} \boldsymbol{\Gamma}_1 & \boldsymbol{\Gamma}_2 & \dots & \boldsymbol{\Gamma}_{2N} \end{bmatrix} = \begin{bmatrix} \boldsymbol{\Phi} \\ \boldsymbol{\Phi}\boldsymbol{\Lambda} \end{bmatrix}; \boldsymbol{\Phi} = \begin{bmatrix} \boldsymbol{\Phi}_1 & \boldsymbol{\Phi}_2 & \dots & \boldsymbol{\Phi}_{2N} \end{bmatrix}; \boldsymbol{\Psi} = \begin{bmatrix} \boldsymbol{\Psi}_1 & \boldsymbol{\Psi}_2 & \dots & \boldsymbol{\Psi}_{2N} \end{bmatrix} = \begin{bmatrix} \boldsymbol{\Psi}_u \\ \boldsymbol{\Psi}_d \end{bmatrix} \tag{16}$$

the orthogonal condition leads to

$$\boldsymbol{\Psi}^T = \boldsymbol{\Gamma}^{-1}; \quad \boldsymbol{\Gamma}^{-1}\boldsymbol{A}_{\text{ef}}\boldsymbol{\Gamma} = \Lambda = diag[\lambda_j] \tag{17}$$

which can be used to determine $\boldsymbol{A}_{ef}(t)$ if needed.

2.2 *Frequency domain buffeting response analysis*

Introducing a transformation $\boldsymbol{Y}(t) = \boldsymbol{P}(t)\boldsymbol{R}(t)$, the state-space equation of motion becomes

$$\dot{\boldsymbol{R}}(t) = \boldsymbol{P}^{-1}(t)[\boldsymbol{A}_{\text{ef}}(t)\boldsymbol{P}(t) - \dot{\boldsymbol{P}}(t)]\boldsymbol{R}(t) + \boldsymbol{P}^{-1}(t)\boldsymbol{B}\boldsymbol{Q}_b(t) \tag{18}$$

If $\boldsymbol{P}(t)$ is a fundamental matrix, i.e., it satisfies the dynamic eigenvalue equation $\dot{\boldsymbol{P}}(t) = \boldsymbol{A}_{\text{ef}}(t)\boldsymbol{P}(t)$, the state-space equation leads to

$$\boldsymbol{Y}(t) = \boldsymbol{\Xi}(t,t_0)\boldsymbol{Y}(t_0) + \int_{t_0}^{t} \boldsymbol{\Xi}(t,\tau)\boldsymbol{B}\boldsymbol{Q}_b(\tau)d\tau \tag{19}$$

where $\boldsymbol{\Xi}(t,\tau) = \boldsymbol{P}(t)\boldsymbol{P}^{-1}(\tau)$ is state transition matrix; and $\boldsymbol{Y}(t_0)$ is the state vector at t_0.

The dynamic eigenvalue equation of the LTV system can be solved, for instance, using an approach introduced by Kloet and Neerhoff (2000), which is based on triangularization of system matrix by Riccati transformation. In this study, it is assumed that the variation rate of complex mode shape $\boldsymbol{\Gamma}(t)$ is relatively small, thus $\dot{\boldsymbol{\Gamma}}(t) \approx 0$, and the fundamental matrix can be approximately given by the "frozen time" complex eigenvalues and vectors as

$$\boldsymbol{P}(t) = \boldsymbol{\Gamma}(t)e^{\int_0^t \boldsymbol{\Lambda}(\tau)d\tau} \tag{20}$$

When the system is from "at rest" at $t = 0$, the generalized displacement and velocity vectors are given as follows based on Eq. (19):

$$\boldsymbol{q}(t) = \int_0^t \boldsymbol{h}_q(t,\tau)\boldsymbol{Q}_b(\tau)d\tau; \quad \dot{\boldsymbol{q}}(t) = \int_0^t \boldsymbol{h}_{\dot{q}}(t,\tau)\boldsymbol{Q}_b(\tau)d\tau \tag{21}$$

$$\boldsymbol{h}_q(t,\tau)=\boldsymbol{\Phi}(t)e^{\int_\tau^t \boldsymbol{\Lambda}(t)dt}\boldsymbol{\Psi}_d^T(\tau)\boldsymbol{M}^{-1};\quad \boldsymbol{h}_{\dot{q}}(t,\tau)=\frac{\partial \boldsymbol{h}_q(t,\tau)}{\partial t}\approx \boldsymbol{\Phi}(t)\boldsymbol{\Lambda}(t)e^{\int_\tau^t \boldsymbol{\Lambda}(t)dt}\boldsymbol{\Psi}_d^T(\tau)\boldsymbol{M}^{-1} \tag{22}$$

where $\boldsymbol{h}_q(t,\tau)$ and $\boldsymbol{h}_{\dot{q}}(t,\tau)$ are impulse response matrices for displacement and velocity.

The variance matrix of generalized displacement vector is then determined as

$$\boldsymbol{R}_q(t)=E[\boldsymbol{q}(t)\boldsymbol{q}^T(t)]=\int_0^t\int_0^t \boldsymbol{h}_q(t,t_1)\boldsymbol{R}_{Qb}(t_1,t_2)\boldsymbol{h}_q^T(t,t_2)dt_1dt_2 \tag{23}$$

$$\boldsymbol{R}_{Qb}(t_1,t_2)=\int_{-\infty}^{\infty}\boldsymbol{S}_{Qb}(\omega,t_1,t_2)e^{-i\omega(t_1-t_2)}d\omega \tag{24}$$

$$\boldsymbol{S}_{Qb}(\omega,t_1,t_2)=\boldsymbol{A}_{bu}(\omega,t_1)\boldsymbol{S}_u(\omega)\boldsymbol{A}_{bu}^{T*}(\omega,t_2)+\boldsymbol{A}_{bw}(\omega,t_1)\boldsymbol{S}_w(\omega)\boldsymbol{A}_{bw}^{T*}(\omega,t_2) \tag{25}$$

where $\boldsymbol{R}_{Qb}(t_1,t_2)$ and $\boldsymbol{S}_{Qb}(\omega,t_1,t_2)$ are the covariance matrix and cross EPSD between $\boldsymbol{Q}_b(t_1)$ and $\boldsymbol{Q}_b(t_2)$. It is assumed that *u*- and *w*-components of wind fluctuations are uncorrelated, while their correlation and cross spectrum can be readily incorporated in the formulations.

