Wind is the motion of air. Complex aerodynamic or/and aeroelastic forces can be produced when the air blows structures. When the structure stiffness is big, the wind effect is mainly static performance. On the contrary, the wind can induce significant dynamic responses. The long-span bridge is a typical line-like structure with small stiffness in horizontal, and buffeting effects can not be ignored in most cases. Estimating the buffeting responses of a long-span bridge is a complicated and difficult task, and can not be mastered by most structure engineers. So the wind engineers and researchers proposed the concept of ESWL (Equivalent Static Wind Load) to solve this problem. ESWL transfers the complex and difficult dynamic calculation into simple static analysis, and be accepted by most countries'/regions' wind load codes/specifications. ESWL can be defined as that the responses produced by the static ESWL are equal/approximate to the responses produced by the real wind load. Then the structure engineers can solve complex dynamic problems by using simple static analysis. ESWL has become the bridge which connected wind engineers and structure engineers, and plays an important role in practical projects.

The main traditional ESWL methods have GLF[1] (Gust Load Factor) method, LRC[2][3][4] (Load-Response Correlation) method, IWL (Inertia Wind Load) method, and LRC+IWL method[5][6][7]. All these methods are single-target methods. When putting the ESWLs which calculated by the above methods on the structures, only the response on the equivalent node is the same as the real one. Later Japanese researchers proposed Universal ESWL method[8]. This method firstly needs to take several different kinds of single-target ESWLs as the basic vectors of the multi-targets ESWLs. Then calculate the optimal coefficients fitting for the ultimate multi-targets ESWLs by the least square method. In fact, the Universal ESWL method is a numerical processing method and the physical meaning is not clear.

The displacement is usually the key response in the design of a long-span bridge. So, using the accurate ESWLs based on the displacement responses to design the long-span bridge can guarantee the safety of the

bridge design. Based on the long-span bridge's characteristics above, an accurate ESWL method based on the displacement responses is proposed in this paper. And a 300 meters simple bridge with ideal thin plate section is taken as an example to prove the validity and effectiveness of the method.

1. ESWLs BASED ON THE DISPLACEMENT RESPONSES

For linear MDOF (multi-degree-of-freedom) system, the governing equation of motion is

$$[M]\{\ddot{q}(t)\}+[C]\{\dot{q}(t)\}+[K]\{q(t)\}=\{F(t)\} \tag{1}$$

Where, $[M],[C],[K]$ are mass, damping, and stiffness matrices respectively; $\{q(t)\}$, $\{\dot{q}(t)\}$, $\{\ddot{q}(t)\}$, $\{F(t)\}$ are dynamic displacement, speed, acceleration and force vectors of the nodes respectively.

According to mode superposition method, $\{q(t)\}$ can be expressed by mode matrix $[\Phi]$ and modal coordinate vector $\{\xi(t)\}$

$$\{q(t)\}=[\Phi]\{\xi(t)\} \tag{2}$$

Submit equation (2) into equation (1), the linear MDOF system can be represented as

$$[I]\{\ddot{\xi}(t)\}+[\bar{M}]^{-1}[\bar{C}]\{\dot{\xi}(t)\}+[\bar{M}]^{-1}[\bar{K}]\{\xi(t)\}=[\bar{M}]^{-1}\{\bar{F}\} \tag{3}$$

Where, $[I]$, $[\Phi_q]^T[M][\Phi_q]=[\bar{M}]$, $[\Phi_q]^T[C][\Phi_q]=[\bar{C}]$, $[\Phi_q]^T[K][\Phi_q]=[\bar{K}]$ are identity matrix, general mass, damping, and stiffness matrices respectively; $[\Phi_q]^T\{F(t)\}=\{\bar{F}\}$ is the general node force vector.

Using normalized general mass matrix, then equation (3) can be represented as

$$[I]\{\ddot{\xi}(t)\}+[\Lambda_c]\{\dot{\xi}(t)\}+[\Lambda_\omega]\{\xi(t)\}=\{\bar{F}\} \tag{4}$$

Where, $[\bar{M}]^{-1}[\bar{C}]=[\Lambda_c]=\mathrm{diag}(2\zeta_1\omega_1\cdots 2\zeta_{\text{N-mode}}\omega_{\text{N-mode}})$, $[\bar{M}]^{-1}[\bar{K}]=[\Lambda_\omega]=\mathrm{diag}(\omega_1^2\cdots\omega_{\text{N-mode}}^2)$.

For equation (4), the modal coordinate vector can be obtained by Duhamel integral equation in time domain. Because it is time consuming in time domain, so, we solve equation (4) by frequency domain method. Fourier transformation is defined as

$$\bar{\xi}(\omega)=\int_{-\infty}^{+\infty}\xi(t)e^{-i\omega t}dt \tag{5}$$

Where, $i=\sqrt{-1}$ is imaginary unit.

Equation (4) is represented in frequency domain as

$$\left(-\omega^2[I]+i\omega[\Lambda_c]+[\Lambda_\omega]\right)\{\bar{\xi}(\omega)\}=[\Phi]^T\{\bar{F}(\omega)\} \tag{6}$$

Define $[H(\omega)]=-\omega^2[I]+i\omega[\Lambda_c]+[\Lambda_\omega]$ as frequency response function matrix. Then the response produced by dynamic loading can be obtained in frequency domain as

$$\{\bar{\xi}(\omega)\}=[H(\omega)]^{-1}[\Phi]^T\{\bar{F}(\omega)\} \tag{7}$$

Wind loading is one type of random dynamic loadings, so the wind induced responses should be represented in the form of RMS. According to equation (7), PSD matrix of the modal coordinate can be represented as

$$\left[S_{\xi\xi}(\omega)\right]=\left[H(\omega)\right]^{-1}[\Phi]^{T}\left[S_{FF}(\omega)\right][\Phi]\left[H(\omega)\right]^{-1*T} \tag{8}$$

Where, $\left[H(\omega)\right]^{-1*T}$ is complex conjugate transpose of matrix $\left[H(\omega)\right]^{-1}$.

The PSD of the displacement responses can be obtained from equation (2)

$$\left[S_{qq}\right]=[\Phi]\left[S_{\xi_i\xi_j}\right][\Phi]^{T} \tag{9}$$

So the covariance matrix of the displacement response can be expressed as

$$\left[\sigma_{qq}^{2}\right]=\left[\int_{0}^{+\infty}S_{qq}(\omega)d\omega\right] \tag{10}$$

Based on the load-responses relationship, displacement responses, the key dynamic responses of the structure, can be obtained as

$$\left\{\hat{R}\right\}=\left[I_q\right]\left\{F_R^{eq}\right\}=g\left\{\sigma_q\right\}=g\left\{\sqrt{\int_{0}^{+\infty}S_{qq}(\omega)d\omega}\right\} \tag{11}$$

Where, $\left\{\hat{R}\right\}$ is the dynamic displacement vector; $\left\{F_R^{eq}\right\}$ is the ESWLs vector; $\left[I_q\right]$ is the influence line matrix. In the calculation, we hypothesize the ESWL on the constraint note whose displacement response is zero, is zero, and the constraint notes are not included in equation (11). Then the ESWLs of the structure can be represented as

$$\left\{F_{R_i}^{eq}\right\}=g\left[I_q\right]^{-1}\left\{\sqrt{\int_{0}^{+\infty}S_{q_iq_i}(\omega)d\omega}\right\} \tag{12}$$

Where, g is the peak factor, and can take g = 3.5 in most cases. $\left[I_q\right]^{-1}$ is the flexibility matrix.

Equation (12) shows that the ESWLs have clear physical significance. If the mean wind loading is not considered, the ESWLs gotten from equation (12) are the only accurate ESWLs based on the displacement responses.

2. ACCURATE ESWLs OF LONG-SPAN BRIDGES BASED ON THE DISPLACEMENT RESPONSES

For long-span bridges, with the increase of the span, the structure stiffness becomes less and less smaller, and buffeting responses induced by wind load can not be ignored. Based on the analysis in part 1, we take the bridge deck as an example to calculate the ESWLs based on the displacement responses. The approach also applies to the bridge tower.

There are mainly three component forces on the bridge deck: lift force, drag force, and twist moment (Figure 1). The buffeting responses are calculated through coupled flutter and buffeting method[9][10][11][12]. Self-exited forces are estimated by Scanlan's calculation model[13] which contains 18 flutter derivatives. Buffeting forces are estimated by Davenport's buffeting calculation model[13]. For convenience, aerodynamic admittances are not considered in the buffeting calculation.

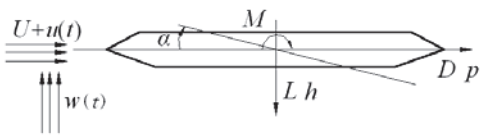

Figure 1. Freedoms and wind forces in the nodes of the bridge deck

The frequency response function can be represented as

$$\left[E_{ij}\right]=\left(-K^2\left[I\right]+iK\left(\left[\Lambda_c\right]-\frac{\rho(2B^4)K}{2}\left[A_{ij}\right]\right)+\left(\left[\Lambda_K\right]-\frac{(2B^4)K^2}{2}\left[B_{ij}\right]\right)\right) \tag{13}$$

Where, $K=\dfrac{\omega B}{U}$ is the reduced frequency; $\dfrac{\rho(2B^4)K}{2}\left[A_{ij}\right]$ and $\dfrac{(2B^4)K^2}{2}\left[B_{ij}\right]$ are aerodynamic damping and aerodynamic stiffness induced by self-exited forces. Detailed derivatives can be found in reference [11]. ω is the natural circular frequency; B is the width of the bridge deck; U is the mean wind speed; ρ is air density.