The EPSD matrix of the generalized displacement vector is determined as

$$\boldsymbol{S}_q(\omega,t)=\boldsymbol{H}_u(\omega,t)\boldsymbol{S}_u(\omega)\boldsymbol{H}_u^{T*}(\omega,t)+\boldsymbol{H}_w(\omega,t)\boldsymbol{S}_w(\omega)\boldsymbol{H}_w^{T*}(\omega,t) \tag{26}$$

$$\boldsymbol{H}_u(\omega,t)=\int_0^t \boldsymbol{h}_q(t,\tau)\boldsymbol{A}_{bu}(\omega,\tau)e^{-i\omega(t-\tau)}d\tau;\qquad \boldsymbol{H}_w(\omega,t)=\int_0^t \boldsymbol{h}_q(t,\tau)\boldsymbol{A}_{bw}(\omega,\tau)e^{-i\omega(t-\tau)}d\tau \tag{27}$$

and the integration of $\boldsymbol{S}_q(\omega,t)$ over the frequency gives $\boldsymbol{R}_q(t)$.

The time-varying variance and ESPD of any response of interest can be susequaently calculated. For a given response $v(t)=\boldsymbol{D}^T\boldsymbol{q}(t)$, these are

$$\sigma_v^2(t)=R_v(t)=\boldsymbol{D}^T\boldsymbol{R}_q(t)\boldsymbol{D};\quad \boldsymbol{S}_v(\omega,t)=\boldsymbol{D}^T\boldsymbol{S}_q(\omega,t)\boldsymbol{D} \tag{28}$$

and similar calculations for any response related to velocity response $\dot{\boldsymbol{q}}(t)$ can be made using the impulse response function matrix $\boldsymbol{h}_{\dot{q}}(t,\tau)$.

The extreme value of $v(t)$ within a time duration of *T*, i.e., $v_{\max}=\max\{v(t),0\le t\le T\}$, can be calculated through upcrossing rate analysis. Under the assumption of Poisson crossings, the cumulative distribution function (CDF) of the extreme response is calculated as

$$F_{\max}(v)=\exp\left(-\int_0^T \mu(v,t)dt\right);\qquad \mu(v,t)=\frac{1}{2\pi}\frac{\sigma_{\dot{v}}(t)}{\sigma_v(t)}\exp\left(-\frac{(v-\bar{v}(t))^2}{2\sigma_v^2(t)}\right) \tag{29}$$

where $\mu(v,t)$ is the crossing rate at level v; $\sigma_{\dot{v}}(t)$ is root-mean-square (RMS) value of $\dot{v}(t)$; and $\bar{v}(t)$ is the time-varying mean response. The mean extreme corresponds to a non-exceeding probability of 0.57 when the extreme distribution can be further modeled as a Gumbel-type distribution. The mean extreme subtracting the maximum of mean and then derived by the maximum of RMS response is referred to as peak factor for the transient response.

2.3 *Application to simplified cases*

Consider the case where the mean wind speed and wind fluctuations are expressed as

$$U(x,t)=U_{\max}U_0(x)d_m(t);\qquad u'(x,t)=u(x,t)d_u(t);\qquad w'(x,t)=w(x,t)d_w(t) \tag{30}$$

where $d_m(t)$, $d_u(t)$ and $d_w(t)$ are time-varying modulation functions for the mean wind speed and wind fluctuations; $U_{\max}$ is maximum mean wind speed over time and space; $U_0(x)$ defines the spanwise variation of the mean wind speed.

The PSDs and coherence functions of $u(x,t)$ and $w(x,t)$ are defined as

$$S_u(x_1,x_2,\omega)=\mathrm{coh}_u(x_1,x_2,\omega)S_u(\omega)I_{u0}^2(x_1)I_{u0}^2(x_2);\quad \mathrm{coh}_u(x_1,x_2,\omega)=\exp\left(-\frac{\lambda_u\omega\,|\,x_1-x_2\,|}{2\pi U_R}\right) \tag{31}$$

$$S_w(x_1,x_2,\omega)=\mathrm{coh}_w(x_1,x_2,\omega)S_w(\omega)I_{w0}^2(x_1)I_{w0}^2(x_2);\ \mathrm{coh}_w(x_1,x_2,\omega)=\exp\left(-\frac{\lambda_w\omega\,|\,x_1-x_2\,|}{2\pi U_R}\right) \tag{32}$$

where λ_u and λ_w are decay factors; $I_{u0}(x)$ and $I_{w0}(x)$ are functions to reflect the spatial variations of PSDs of wind fluctuations; and $U_R=U_{\max}[U_0(x_1)+U_0(x_2)]/2$. It is also assumed that the admittance functions are functions of reduced frequency $k=\omega b/(U_{\max}U_0(x))$, thus are functions of spanwise location x and frequency ω, but are independent of time t.

Accordingly, the buffeting force matrices are calculated as

$$\boldsymbol{A}_{bu}(\omega,t)=\boldsymbol{A}_{bu0}(\omega)d_m(t)d_u(t);\qquad \boldsymbol{A}_{bw}(\omega,t)=\boldsymbol{A}_{bw0}(\omega)d_m(t)d_w(t) \tag{33}$$

and the ESPD matrix of generalized displacement vector is estimated as

$$\boldsymbol{S}_q(\omega,t)=\boldsymbol{H}_{q0u}(\omega,t)\boldsymbol{S}_{Qbu}^{(0)}(\omega)\boldsymbol{H}_{q0u}^{T*}(\omega,t)+\boldsymbol{H}_{q0w}(\omega,t)\boldsymbol{S}_{Qbw}^{(0)}(\omega)\boldsymbol{H}_{q0w}^{T*}(\omega,t) \tag{34}$$

$$\boldsymbol{H}_{q0u}(\omega,t)=\int_0^t\boldsymbol{h}_q(t,\tau)d_m(\tau)d_u(\tau)e^{-i\omega(t-\tau)}d\tau;\quad \boldsymbol{H}_{q0w}(\omega,t)=\int_0^t\boldsymbol{h}_q(t,\tau)d_m(\tau)d_w(\tau)e^{-i\omega(t-\tau)}d\tau \tag{35}$$

$$\boldsymbol{S}_{Qbu}^{(0)}(\omega)=\boldsymbol{A}_{bu0}(\omega)\boldsymbol{S}_u(\omega)\boldsymbol{A}_{bu0}^{T*}(\omega);\quad \boldsymbol{S}_{Qbw}^{(0)}(\omega)=\boldsymbol{A}_{buw}(\omega)\boldsymbol{S}_w(\omega)\boldsymbol{A}_{bw0}^{T*}(\omega) \tag{36}$$

It is noted that the transient characteristics of response is reflected by the time dependence of $\boldsymbol{H}_{q0u}(\omega,t)$ and $\boldsymbol{H}_{q0w}(\omega,t)$. In the case of the time-invariant mean wind speed and stationary wind fluctuations, i.e., $d_m(t)=d_u(t)=d_w(t)=1$, $\boldsymbol{H}_{q0u}(\omega,t)$ and $\boldsymbol{H}_{q0w}(\omega,t)$, thus $\boldsymbol{S}_q(\omega,t)$ and $\boldsymbol{R}_q(t)$ approach to the steady-state values when time t is sufficiently large. The framework presented in this study reduces to that for multimode coupled buffeting analysis of bridge aeroelastic system under stationary winds (e.g., Chen and Kareem 2000a; Chen 2006). It is also worthy of noting that when the aerodynamic inter-modal coupling is negligible, $\boldsymbol{H}_{q0u}(\omega,t)$ and $\boldsymbol{H}_{q0w}(\omega,t)$ are diagonal matrices. The transient buffeting response of each mode can be estimated separately and then combined by using the square-root-of-sum-of-squares (SRSS) combination rule.

3 NUMERICAL EXAMPLES AND DISCUSSIONS

3.1 *A long span suspension bridge under nonstationary wind excitations*

A suspension bridge with a main span of nearly 2000 m was used as an example. The first 15 natural modes with frequencies ranging from 0.003 to 0.2 Hz were considered for describing the dynamic behavior of the bridge. The modal damping ratio was assumed to be 0.0032. For simplicity and without loss of generality, only the aerodynamic forces acting on the bridge deck were considered. The self-excited lift and pitching moment were calculated based on the flutter derivatives derived from Theodorsen function. The self-excited drag was evaluated based on the quasi-steady theory. The admittance functions used were based on Davenport's formula for drag with a decay factor of 8, and Sears function for lift and pitching moment. Two different joint acceptance functions were used for the buffeting force components associated with *u*- and *w*-components, respectively. The mean wind speed is uniform over the bridge span but with a time-varying amplitude, i.e.,

$$U_0(x)=1; \quad d_m(t)=\exp\{-(t-t_0)^2/2D_t^2\} \tag{37}$$

where t_0 is the time instance at which the wind speed reach its maximum; and D_t is wind storm duration parameter defining the time variation of wind speed.

The modulation functions of *u*- and *w*-components of wind fluctuations were identical to that of the mean wind speed, i.e., $d_u(t)=d_w(t)=d_m(t)$. The von Karman spectra were used to describe the underlying stationary wind fluctuations. The turbulence intensities and integral length scales were assumed to be 10 and 7.5%, and 80 and 40 m, for *u*- and *w*-components, respectively. The spectral characteristics of wind fluctuations were uniform over the bridge, i.e., $I_{u0}(x)=I_{w0}(x)=1$. The decay factors of the coherence functions for *u*- and *w*-components were $\lambda_u=\lambda_w=8$. Fig.1 shows the time modulation function $d_m(t)$ with t_0 =300 sec, and D_t =120, 180, 240 and 300 sec. A smaller value of D_t indicates a short duration of strong storm, i.e., a larger variation of mean wind speed.

3.2 *Results and discussions*

The modal frequencies, damping ratios and complex modal shapes at different mean wind speeds are calculated, which are used to calculate the impulse response function matrix. Fig.2 shows the modal damping ratios at different mean wind speeds. The coupled flutter onset velocity is estimated to be 69.4 m/s. Fig.3 displays the EPSD of the torsional displacement at main span center with $U_{\max}=60$ m/s, $t_0=300$ sec, and $D_t=120$ sec. Fig.4 portrays the time-varying mean and RMS values of bridge deck displacements at center of main span. It is noted that the maximum RMS is delayed with respect to the time at which the mean wind speed reaches its maximum, which is due to transient effect of bridge dynamic system. The delay is more noticeable for lateral displacement that is dominated by first lateral mode with lower frequency and damping. Fig.5 shows the maximum values of static and RMS, and mean extreme (including static) response within 10 min at different spanwise location in terms of bridge deck vertical, lateral and torsional displacements. The results from ensemble average of 50 time domain simulation samples are also presented. The predictions in frequency and time domains are very agreeable.