Matrix $\left[E\right]$ contains the influence of self-exited forces, so it is called aerodynamic frequency response function[14]. After getting the PSD of buffeting forces $\left[S_{b_ib_j}(\omega)\right]$, the PSD of the modal coordinate can be obtained by equation (8)

$$\left[S_{\xi_i\xi_j}\right]=\left(\frac{\rho B^4}{2U}\right)^2\left[E_{ij}\right]^{-1}\left[S_{b_ib_j}(\omega)\right]\left(\left[E_{ij}\right]^{-1}\right)^{*T} \tag{14}$$

So the PSD of the displacement responses in vertical, horizontal, and twist can be expressed as

$$\left(\left[S_{h_ih_j}\right]\quad\left[S_{p_ip_j}\right]\quad\left[S_{\alpha_i\alpha_j}\right]\right)=\left([Bh]\left[S_{\xi_i\xi_j}\right][Bh]^T\quad[Bp]\left[S_{\xi_i\xi_j}\right][Bp]^T\quad[\alpha]\left[S_{\xi_i\xi_j}\right][\alpha]^T\right) \tag{15}$$

For long-span bridges, the influence line functions in vertical, horizontal, and twist i.e. $\left[I_h\right]$, $\left[I_p\right]$, $\left[I_\alpha\right]$, are independent. The ESWLs in vertical, horizontal, and twist can be obtained through equation (12)

$$\left\{F_{L1}^{eq}\quad\cdots\quad F_{\text{LN-node}}^{eq}\right\}^T=g\left[I_h\right]^{-1}\left\{\sqrt{\int_0^{+\infty}S_{h_1h_1}(K)dK}\quad\cdots\quad\sqrt{\int_0^{+\infty}S_{h_{\text{N-node}}h_{\text{N-node}}}(K)dK}\right\}^T \tag{16-a}$$

$$\left\{F_{D1}^{eq}\quad\cdots\quad F_{\text{DN-node}}^{eq}\right\}^T=g\left[I_p\right]^{-1}\left\{\sqrt{\int_0^{+\infty}S_{p_1p_1}(K)dK}\quad\cdots\quad\sqrt{\int_0^{+\infty}S_{p_{\text{N-node}}p_{\text{N-node}}}(K)dK}\right\}^T \tag{16-b}$$

$$\left\{F_{M1}^{eq}\quad\cdots\quad F_{\text{MN-node}}^{eq}\right\}^T=g\left[I_\alpha\right]^{-1}\left\{\sqrt{\int_0^{+\infty}S_{\alpha_1\alpha_1}(K)dK}\quad\cdots\quad\sqrt{\int_0^{+\infty}S_{\alpha_{\text{N-node}}\alpha_{\text{N-node}}}(K)dK}\right\}^T \tag{16-c}$$

3. EXAMPLE OF ONE SIMPLE BRIDGE WITH IDEAL THIN PLATE SECTION

Due to the aerodynamic forces of the ideal thin plate having theory expression, we take a simple bridge with ideal thin plate section as an example to verify the validity and effectiveness of the method. The length of the simple bridge is L = 300m, and the width of the bridge deck is B = 40m. The stiffness of the bridge in vertical, horizontal, and twist are separately $EI_z = 2.1\times10^6$ MPa·m^4, $EI_y = 1.8\times10^7$ MPa·m^4, $GI_t = 4.1\times10^5$ MPa·m^4. The mass per unit length is m_{beam} = 20,000kg/m; the mass moment of inertia per unit length is $I_m = 4.5\times10^6$ kg·m^2/m; the air density is $\rho = 1.225$ kg/m^3; the modal damping ratios are assumed to 0.005.

The finite element model of the simple bridge is established by ANSYS software. The bridge deck is simulated by Beam 4 element, and the total bridge is divided into 30 finite elements. In the analysis, the elastic modulus is $E = 2.06\times10^{11}$ Pa, the shear modulus $G = 0.79\times10^{11}$ Pa. In the finite element model, there are relationships as follows:

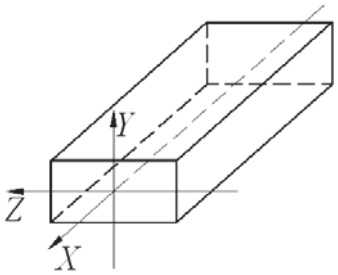

Figure 2. Directions of Beam 4 element

$$I_m = \int_A r^2 \cdot dm = \int_A r^2 \cdot d(A\rho) = \rho \int_A (y^2 + z^2) \cdot dA = \rho \left(\int_A y^2 \cdot dA + \int_A z^2 \cdot dA \right) = \rho (I_z + I_y) \quad (17)$$

From equation (17), we can get following equation

$$A_{beam} = m_{beam} / \rho = m_{beam} \Big/ \left(I_m \Big/ (I_z + I_y) \right) = m_{beam} (I_z + I_y) \Big/ I_m \quad (18)$$

Where, I_y , I_z are the inertia moment around Y and Z axis separately. A_{beam} is the section area of the bridge deck.

The boundary conditions of the simple bridge finite element model are as follows: For the left node, constrain UX, UY, UZ and RotX; For the right node, constrain UY, UZ and RotX. (X is the along bridge deck direction; Y is the vertical direction, and Z is the cross bridge deck direction.) The top 50 modes of the simple bridge are gotten using modal analysis. In the modal analysis, the mass matrix is consistent matrix, and the damping is not considered. The top 10 modes are shown in Table 1.

Table 1. Natural frequency and mode shape of simple bridge with ideal thin plate section

Mode No.	Frequence(Hz)	Mode shape	Mode No.	Frequence (Hz)	Mode shape
1	0.1786	1-S-V	6	1.5154	2-S-T
2	0.5033	1-S-T	7	1.5912	2-S-V
3	0.5179	1-S-L	8	1.7614	AD
4	0.7117	1-AS-V	9	2.0076	1-AS-L
5	1.0080	1-AS-T	10	2.0270	2-AS-T

V: vertical bending; T: torsion; L: lateral bending; S: symmetrical; AS: antisymmetrical; A: axial deformation

The self-exited forces of the bridge deck with ideal thin plate section can be expressed by Theodorson function: $C(k)=F(k)+ iG(k)$, and can also be represented using R. T. Jones's approximate expressions[15].

$$\begin{cases} F(k) = 1 - \dfrac{0.165}{1 + \left(\dfrac{0.0455}{k} \right)^2} - \dfrac{0.335}{1 + \left(\dfrac{0.03}{k} \right)^2} \\ G(k) = -\dfrac{0.165 \times 0.0455 / k}{1 + \left(\dfrac{0.0455}{k} \right)^2} - \dfrac{0.335 \times 0.03 / k}{1 + \left(\dfrac{0.03}{k} \right)^2} \end{cases} \quad (19)$$

Where, $k = \omega b/U = K/2$ is reduced frequency. Flutter derivatives of the ideal thin plate section bridge deck, i.e. H_i^*, A_i^* (i=1~4), can be obtained from equation (19).

$$\begin{cases} 4H_1^* = \dfrac{-2\pi F}{k}; & 8H_2^* = \dfrac{-\pi}{k}\left(1+F+\dfrac{2G}{k}\right) \\ 8H_3^* = \dfrac{-2\pi}{k^2}\left(F-\dfrac{kG}{2}\right); & 4H_4^* = 2\pi\left(\dfrac{1}{2}+\dfrac{G}{k}\right) \\ 8A_1^* = \dfrac{\pi F}{k}; & 16A_2^* = \dfrac{\pi}{k}\left(\dfrac{G}{k}+\dfrac{F-1}{2}\right) \\ 16A_3^* = \dfrac{\pi}{k^2}\left(F-\dfrac{kG}{2}+\dfrac{k^2}{8}\right); & 8A_4^* = \dfrac{-\pi G}{k} \end{cases} \tag{20}$$

The flutter derivatives obtained from equation (20) are shown in Figure 3.

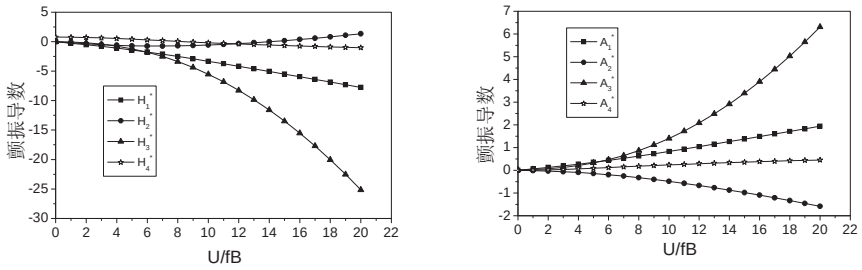

图 3　理想平板断面的颤振导数

Figure 3.　Flutter derivatives of the ideal thin plate section bridge deck

In order to calculate the buffeting responses, the aerodynamic parameters are taken the same values as reference [12]. The aerodynamic force coefficients in 0 wind attack angle are C_L = 0.128, C_D = 0.0697, C_M = –0.0074, $dC_L/d\alpha$ = –5.5577, $dC_D/d\alpha$ = 0.0 and $dC_M/d\alpha$ = 1.2662. The height of the bridge deck above the ground is z=60m. The roughness length is z_0=0.01m[16].

The Kaimal spectra[13] is chosen as the power spectra of the fluctuating wind in horizontal direction:

$$\frac{nS_{uu}(n)}{u_*^2} = \frac{200f}{(1+50f)^{5/3}} \tag{21}$$

Where, $f = \dfrac{nz}{U(z)}$ is the Monin (or similarity) coordinate; z is the height of the bridge deck above ground; $U(z)$ is the meaning wind speed at the height of z. $u_* = \dfrac{KU(z)}{\ln(\dfrac{z}{z_0})}$ is the friction velocity, a function of the surface roughness. $K \approx 0.4$ is the Karman constant. z_0 is the roughness length. n is the frequency of the fluctuating wind (Unit: Hz).

The Lumley – Panofsky spectra[13] is chosen as the power spectra of the fluctuating wind in vertical direction:

$$\frac{nS_{ww}(n)}{u_*^2} = \frac{3.36f}{1+10f^{5/3}} \tag{21}$$

The cross spectra can be expressed as

$$S_{uw}(n) = C_{uw}(n) + iQ_{uw}(n) \tag{22}$$

Where, $C_{uw}(n)$ is the cospectrum, choosing an empirical formula which is suitable for engineering applications; $Q_{uw}(n)$ is the quadrature spectrum which has not quantitative assessment, and be ignored in the calculation.

$$\frac{nC_{uw}(n)}{u_*^2} = \frac{14f}{1+9.6f^{2.4}} \tag{23}$$

The correlation in spanwise of the fluctuating wind can be expressed in conventional form[13] as

$$S\left(x_i, x_j, n\right) = S\left(n\right) e^{\frac{\lambda n}{U}\left|x_i - x_j\right|} \tag{24}$$

Where, $7 \le \lambda \le 21$, in the calculation $\lambda = 7$ considering the safety factor; x_i, x_j are the coordinate in the spanwise; $\left|x_i - x_j\right|$ is the length between x_i and x_j.

The maximal displacement responses of the simple bridge had all occurred in the mid-span, and the RMS of the displacement responses including 50 modes are shown in figure 4.

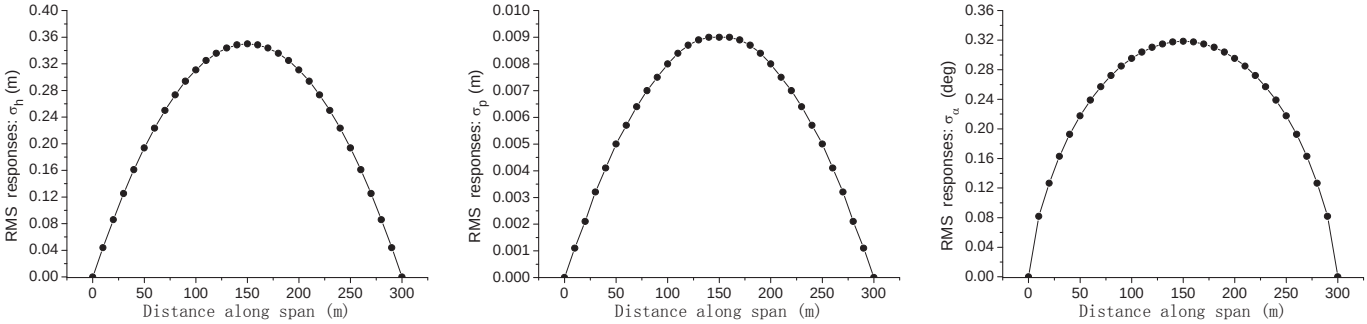

Figure 4. RMS of responses of the simple bridge with ideal thin plate section (50 modes)

According to equation (16), the accurate ESWLs of the simple bridge with ideal thin plate section in vertical, horizontal, and twist are shown in Figure 5 (exclude the mean wind load).

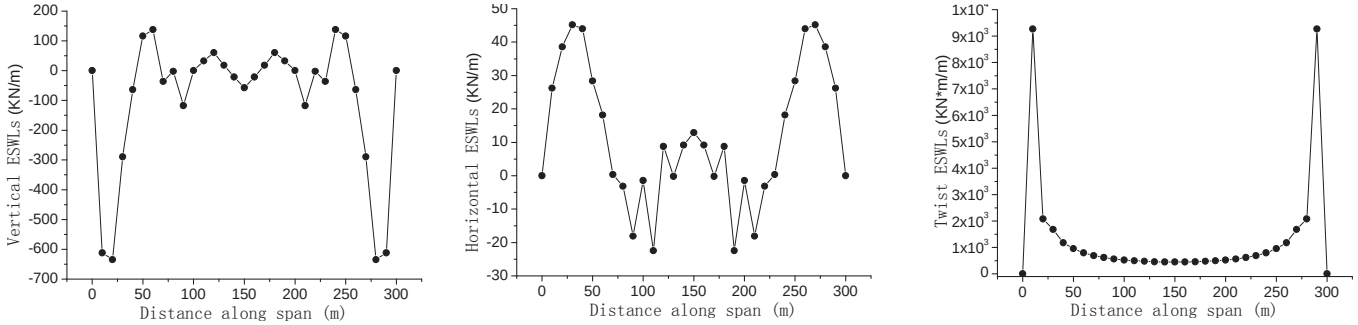

Figure 5. ESWLs of simple bridge with ideal thin plate section

In order to verify the validity of the method, we take the mid-span as an example to check the results. The influence lines of the mid-span are shown in figure 6. Put the ESWLs calculated by the method in this paper on the simple bridge, then the displacement responses can be obtained through static calculation. The results are shown in equation (24).

$$\hat{R}_h = 1.225m = 3.5\sigma_h;\ \ \hat{R}_p = 0.0316m = 3.5\sigma_p;\ \ \hat{R}_\alpha = 1.115m = 3.5\sigma_\alpha; \tag{24}$$

Equation (24) shows that the method proposed in this paper according to get equivalent static wind load on the structure, the structure of the displacement response and according to the theories of random vibration dynamic response of the structure of the get extreme value are exactly the same, so as to prove the correctness and effectiveness of this method.

The results show that the displacement responses calculated by ESWLs by method in this paper are the same as that calculated by the coupled flutter and buffeting analysis method. So the ESWL method in this paper is validity and effectiveness.

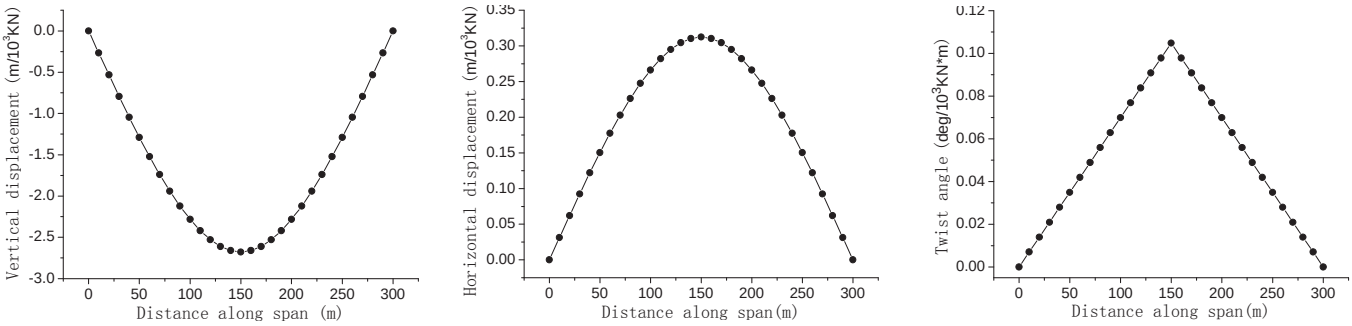

Table 6. Midspan influence line of the simple bridge with ideal thin plate section

4. CONCLUSION

According to the characteristics of the long-span bridge, one accurate ESWL method based on the displacement responses is proposed in this paper. This paper firstly calculates the mode and influence matrix using finite element method, then getting the PSD matrix of the buffeting forces by coupled flutter and buffeting vibration method. According to random vibration and structure dynamics, the ESWLs of long-span bridges in vertical, horizontal and torsional can be expressed by the mode matrix, influence matrix, aerodynamic mechanical admittance matrix, and PSD matrix of the buffeting forces. According to the load-response relationship, the ESWLs calculated through the method above are the only accurate solution which based on the displacements of the long-span bridge.