The procedure for simulating the time history of transient response is essentially the same as that introduced in Chen et al. (2000b). The underlying stationary wind turbulence field is firstly generated based on their spectral characteristics using spectral representation method. The nonstationary wind turbulence field is then calculated by multiplying the modulation functions. The flutter derivatives, admittance functions and joint acceptance functions are represented as rational functions of reduced frequency. Based on the quasi-static assumption concerning the influence of time-varying mean wind speed on aerodynamics, the time histories of self-excited and

buffeting forces are generated and the resulting buffeting response is calculated using step-by-step solution of the dynamic equations.

(a) RMS (b) Peak factor

Figure 7. Influence of storm duration parameter on torsional displacement at main span center

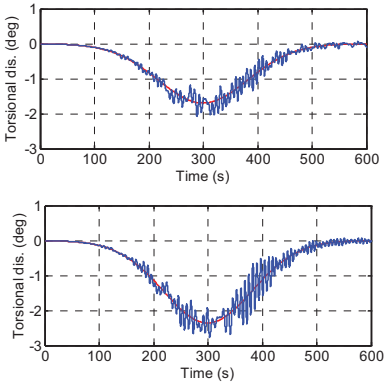

Figure 8. Time history samples of torsional displcament at U_{max}= 60 and 70 m/s

Fig.6 shows the steady state buffeting response when mean wind speed is a constant of 60 m/s, which corresponds to traditional buffeting analysis. Fig.7 is the predicted maximum RMS responses and peak factors at different values of D_t with $U_{\max} = 40$, 60 and 70 m/s and $t_0 = 300$ sec. It is obvious that the transient excitation results in reduced RMS response as compared to

steady state response. It is due to the lack of sufficient "build-up" time of response to reach the steady state level. At 70 m/s, the steady state buffeting response will be unstable as it exceeds the flutter onset speed. However, under the transient wind excitation the bridge shows stable response as the lack of sufficient "build-up" time of unstable response as shown in Fig.8. Take a single degree-of-freedom system as an example. The "build-up" time is the time required to make $\exp(-2\xi\omega t)$ close to zero in the case of positive damping, where ξ and ω are the system damping ratio and frequency. Clearly, a large value of $\xi\omega$, a shorter "build-up" time needed, and the RMS response becomes closer to the steady state value. Since the lateral displacement is dominated by lower frequency and with a lower modal damping, the transient effect is most significant. The build-up rate of unstable dynamic response is also proportional to the value of $\xi\omega$. At higher wind speeds with larger negative damping, the buffeting responses will develop into significant amplitudes even under transient wind excitations.

The extreme value and peak factor of transient buffeting response are significantly lower than those of stationary response. For instance of case with $U_{\max} = 60$ m/s, $t_0 = 300$ sec, and $D_t = 120$ sec, the peak factors of the bridge deck displacements in vertical, lateral and torsional directions at the main span center are 2.11, 1.43, and 2.08, respectively. These are 2.98, 2.68 and 3.07, respectively, in the case of steady state response under constant mean wind speed. The lower peak factor or extreme response is due to the fact that large response is only observed in a relatively short of time as compared to the stationary case where it occurs over the entire time duration. The crossing rate at a given response level is much lower than that of the state sate response.

4 CONCLUSIONS

This study presented a general frequency domain approach for quantifying buffeting response of long span bridges when subjected to transient nonstationary winds. The wind fluctuations were modeled as evolutionary random processes with time-varying mean. Formulations for calculating static, self-excited and buffeting forces were presented to account for the transient wind excitation. The bridge response to time-varying mean wind loading was determined through quasi-static analysis with an iterative procedure for solution of statically nonlinear problem. The dynamic bridge aeroelastic system was regarded as a linear time-variant system with slowly varying modal characteristics. The impulse response function matrix of the system was defined by the modal properties at "frozen time", which were determined through complex eigenvalue analysis at given mean wind speeds. Formulations were given for calculating the EPSD, time-varying RMS value, probability distribution of extreme response and peak factor. The traditional multi-mode coupled buffeting analysis framework to stationary wind excitation is the special case of the general framework presented in this study.

The analysis of buffeting response of the long span suspension bridge showed that transient wind excitation results in reduced RMS response attributed to the lack of sufficient "build-up" time of response to reach the steady state level. The lateral bridge deck displacement was more noticeably affected by the transient effect as it was dominated by the modal response with lower frequency and damping ratio. The duration of wind storm played a significant role in the generation of extreme buffeting response especially for very flexible structures with low frequency and damping. The extreme value and peak factor of transient response were much lower than those of steady-state response.

It is worthy of mentioning that the effects of transient aerodynamics, i.e., the potential changes in the aerodynamic force characteristics under transient winds, were neglected, which may be considerable in the case of rapidly varying transient winds. The information of transient

aerodynamics, when available, can be readily synthesized with the proposed approach and lead to a better prediction of structural response.

ABSTRACT: This work is concerned with the aerodynamic characterization of a cable-stayed bridge tower in free-standing stage; experimental tests were performed at CA-1 wind tunnel (wind tunnel laboratory at Chang'an University, Xi'an, China) under turbulent flow condition. The aerodynamic behavior of the tower was investigated through full aeroelastic model in stand-alone configuration using a 1:50 scale. Aim of this paper is to discuss the buffeting character of a cable-stayed bridge tower at free-standing stage under yaw wind.