ABSTRACT: In order to verify the current time-domain buffeting theory, the buffeting-induced structural displacements were measured in a full model test of the Hangzhou Bay Bridge. A time-domain buffeting analysis of aerodynamic forces on bridge deck, towers and main cables was performed to get the buffeting responses, where the aerodynamic admittance function was set as 1 and Sears, respectively, and the equivalent wind spectrum was used to calculate the buffeting loads while considering aerodynamic admittance function. Wind tunnel tests were carried out to study the spatial correlation, and the influences of Sears admittance function and spatial correlation on the buffeting responses were also investigated. The numerical results were compared with those of wind tunnel test. It shows that when the decay factor λ is 12.9, wind tunnel test results fall between buffeting responses with aerodynamic admittance being set to 1 and Sears, the results calculated with Sears function being on the unsafe side. Spatial correlation greatly influences buffeting responses, the buffeting responses can be reduced by about 13%~22% using the coefficient of spatial correlation obtained in wind tunnel test instead of that proposed in 《Wind-resistent Design Specification for Highway Bridges》. Analysis of the Hangzhou Bay Bridge shows that the current timedomain buffeting theory cannot predict bridge buffeting-induced responses accurately, certain discrepancy exists between the calculation and the tunnel test results.

Keywords: cable-stayed bridge; time-domain; buffeting analysis; aerodynamic admittance; Sears function; spatial correlation

1. Introduction

Due to diversity of factors involved in long-span bridges buffeting and comparatively complex theoretical analysis, so far there have been many proposed methods to predict buffeting response of long-span bridges (Aas-Jakobsena and Strommen,2001; Scanlan and Gade,1977; Scanlan,1977; Jain et al,1996; Ding,2001). Analysis in frequency domain is a conventional approach to predict the buffeting response. However, for a super long-span bridge, where highly nonlinear and coupled responses due to significant wind-structure interaction are encountered, the time-domain approach is more competitive. Long-span bridge nonlinear time-domain buffeting analysis consists of three key components: numerical simulation of wind field, expression of aerodynamic forces and calculation of buffeting responses. The overall stochastic wind field of long

span bridge was simulated by the improved WAWS in this paper while only the deck wind field was usually simulated in the former time-domain analysis. In the full model test of the Hangzhou Bay Bridge, the buffeting response of the full model was obtained under the action of the turbulent flow generated in the wind tunnel. Therefore, the analytical results will agree better with the experimental results if the wind-tunnel turbulence is used as the input. For that idea, records of wind tunnel turbulence of the full model test are analyzed to extract its statistical characteristics, which will in turn serve as the target input to the numerical simulation. Spatial correlation is an important factor that influences buffeting responses, however, data from field measurement of spatial correlation of natural wind are generally not available. Decay factor ranges from 7 to 20 and decay factor is set as 7 when there are not data from field measurement of spatial correlation, which is specified in《Wind-resistent Design Specification for Highway Bridges》. A study on spatial correlation of wind tunnel was carried out in the wind tunnel test. In order to evaluate the effect of the wind spatial correlation on buffeting responses, buffeting response analysis were conducted and decay factor was set as test result, 7 and 20 respectively in the course of wind field simulation. Buffeting analysis has been based on the quasi-steady theory considering Sears admittance function since Sears (Sears,1941) put forward the notion of aerodynamic admittance , however, the values calculated based on which are not always agreement with test results. How much the difference will be? Whether the influence of Sears admittance function to each component of buffeting responses (such as RMS of vertical, lateral, torsional displacements) will be similar? All of these will be investigated in this paper.

1. Turbulence characteristics

1.1. Characteristics of turbulence generated in the wind tunnel

Measured horizontal and upward wind spectrum in wind tunnel can be expressed by Eq.(1), the measured and fitted auto spectrum of *u* and *w* are shown in Fig.1 and Fig.2.

$$nS_a / u_*^2 = af / \left(1 + bf\right)^{cm} \tag{1}$$

where, the subscript *a* of *S* can be *u, v* or w, indicating the alongwind, horizontal and upward components of velocity fluctuations of wind turbulence, respectively; c=5/3 for the auto spectra; and a, b, *m* are the parameters fitted with non-linear least square method based on the measured spectral data.

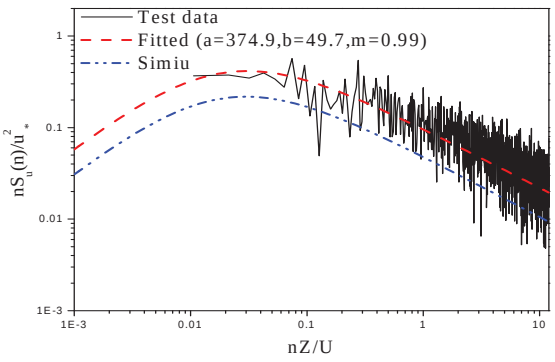

Fig.1. Auto spectra of component u

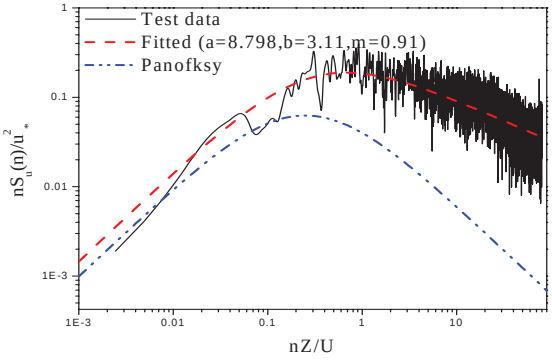

Fig.2. Auto spectra of component w

Co-coherence of wind is often expressed by an exponential function:

$$coh = \frac{S_{uu}^{C}(x_1, x_2, f)}{\sqrt{S_{uu}(x_1, f) S_{uu}(x_2, f)}} = \exp\left(-\lambda \frac{fD}{U}\right) \tag{2}$$

where, $S_{uu}(x_1, f)$ is the power spectrum of along wind-speed fluctuation u at x_1, $S_{uu}^{C}(x_1, x_2, f)$ is the real part of cross-spectrum of u between x_1 and x_2, λ the decay factor, f the frequency, $D = |x_1 - x_2|$ the transverse distance and U the mean wind speed.

A study on spatial correlation in wind tunnel was carried out in the full model test of the Hangzhou Bay Bridge . Spatial correlation is the function of f and D, In the measurement, D is set as 1.12、2.24、3.39 and 4.54m respectively, the least square method was used to achieve λ according Eq.(2), the decay factor λ ranges from 10.8 to 15.7 and the average of all data is 12.91.

2.3. Results of wind turbulence simulation and checks

The improved WAWS was chosen to simulate characteristics of wind field at Hangzhou Bay Bridge (Fig.3). The measured turbulence wind spectra and spatial correlation were used in the simulation. Main parameters in the simulation: K=0.4, z_0=0.03, U(55.41) = 40m/s; upper cutoff frequency ω_{up}=4π(rad/s).

Figs.4-6 show comparisons of target and simulated auto spectra, coherence function and correlation variance respectively by the improved WAWS. The spectra, coherence function and correlation variance of the simulated turbulence agree well with the input target on the whole.

2. Wind Tunnel Test and Analysis

Hangzhou Bay Bridge is a cable-stayed bridge with a span arrangement of 70+160+448+160+70 m, a twin girder steel deck, two inverted Y reinforced concrete pylons.

The full bridge aeroelastic model test was carried out in the TJ-3 Boundary Layer Wind Tunnel of the State Key Laboratory for Disaster Reduction in Civil Engineering at Tongji University. The model, shown in Fig.7, was manufactured at a geometric scale of 1:100. The total length and height of the model are 9.08m and 1.83m, respectively.

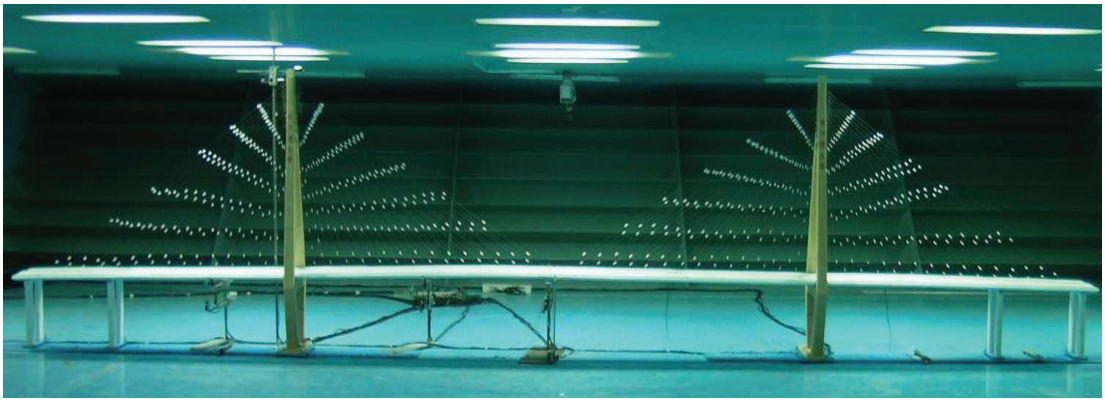

Fig.7. Full bridge aeroelastic model in TJ-3 Wind Tunnel

3. Buffeting-induced displacements test and analysis

3.1. Interaction between deck, towers and cables

In previous time-domain buffeting analyses, only deck wind field was simulated, this primarily owing to buffeting analytical method limitation. In this section, besides the buffeting forces and aeroelastic forces on the bridge deck, the buffeting forces on the towers and the cables are also included in the computation. The results are denoted by the term “full bridge”. The full-bridge results are then compared with those forces on the bridge deck only, both on the bridge deck and tower, and both on the bridge deck

and cable respectively. In this way, the interaction between the bridge deck, towers, and main cables can be examined.