KEYWORDS: Free-standing; Tower; Aeroelastic model; Buffeting; Yaw wind

1. INTRODUCTION

A great number of cable-supported bridges across large rivers, lakes, sea bays and channels, have been built or are under construction since the completion of Shanghai Nanpu Bridge (a cable-stayed bridge with a main span of 423 m) in the earlier1990s. Among these bridges, Hongkong-Zhuhai-Macao Bridge, a key project across the LingDing Sea, is an extraordinary one in China for its steel structure for both bridge deck and towers, which results in lower structural damping compared with concrete structures. There are three bridges in this new road transport channel. The JiangHai Navigation Channel Bridge, a cable-stayed bridge with single-plane harp stayed cables, has three towers and six spans of 110+129+258+258+129+110=994 m, The deck is streamline closed box girder with two wind-fairings (4.5m high and 38.8 m wide). The three towers are, the central tower of 103.81m height and both side-towers of 102.55m height, of steel frame-structure .the configuration of the towers seem like a dolphin in the elevation plane. The cross section of tower's main column is rectangular, and the auxillary column is chamfered-corner rectangular (Layout and Typical sections of bridge tower are following Fig.1~2).

Buffeting is a kind of stochastic forced vibration and caused by the turbulence of incoming wind in conjunction with the so-called "rear wake induced turbulence". Buffeting is hence inevitable for any bridges exposed to the natural wind. Furthermore, buffeting may occur for the long-span bridges in strong-wind prevailing area. Such serious cause as strength and fatigue problems of structural components and instability of the vehicles traveling on the bridges may occur. Mitigated measures shall be introduced. For the great flexibility, modern long-span bridges are usually prone to strong winds induced damage, and the wind-resistant design becomes one of key issues for successful construction of bridges. Also for the tower, the higher the tower is, the slender the tower is. And the slender bridge tower is prone to aerodynamic problems connected to wind–structure interaction. For this reason, the design of these structures requires wind tunnel tests on scaled down models. At the free standing stage, the tower is of low stiffness and small damping without stay-cables system constraints, and wind-induced vibration will become one of the key factors in the design scheme. Therefore, prediction or evaluation of buffeting performances becomes very important for the towers of long-span bridges. Although many complicated approaches have been presented for the buffeting analysis (Scanlan and Gade,1977; Scanlan,1978b; Scanlan.,1978; Lin,1979;Scanlan andJones.,1990; Jain etal.,1996;Xu

etal.,1998;Boonyapinyo etal.,1999;Cai etal.,1999; Diana etal.,1999; Katsuchietal.,1999; Chen etal.,2000; Chen etal.,2001; Ding etal.,2002a; Zhu and Xu,2005;Xu and Zhu,2005), wind tunnel test of aeroelastic model will still be the most important approach in evaluating the wind-resistant performance of finalised scheme.

This paper discussed the buffeting character of a cable-stayed bridge tower at free-standing stage, wind tunnel tests on 1:50 aeroelastic model of tower were performed in the CA-1 wind tunnel (wind tunnel laboratory at Chang'an University, Xi'an, China) in turbulent flow. The model simulated the first four natural frequencies and mode shapes of the structure.

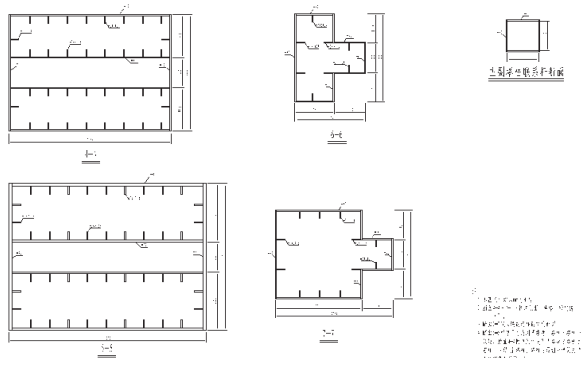

Fig 2. Typical section of bridge tower

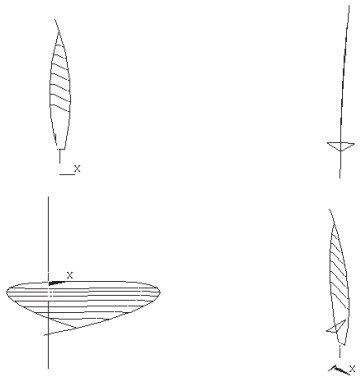
2. MODAL ANALYSIS

The modal analysis of the bridge tower was carried out using a famous finite element program, ANSYS. The tower is completely consolidation at the bottom. The members of bridge tower were modeled with spatial beam elements. The natural frequencies of some major modes of free-standing tower are listed in Table 1. The fundamental frequencies and mode shapes are shown in Fig 3 for the tower.

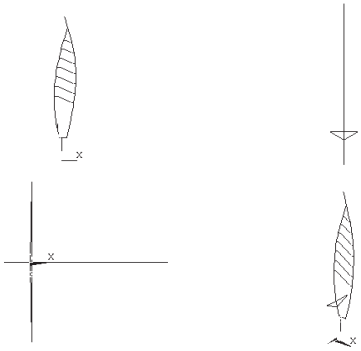
Table 1. Dynamic properties of aeroelastic model

Modes	Computed frequency of prototype(Hz)	Design values(Hz)	Measured values (Hz)	Discrepancy (%)	Measured Damping ratio(‰)
L1	0.8293	5.32	5.37	0.94	6.00
LT1	1.5357	8.26	8.3	0.48	7.00
L2	3.0053	18.1	17.58	2.87	7.80
T1	3.6155	21.78	22.46	3.12	5.00

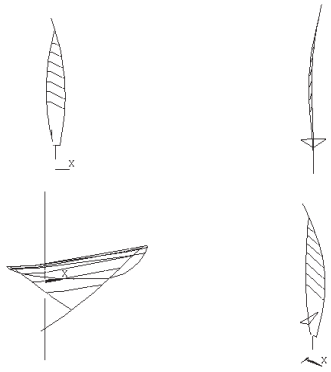
Note: L—Lateral bending of tower; LT—Longitudinal bending of tower; T—Torsional bending of tower; number—mode order.
From table 1, we can see that the errors of measured damping ratio are all within the scope of the permit.