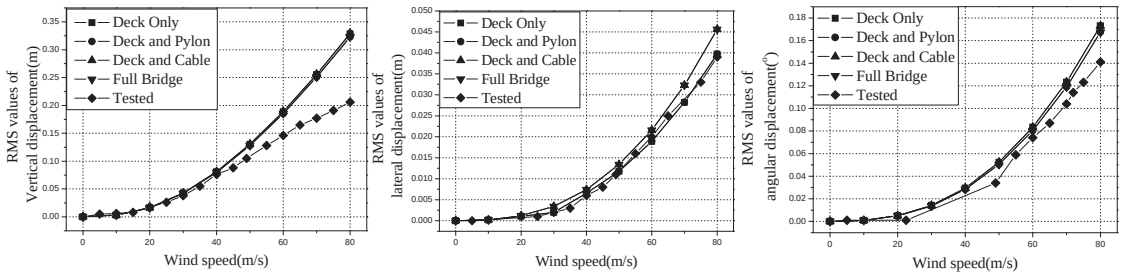

Fig.8. Comparisons of displacement responses RMS values at mid-span

Fig.8 shows the variable curves of mid-span's vertical, lateral and angular displacement RMS values for the full bridge, for the deck only, for both of the deck and tower, for both of the deck and cable and the test values. Table 1 presents comparisons of mid-span's lateral displacement RMS values for the full bridge, for the deck only the test values. As shown in the Fig.8 and Table 1, conclusions can be drawn as follows: 1), The buffeting forces on the cables and towers have a mild effect on the vertical and torsional displacement responses of the bridge deck at mid-span. 2), The buffeting forces on the towers contribute little to the lateral buffeting-induced responses of bridge deck. 3), Due to the consideration of buffeting forces on the main cables, the lateral displacement response of the bridge deck increases greatly. Take designed wind speed of 50m/s as an example, the full bridge lateral displacement response RMS value is 0.0134m, 13.8% larger than the value of 0.0118m if only taking deck wind field into consideration. Moreover, the differences become larger when wind speed increases. Therefore, the cable wind field must be taken into consideration, especially in the buffeting analysis of super long-span cable-stayed bridges whose cables are very long. 4) The displacement RMS values of deck at midspan are a little larger than wind tunnel test results and agree well with each other on the whole, especially for lateral and torsional displacement RMS values. For vertical displacement RMS values of mid-span, calculated values and test values have a good accordance at low wind speeds. The calculated vertical displacement RMS value at mid-span is 1.17 times larger than test values at design wind speed of 50m/s, whereas the difference become larger when wind speed increases.

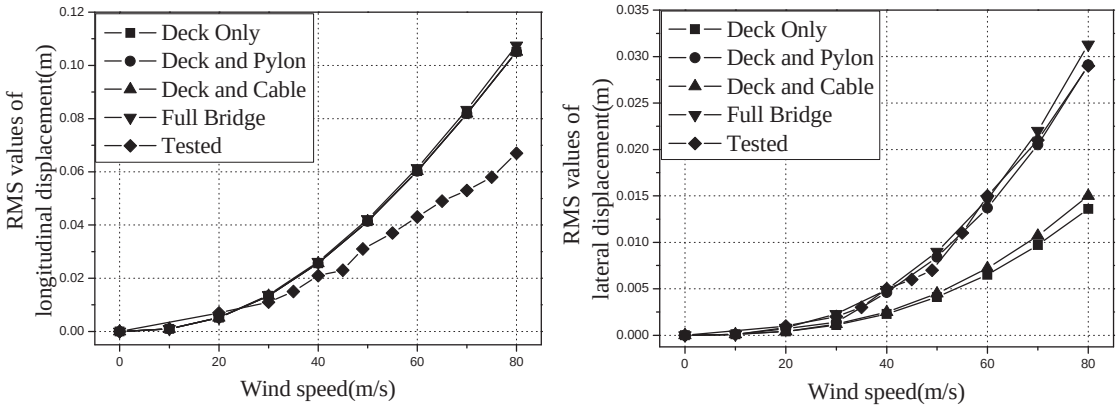

Fig.9. Comparison of displacement response RMS values at the top of pylon

Some conclusions can be found from Fig.9: 1), The buffeting forces on the cables have a little influence on lateral displacement at the top of pylon. At designed wind speed of 50m/s, the lateral displacement response RMS value with buffeting forces on the deck and cables is 0.0045m, 9.7% larger than the value of 0.0041m if only taking deck wind field into consideration. 2), The buffeting forces on the towers have a considerable influence on the lateral displacement RMS values. At designed wind speed of 50m/s, the full bridge lateral displacement response RMS value is 0.0084m, 104.8% larger than the value of 0.0041m if only taking deck wind field into consideration. 3) The full-bridge lateral displacement response RMS values at the top of pylon agree with the test values well while those forces on the bridge deck only are much smaller than the tested values. Therefore, ignorance of buffeting forces on pylon and cable will achieve insecure results.

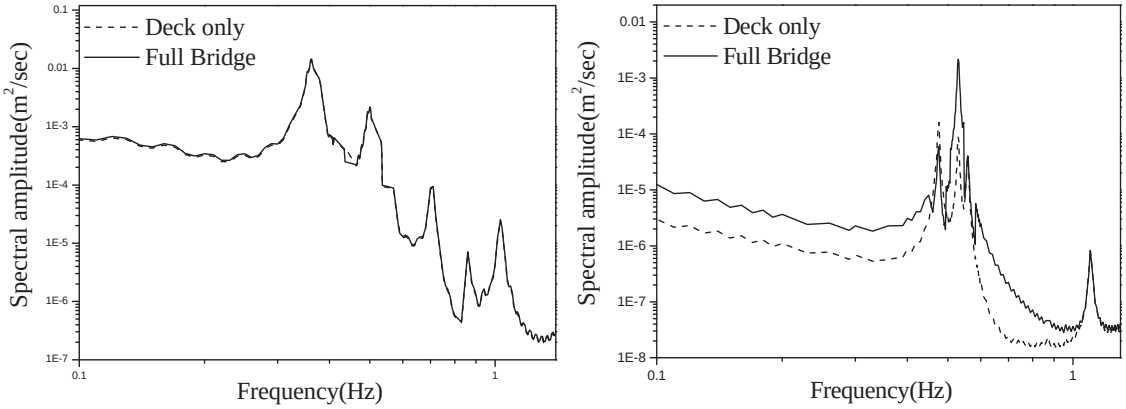

Fig.10. Comparison of power spectrum density of displacement response at the top of pylon

Table 1
Main modes of Hangzhou Bay Bridge

Mode	Frequency (Hz)	Mode type	Mode	Frequency (Hz)	Mode type
1	0.11186	LF	8	0.87337	A-L-1
2	0.36851	S-V-1	9	0.87611	A-V-2
3	0.47598	S-L-1	15	0.95133	S-T-1
4	0.50541	A-V-1	17	1.02839	S-V-3
5	0.53307	A-L(Tower)	23	1.16229	A-V-3
6	0.56004	S-L-2	24	1.41749	A-T-1
7	0.72903	S-V-2	25	1.45489	S-V-4

Note:S=Symmetrical; A=Antisymmetrical; LF=Longitudinal Floating; V=Vertical; T=Torsion; L=Lateral.

The spectra of the lateral and longitudinal displacement responses at the top of pylon are shown in Fig.10. The longitudinal displacement response spectra for the full bridge are almost agreement with the deck only. Five peak values occur in each power spectrum density curve VS the frequency of mode 2, 4, 7, 9, and 17. Moreover, the mode

types of these five peak values are all vertical symmetric bending or vertical dissymmetric bending of deck (Table 3). Therefore, can conclude that the longitudinal vibration of pylon mainly depend on the vertical vibration of deck. The lateral displacement response spectra for the deck only are obviously smaller than those for the full bridge. The former three peak values occur in each power spectrum density curve VS the frequency of mode 3, 5 and 6. The type of mode 5 is a dissymmetric lateral bending of pylon, but the type of mode 3 and 6 are both symmetric lateral bending of deck. Compared with the case only considering deck wind field, the contribution of mode 5 becomes more significant, and the contributions of mode 3 and 6 become weaker when taking full bridge into account.

3.2. Influence of aerodynamic admittance

Since Sears established the conception of aerodynamic admittance in 1940s, buffeting analysis is always carried out based on quasi-steady theory considering Sears admittance function. The difference in the actual value and the predicted value adopting Sears admittance function can't be ignored in practical projects. But how much the difference will be and how Sears function influence the displacement response (such as vertical, lateral and torsional displacement response RMS values) are still unknown to us. Therefore some researches are needed to resolve the above problems and are presented in this paper also.