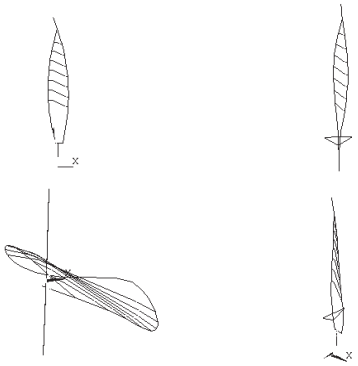
a. Lateral (0.8293Hz)



b. Longitudinal (1.5357Hz)



c. Lateral (3.0053Hz)



d. Torsional (3.6155Hz)

3. MODEL DESIGN AND MANUFACTURE

The full tower aeroelastic model test was carried out in the CA-1 wind tunnel, wind tunnel laboratory at Chang'an University. China. As shown in Fig 4. The wind tunnel is a large boundary layer wind tunnel with a closed testing section of 3 m width, 2.5m height and 15m length. The flow inside is driven by motor fans and circulates vertically. The achievable mean wind speed of empty wind tunnel ranges from 1.0 to 53 m/s, adjustable continuously.

The wind tunnel test of aeroelastic model not only require model and prototype meet geometrically similar, but also need to satisfy gravity, inertia parameters, elastic parameter, viscous parameters and damping parameters are consistent. This aeroelastic model meets the geometrically similar, inertia and damping parameters similar. A 1:50 scale full aeroelastic model of the tower was manufactured to reproduce the first four natural frequencies and mode shapes of the real structure. The similarity relations and the control parameters between aeroelastic model and prototype, we can refer to literature [1].

The model was comprised of steel core beam (simulating the tower stiffness), perspex coats (simulating the tower appearance) and plumbum compensating weights. The compensating weights were installed in the perspex coats to adjust the mass and mass moment of inertia of the tower. The perspex coats were connected to the core beam (We can refer to literature [8] for specific content.). As shown in Fig. 5 for the photo of the model in wind tunnel test.

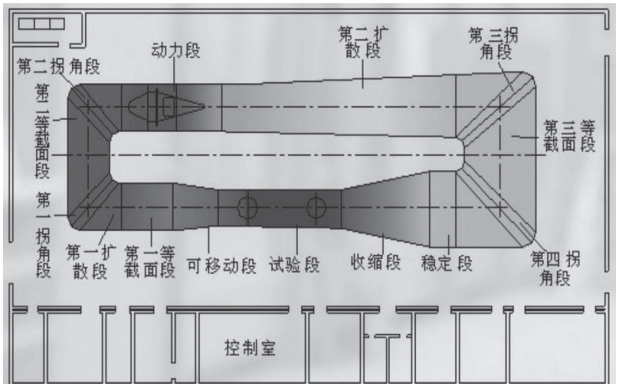

Fig 4. General layout of CA-1wind tunnel.

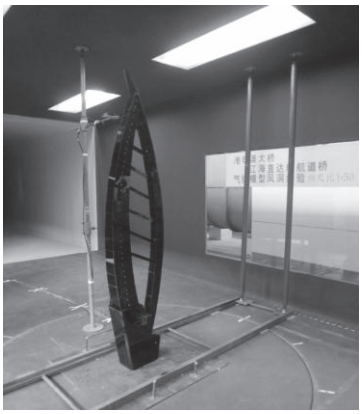

Fig 5. Photo of the model in wind tunnel test

4. MODAL CHECK OF THE AEROELASTIC MODEL

To ensure the accuracy of simulating the bridge dynamic properties, the modal parameters of the model, including natural frequencies, mode shapes and modal damping ratios of the model were carefully checked and compared with the design values.

Because of the small amplitude of vibration due to ambient excitation, the modal damping ratios of the mode were identified with conventional approach of free decay vibration stimulated with initial displacement for lower frequency modes or with initial impulse for higher frequency modes. The frequencies and modal damping of the free-standing state by this way are also listed in Table1. Furthermore, the modal damping ratios identified with free-decay vibration approach were between 0.5% and 2%, which were close to that suggested in the literature [5] for steel and concrete.

5. WIND PARAMETERS AT BRIDGE SITE

According to The Annual Report of Continuous Meteorological Observation and Wind Parameters Studies of the site of the Hong Kong-Zhuhai-Macao Bridge, the exponent (α) of mean wind profile at the bridge site is about 0.098, and the basic wind speed at the bridge site (U_{10}), namely the yearly-maximum 10-min averaged mean wind speed at 10m height corresponding to 120-year return period, is 47.2m/s. Thus, the design reference wind speed at deck level (33.8m above normal water level) for the service state (U_d) is as follows:

$$U_d = U_{10} \times (33.8/10)0.098 = 53.18 \text{m/s} \quad (1)$$

For construction state, the return period is taken as 10 years, and the corresponding design reference wind speed at deck level (U_{sd}) is determined as:

$$U_{sd} = 0.84 \times 53.18 = 44.67 \text{m/s} \quad (2)$$

The top of the tower is 107.81m above normal water level, and 65% height of the tower is 70.08m above normal water level, so the design reference wind speed of the tower is U_d=57.12m/s, For construction state, the corresponding design reference wind speed is U_{sd}=0.84×57.12=47.98m/s.

6. SIMULATION OF WIND FIELD

The atmospheric boundary layer was simulated in the CA-1 wind tunnel using spirelets, as shown in Fig 6. The simulated profiles of mean wind, along wind and vertical turbulent intensities are shown in Figs. 7–8. The fitted exponent of turbulent wind profile was 0.09.

Fig 6. Passive devices for simulation of turbulent wind field of boundary layer.

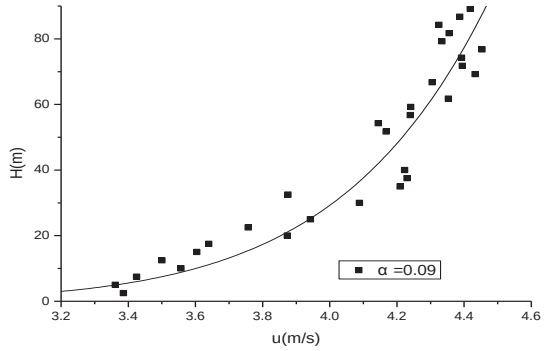

Fig 7. Mean wind profile of simulated wind field

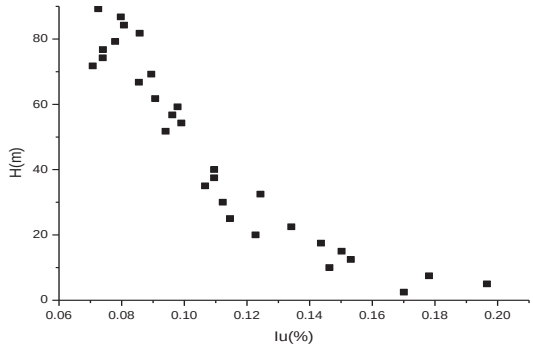

Fig 8. Turbulent intensity profile of simulated wind field

7. MAJOR TEST RESULTS

The case of tests is arranged as following, seven wind exposures(β), β =0°, 30°, 60°, 90°, 120°,150°,180° were considered(β -the angle between the direction of wind and the tower plane Fig 9).The test wind speed ranges from 0 to12m/s, it is corresponding to the speed ranges from 0 to 92.4m/s at the 65% height of tower.

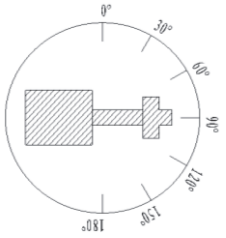

Fig 9.Section geometry and wind exposures

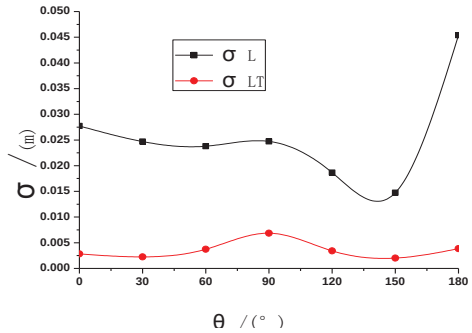
7.1 Variation of standard deviation of responses vs. wind yaw angle

From literature [8], we can know that for the construction state, the corresponding design reference wind speed is 47.98m/s.

Fig 10 shows, respectively, the test curves of the lateral, longitudinal and torsional standard deviations (σ_L, σ_{LT} and σ_T) at the top and at the 2/3 height of tower at the speed of 50m/s vs. wind yaw angle. It is found that the variation of buffeting response of free-standing tower with wind yaw angle is not monotonous. The standard deviation of displacement responses vs. wind yaw angle is very similar at the top and at the 2/3 height of tower. The lateral buffeting response on the top of the free-standing tower reach their minimal values (the top of tower is 0.015m, 2/3 height is 0.0006m) and maximal values (the top of tower is 0.0454m, 2/3 height is 0.0016m) at around 150°and 180°of wind yaw angle respectively, when the angle is over 150°, the response is increasing with wind angle. The longitudinal buffeting response gets their maximal values at around 90°of wind yaw angle.

a



b

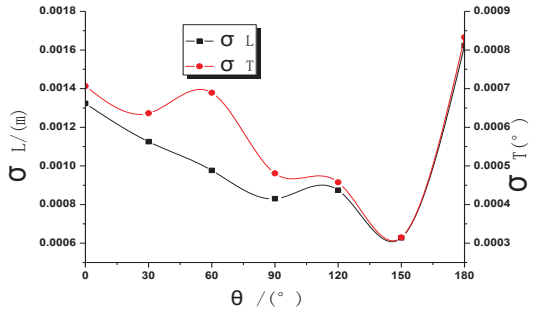


Fig 10. Variation of standard deviation of responses vs. wind yaw angle: (a) Top of the tower, (b) 2/3 height of the tower (v=50m/s)

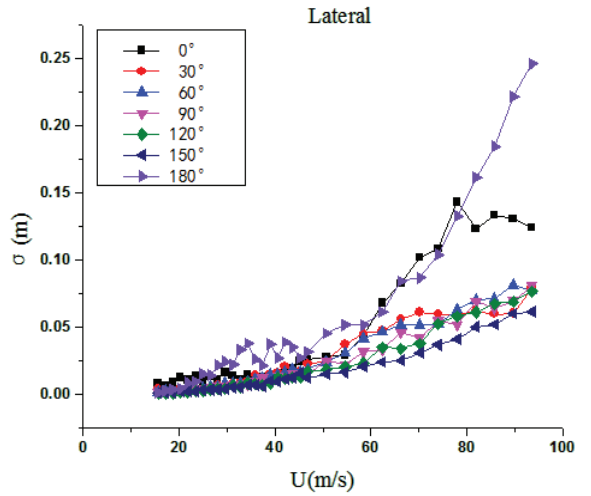
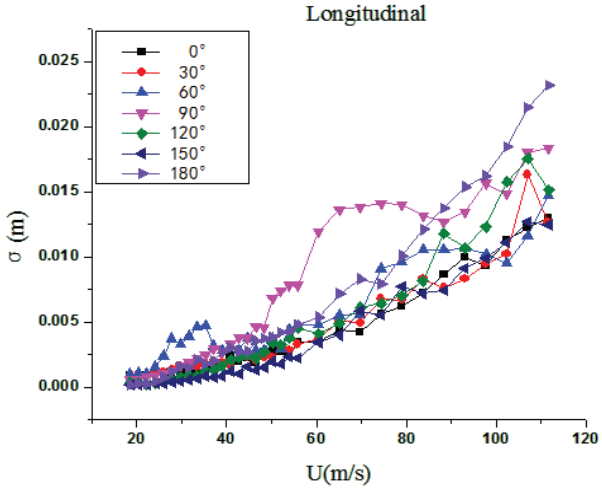
For the tower is frame structure in longitudinal, its stiffness is significantly greater than the lateral stiffness. Therefore σ_L is much larger than σ_{LA}.