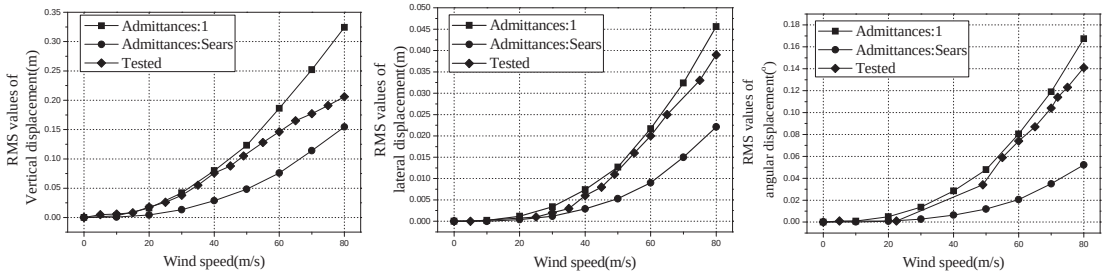

Fig.11. Comparison of displacement response RMS values at mid-span

Fig.11 show the buffeting responses at mid-span with and without consideration of Sears aerodynamic admittance. Some conclusions can be obtained thereinafter: 1), The RMS values considering Sears function are smaller than those without considering admittance function and the ones in wind tunnel. 2), The influence of Sears admittance function to each component of buffeting-induced displacement responses is different. Compared with vertical and lateral displacement responses, the ratios of torsional RMS values considering Sears admittance function to those without considering admittance function and the ones in wind tunnel are much smaller.

5. Conclusions

1) The buffeting forces on the cables and towers have a little effect on the vertical and torsional displacement responses of the bridge deck and the longitudinal responses of tower. The buffeting forces on the cables contribute mainly to the lateral responses of bridge deck while the buffeting forces on the towers can increase the lateral responses

of pylon significantly. Therefore, ignorance of buffeting forces on pylon and cable will achieve insecure results.

2) The calculated buffeting RMS values are slightly larger than wind tunnel test results and agree with the wind tunnel test results on the whole when admittance function is 1 and λ is 12.9. It is suggested that buffeting RMS values when admittance function is 1 and the value of λ is from field measurement can be served as controlling values in wind-resistance design when appropriate admittance function is not available.

ABSTRACT: The concept of aerodynamic admittance functions was introduced into buffeting analysis of long-span bridges to consider the unsteadiness and spatial variation of wind turbulence and plays an important role in improving the accuracy of buffeting response. Because of the signature turbulence effect and aerodynamic interference effect, the aerodynamic admittance of bridge with two separated paralleled decks may no longer behave as Sears function. Taking Tanggu Haihe Bridge in Tianjin as an engineering back ground, the aerodynamic admittances of a semi-closed box deck a full-closed box deck were measured and analyzed in this article. Moreover, the aerodynamic interference effect on the equivalent aerodynamic admittance with different types of bridge decks at the windward or leeward position and with different distances between two decks were also investigated via wind tunnel test by the method of force measurement. The results show that the equivalent aerodynamic admittances of windward and leeward deck are quite different from that of single deck in their characteristics due to the aerodynamic interference effect. The aerodynamic interference effect on the $|\chi_D|^2$ curve is more significant than those on the $|\chi_L|^2$ and $|\chi_M|^2$ curves, and that on the leeward deck is much stronger than that on the windward deck. Furthermore, with variation of the ratios of D/B (the ratios of distance between two decks over the deck width), the aerodynamic interference may exert different effects on the equivalent aerodynamic admittances. For both of the $|\chi_D|^2$of the windward and leeward decks, the admittance curves approach to that of the single deck gradually with the increasing reduced frequency. And for the $|\chi_L|^2$ and $|\chi_M|^2$, there is no significant difference between the admittance curves of the windward deck and the single deck, whilst that of leeward deck are remarkable different from that of single deck, especially for the $|\chi_L|^2$ curves.

KEYWORDS: long-span bridge; wind tunnel test; aerodynamic admittance; signature turbulence effect; aerodynamic interference effect

1 INTRODUCTION

Buffeting is one of important types of wind-induced vibration of long-span bridges due to their flexibility and lower fundamental natural frequencies, and has been paid great attentions to in both wind engineering and bridge engineering fields. Up to now, apart from wind tunnel test means, various analysis methods have been developed for predicting buffeting responses of long-span bridges. The Davenport buffeting theory and linear self-excited aeroelastic force model introduced by Scanlan and his co-workers were generally accepted in the above analysis methods. In Davenport buffeting response prediction, Quasi-steady theory was employed to establish the buffeting forces on the bridge and aerodynamic admittance functions were introduced to consider the unsteadiness and spatial variation of wind turbulence surrounding bridge deck cross sections. The aerodynamic admittance can either be approximated as in Liepmanm(1952),Davenport(1962), Irwin(1977), or measured as in Holmes(1975), Kawatani & Kim (1992), Sankaran & Jancauskas(1992), Larose(1992) and Bogunovic Sears' function is most commonly used form of the lift aerodynamic admittance

of a thin airfoil in fully correlated gusts with sinusoidal fluctuations(Liepmanm 1952):

$$\left|\chi_L\left(f^*\right)\right|^2 = \frac{1}{1+2\pi^2 f^*} \tag{1}$$

where $|\chi_L|^2$ is the square of modules of equivalent aerodynamic admittances of lift; f^* is a reduced frequency $= fB/U$, U is the mean wind speed, and B is the whole width of the deck in this paper.

However, the buffeting forces in most of the current buffeting analysis are determined based on the quasi-steady theory, where, only the turbulence of incident wind is included. The signature turbulence caused by the interaction between structure and flow around it is normally ignored. Up to the present, the extent of signature turbulence effect on the bridge buffeting responses has not been understood yet and has rarely been investigated, although this issue was already regarded as one of major challenges in the prediction of long-span bridge response to wind (Jones 1999).

With the development of traffic flow, bridge with two separated paralleled decks has been built to accommodate the traffic requirement in long-span bridge engineering field, and it has been observed that aerodynamic interference phenomena exist between the two neighboring decks. And the interference behavior largely depends on the distance between the two decks (Honda et al., 1993; Larsen et al., 2000; Stoyanoff et al., 2003; Kimura et al., 2008). If the two bridge decks are close enough to each other, the surrounding flows around one bridge deck will be influenced by another, and vice versa. Consequently, the performance of cross-sectional aerodynamic admittance of each deck will be inevitably and significantly affected by another deck. However, Most of the conducted researches referred to above focused extensively on revealing the complicated behavior of the aerodynamic interference phenomenon, little research has been conducted to aerodynamic interference effect on the aerodynamic admittances, which may make significant effect on the buffeting response.

In this connection, the equivalent aerodynamic admittances are investigated in this study via force measurement wind tunnel tests of sectional model in turbulence flow. Because the signature turbulence is regarded to be much more significant for bridge decks with separate boxes than other types of decks, the existing and new Tanggu Haihe Bridge in Tianjin(see Figure 1), which are both cable-stayed single tower bridge with a main span of 310, are thus taken as a engineering back ground in this study. Furthermore, the aerodynamic interference effect on the equivalent aerodynamic admittances of bridge with two separated paralleled decks are also surveyed in these wind tunnel tests, which adopted seven D/Bs(the ratio of distance between two decks and deck width) conditions and six cases with the combinations of different type decks. The details of the research are to be introduced in the following sections.

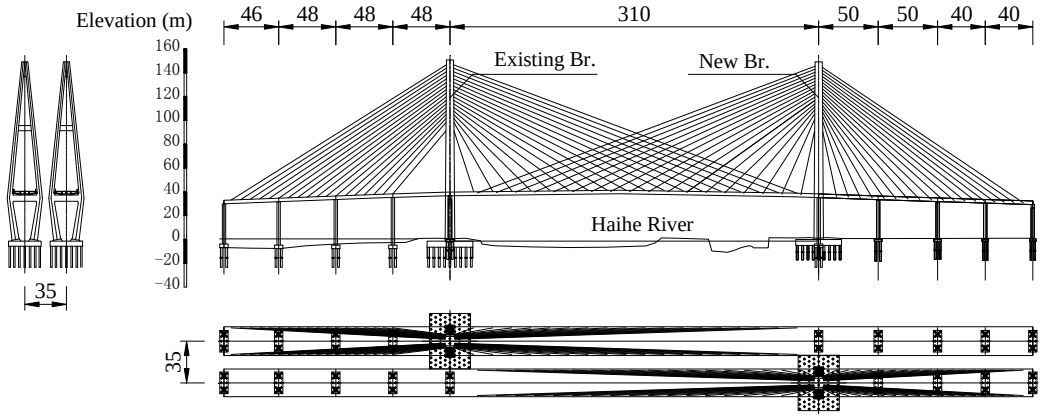

Figure 1 Layout of the existing and new Tanggu Haihe Bridge in Tianjin (Unit: m)

2 DESCRIPTION OF SECTIONAL MODEL TEST

The motionless sectional model tests for the equivalent aerodynamic admittances of the bridge deck were carried out in the TJ-2 Boundary Layer Wind Tunnel at a length scale of 1/60 and with turbulent intensities of 15%. In these wind tunnel tests, two types of sectional models, designed based on the existing and new Tanggu Haihe Bridge decks, were with the shape of semi- and full-closed box deck respectively(see Figure 2). The case simulating real Tanggu Haihe Bridge, full-closed box deck at windward and semi-closed box deck at leeward, is called as case FSD for short in this paper, and called as case SFD vice versa. Another two cases, two semi-closed box deck(case SSD) and two full-closed box deck(case FFD), are also investigated in order to reveal the relationship between aerodynamic interference effect and distance between two decks. And D/Bs of 0, 0.25,0.5,0.75,1,1.5,2 were adopted in these tests. Moreover, in order to compared with the cases mentioned above, two cases were also measured in additionally, and the case with single full-closed box deck is named as case FD, and likewise the case with single semi-closed box deck is called case SD in this paper.