Also the torsional response is small, the standard deviation of displacement responses vs. wind yaw angle is very similar for torsional and lateral response, torsional buffeting response get their minimal values (0.00031°) at around 150° of wind yaw angle, and at around 180° achieve the maximal values (0.00083°). The torsional response curve has large fluctuation with wind angle.

a



b



c

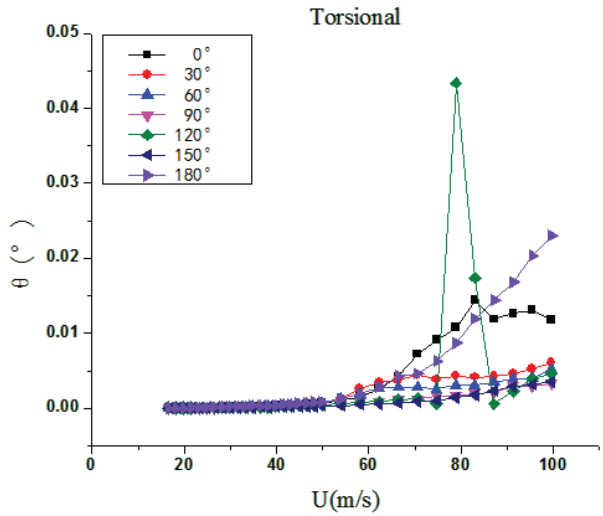


Fig 11. Variation of standard deviation of responses vs. wind speed:(a) lateral, (b) longitudinal, (c) torsional.

7.2 Variation of standard deviation of responses vs. wind speed

Fig 11.Shows, respectively, the test curves of the lateral, longitudinal and torsional standard deviations vs. mean wind speed (U), for the responses at top of the tower to turbulent wind with various wind yaw angles. From these figures, one can find by curve fitting that the buffeting responses of tower vary with wind speed at conic curves approximately, the maximal standard

deviations of the lateral, longitudinal and torsional responses at the tower top were about0.248, 0.025 m and0.045°, respectively, and the corresponding wind yaw angles were about 180° and 120°, respectively. The test results demonstrate that the most unfavorable buffeting responses of tower also occur in the yaw wind cases.

8. CONCLUSION

Wind tunnel tests are nowadays the most used and reliable method to evaluate the wind effects on slender structures that are sensitive to wind induced vibrations such as vortex shedding and galloping. This paper has presented a case study on a bridge tower where wind tunnel tests were carried out on a full tower aeroelastic model. The buffeting performance of free-standing tower of Jianghai Navigation Channel Bridge, a cable-stayed bridge, under yaw wind is investigated by means of wind tunnel test of aeroelastic model. It is very useful to understand the wind-induced vibration performance of free-standing tower in the construction states. Similarly, it is meaningful to ensure the safety of the long span bridges in construction states.

The following major conclusions can thus be drawn according to the results of wind tunnel test:

(1) The variation of buffeting response of free-standing tower with wind yaw angle is not monotonous.
(2) The lateral buffeting response on the top of the free-standing tower reach their minimal values and maximal values at around 150°and 180°of wind yaw angle respectively and the longitudinal buffeting response attain their maximal values at around 90°of wind yaw angle.
(3) The torsional buffeting response get their minimal values at around 150°of wind yaw angle, and at around 180°achieve the maximal values. And the response curve has large fluctuation with wind angle.
(4) Buffeting responses of the bridge to turbulent wind may reach the maximal values in yaw wind case. The normal wind case may not be the most unfavorable case.
(5) The buffeting response changes with the wind speed at a conic curve approximately.

9. ACKNOWLEDGMENTS

The work described in this paper is a part of a project supported by the Construction Commanding Office of Hongkong-Zhuhai-Macao Bridge, and is also financially supported by China Highway Planning and Design Institute, to which the writers are most grateful. Our sincerey thanks should also go to the Construction Commanding Office of Hongkong-Zhuhai-Maco Bridge for kindly supporting the wind-resistant research project of the bridge. Any opinions and concluding remarks presented in this paper are entirely those of the writers.

ABSTRACT: Equivalent Static Wind load (ESWL) connects structure engineers and wind engineering researchers, and plays an important role in the field of civil engineering. The long-span bridge is a typical flexible line-like structure in horizontal direction. The displacements are usually the controlling responses in the structure design. Traditional ESWL calculating methods which are based on the most disadvantageous response of one node, such as the displacement in the mid-span or quarter-span, are single target methods. When putting the ESWLs calculated by the traditional single target methods on the bridge, except the most disadvantage node, the other nodes' responses are different from the real values. This paper firstly gets the modes and influence matrix using finite element method, then calculating the PSD matrix of the buffeting forces by coupled flutter and buffeting vibration method. According to random vibration theory and structure dynamics, the ESWLs of long-span bridges in vertical, horizontal and torsional can be expressed by the mode, influence matrix, aerodynamic mechanical admittance matrix, and PSD matrix of the buffeting forces. On the basis of the load-response relationship, the ESWLs calculated through the above method are the only accurate solution which based on the displacements of the bridge.

KEYWORDS: Equivalent static wind load, Long-span bridges, Displacement responses, Mode matrix, Influence matrix, Coupled flutter and buffeting vibration.