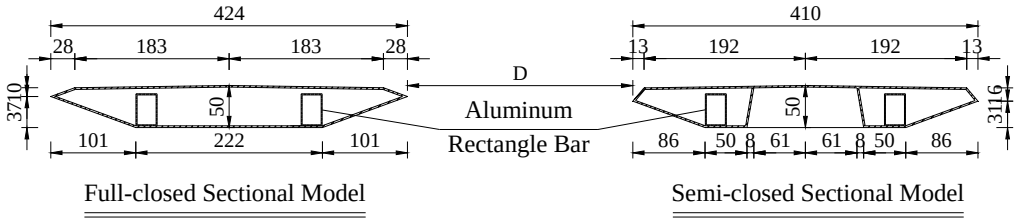

Figure 2 Measured segment of sectional model with semi- and full-closed box deck (Unit: mm)

Figure 3 Sectional model in TJ-2 Boundary Layer Wind Tunnel

Figure 3 shows the sectional model mounted in the TJ-2 wind tunnel. The sectional model was designed in such a way that the fluctuating forces could be synchronously measured in the test for the windward and leeward deck. Therefore, the sectional model was comprised of two measured segments and two upper compensatory segments. The windward segment and its upper compensatory segment were simulated the aerodynamic shape of windward bridge deck, and so does the leeward segment. The measured segment was made of wood and an aluminum link endplate, which was used to connect the measured segment to the balance. The measured segment of semi-closed box deck was 0.4m long (excluding the end plate), 0.05m high and 0.424m wide, and that of full-closed box deck also 0.4m long (excluding the end plate) and 0.05m high, but 0.41m wide. The total mass of the measured segments with

semi- and full-closed box are 1.01kg and 1.42kg, respectively. The aluminum end plate had a basic shape as same as the cross section shape of the measure segment, but its middle part was circular with a diameter as same as the force balance. Two upper compensatory segments were also 0.4m long and were made of same material, but empty inside for reducing weights.

Before the test, a steel frame for the installation of compensatory segments was mounted on the turntable at first. Two five-component force balances were then fixed separately on sectional steel bars with sliding grooves, and their surfaces was 0.3m upon the tunnel floor. Afterwards, to depress the disadvantageous effects of boundary layer above the tunnel floor and 3D flow around the lower end of the sectional model, a rectangular separating plate made of Perspex was then mounted upon the turntable with its bottom surface level a little bit lower than the top surface level of the force balance. In the middle region of the separating plate, there was an opening with a shape similar to the aluminum end plate of the measured segment, but a little bit larger than the latter. The separating plate must keep no touch to the top perceptional surface of the force balance. In the next step, two measured segment were vertically mounted on the force balances through the preset opening of the separating plate without any contact, and two upper compensatory segments were installed on the steel frame at their top ends and were kept a narrow gap of 1-2mm from the measured segment at their bottom ends. Finally two upper compensatory segments were connected to each other through the transverse link beam model to increase their stiffness. As a result, the fundamental natural frequencies of the measured segment with semi-closed box were 33Hz, 58Hz in the directions in and out of the deck plane(*F*x and *F*y), respectively, and 82Hz in torsional direction(*M*z). Consequently, the fundamental natural frequencies of the measured segment with full-closed box were 33Hz of *F*x, 50Hz of *F*y and 71Hz of *M*z. Both of the frequencies mentioned above were much higher than 15Hz calculated by the third vertical bending frequency of Tanggu Haihe Bridge and the frequency ratio of wind tunnel test.

3 RESULTS OF EQUIVALENT AERODYNAMIC ADMITTANCES

The spectra of buffeting drag (S_{DD}), lift (S_{LL}) and torsion moment (S_{MM}) on the bridge deck can be expressed with the following equations according to the quasi-steady theory (Chen et al. 2001):

$$\begin{aligned} S_{DD} &= (\rho UB/2)^2 \Big[4C_D^2 |\chi_{Du}|^2 S_{uu} + \left(-C_L + C_D^{'}\right)^2 |\chi_{Dw}|^2 S_{ww} \\ &\quad + 2C_D \left(-C_L + C_D^{'}\right)(\chi_{Du}^{*}\chi_{Dw} S_{uw} + \chi_{Du}\chi_{Dw}^{*} S_{uw}^{*}) \Big] \\ &= (\rho UB/2)^2 \Big[4C_D^2 S_{uu} + 4C_D \left(-C_L + C_D^{'}\right) C_{uw} + \left(-C_L + C_D^{'}\right)^2 S_{ww} \Big] |\chi_D|^2 \end{aligned} \tag{2}$$

$$\begin{aligned} S_{LL} &= \left(\frac{\rho UB}{2}\right)^2 \Big[4C_L^2 |\chi_{Lu}|^2 S_{uu} + \left(C_D + C_L^{'}\right)^2 |\chi_{Lw}|^2 S_{ww} \\ &\quad + 2C_L \left(C_D + C_L^{'}\right)(\chi_{Lu}^{*}\chi_{Lw} S_{uw} + \chi_{Lu}\chi_{Lw}^{*} S_{uw}^{*}) \Big] \\ &= (\rho UB/2)^2 \Big[4C_L^2 S_{uu} + 4C_L \left(C_D + C_L^{'}\right) C_{uw} + \left(C_D + C_L^{'}\right)^2 S_{ww} \Big] |\chi_L|^2 \end{aligned} \tag{3}$$

$$\begin{aligned} S_{MM} &= \left(\frac{\rho UB}{2}\right)^2 \Big[4C_M^2 |\chi_{Mu}|^2 S_{uu} + C_M^{'2} |\chi_{Mw}|^2 S_{ww} \\ &\quad + 2C_M C_M^{'} (\chi_{Mu}^{*}\chi_{Mw} S_{uw} + \chi_{Mu}\chi_{Mw}^{*} S_{uw}^{*}) \Big] \\ &= (\rho UB/2)^2 \Big[4C_M^2 S_{uu} + 4C_M C_M^{'} C_{uw} + C_M^{'2} S_{ww} \Big] |\chi_M|^2 \end{aligned} \tag{4}$$

where the superscript * indicates the conjugate operation; ρ is the density of air; C_D, C_L and

C_M are the aerodynamic coefficients of mean drag, lift and torsion moment, respectively; $C'_D = dC_D / d\alpha$, $C'_L = dC_L / d\alpha$; χ_{Du}, χ_{Dw}, χ_{Lu}, χ_{Lw}, χ_{Mu} and χ_{Mw} are the equivalent aerodynamic admittances, which are the function of $K=\omega B/U$, respectively; ω is circular frequency; S_{uu} and S_{ww} are auto spectra of fluctuating wind components u and w, respectively; S_{uw} and C_{uu}, are the cross spectrum and co-spectrum between u and w, respectively; $|\chi_D|^2$, $|\chi_L|^2$ and $|\chi_M|^2$ are the square of modules of equivalent aerodynamic admittances of drag, lift and torsion moment, respectively, considering the joint contribution of u and w.

Figure 4 shows the results of $|\chi_D|^2$, $|\chi_L|^2$ and $|\chi_M|^2$ of case FSD measured in the turbulence flow field with the mean attack angle of zero. The measured data are then fitted using the following target functions of fraction series of Eq.(5) for the incident turbulence contribution and of Eq.(6) for the signature turbulence contribution, respectively, and the corresponding fitted curves are also plotted in Figure 4.

$$|\chi_l|^2 = \frac{\alpha}{1+\beta K^r} \tag{5}$$

$$|\chi_s|^2 = \sum_{i=1}^{n} \frac{c_{1i} + c_{2i} K}{(K - c_{3i})^2 + c_{4i}} \tag{6}$$

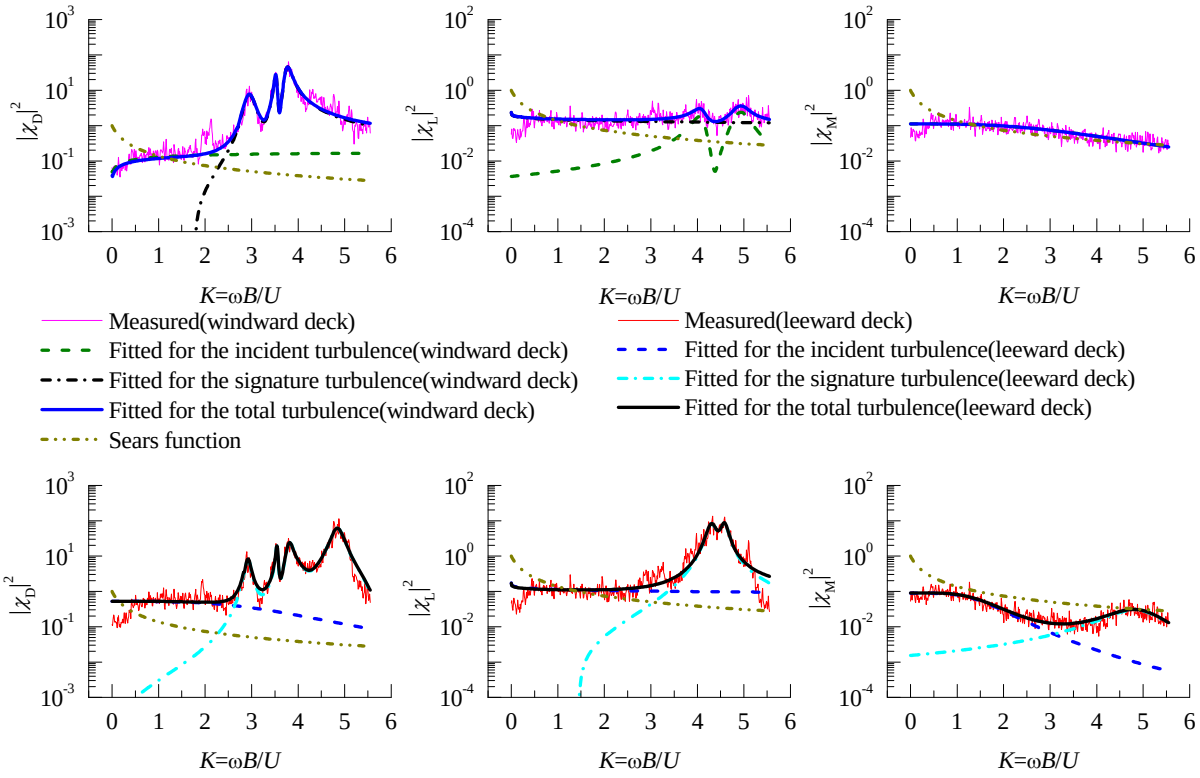

Figure 4 Measured and fitted equivalent aerodynamic admittances(EAA) of case FSD

From Figure 4, it can be seen that whatever windward deck or leeward deck, the tendencies of the measured equivalent aerodynamic admittances are not similar to that of Sears function. Due to the effect of signature turbulence, the $|\chi_D|^2$ and $|\chi_L|^2$ curves don't decrease with the increase of the reduced frequency, but generally, the $|\chi_M|^2$ curve still follows the reducing tendency as Sears function. In additional, the measured equivalent aerodynamic admittances are generally smaller than Sears function for K<1, and for K>1, the measured equivalent aerodynamic admittances of $|\chi_D|^2$ and $|\chi_L|^2$ are mostly somewhat much lager than Sears function whilst the $|\chi_M|^2$ of windward deck is close to Sears function and the $|\chi_M|^2$ of leeward deck is almost a bit little than Sears function. Furthermore, compared measured equivalent aerodynamic admittances of windward and leeward deck, the $|\chi_D|^2$ of windward and leeward deck have a similar characteristic that there are more than three significant peaks

at the range of K>3. Although the $|\chi_L|^2$ and $|\chi_M|^2$ of leeward deck are obviously influenced by the signature turbulence effect, that of windward almost does not affected by the signature turbulence.

Besides, it is found that for windward deck, the effect of signature turbulence makes the $|\chi_D|^2$ curve of having three significant peaks at about K=2.9, 3.5&3.8, and the $|\chi_L|^2$ curve of having two somewhat peaks appreciable peaks at 4&5, but doesn't influence the $|\chi_M|^2$ curve. For the leeward box, the effect of signature turbulence exerts remarkable influence on all the three equivalent aerodynamic admittances within the reduced frequency zone between 2.5 and 6, and makes the $|\chi_D|^2$ curve of having four peaks with a value much higher than 1.0 at about K= 2.9, 3.5,3.8 and 4.8, and influences the $|\chi_L|^2$ and $|\chi_M|^2$ curves of having a peak at about K=4.5 and 5, respectively. According to predecessors' research, the equivalent aerodynamic admittance of the signature turbulence is regarded to the aerodynamic shape of bridge deck and the inflow wind spectrum, Therefore, the equivalent aerodynamic admittances of incident and signature turbulence are fitted separated by different formula(Eq.(5) and Eq.(6), respectively) in Figure 4, and the result fitted for total turbulence is the sum of that of incident and signature turbulence.

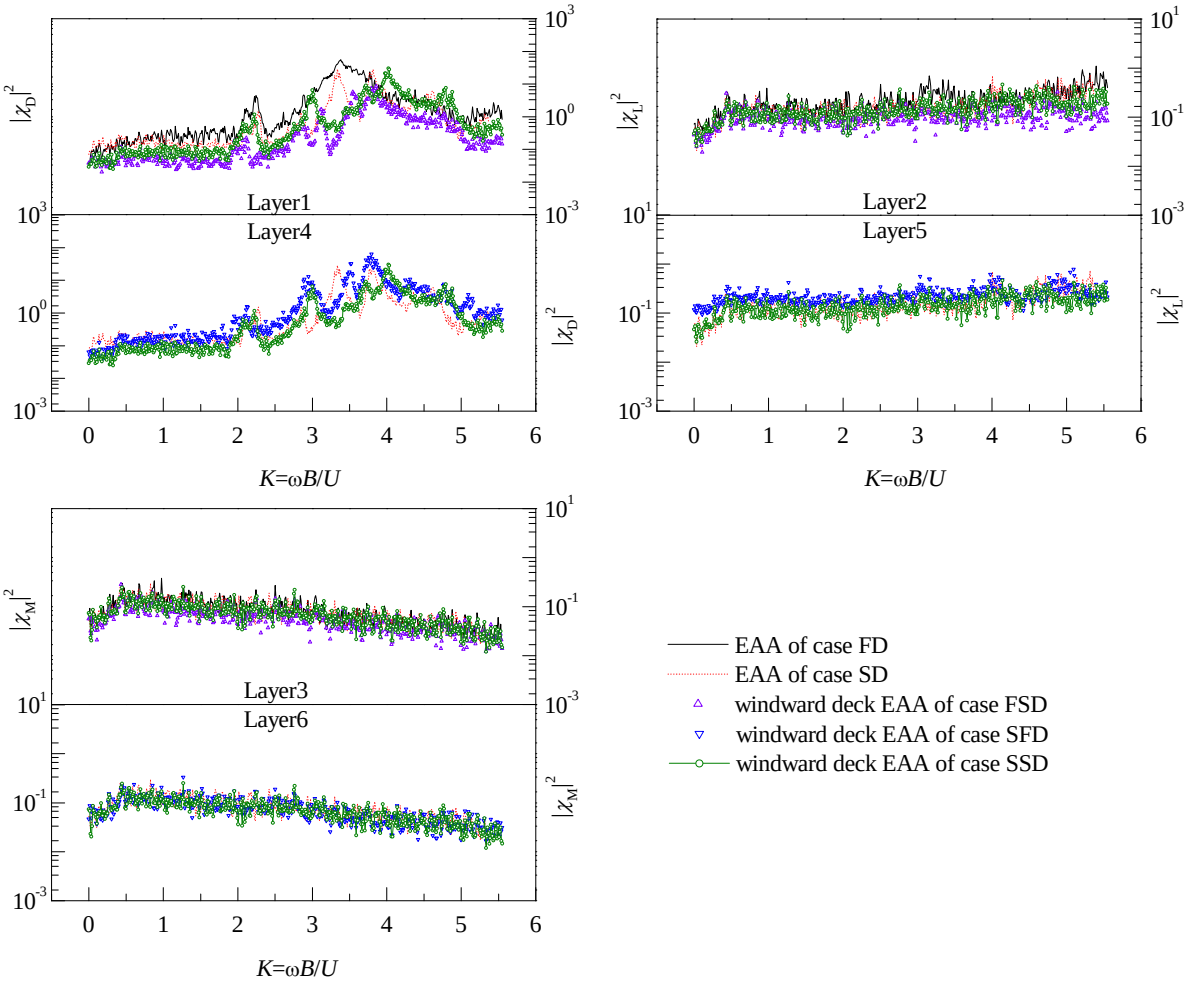

Figure 5 Comparison of equivalent aerodynamic admittances(EAA) of windward deck between different cases

4 EFFECT OF AERODYNAMIC INTERFRENCE

4.1 *Discussion of aerodynamic interference effect between different cases*

Figure 5 shows the comparison of the measured equivalent aerodynamic admittances of

windward deck between different cases. There are six layers of Figure 5 in which layer 1~3 present the measured $|\chi_D|^2$, $|\chi_L|^2$ and $|\chi_M|^2$ of windward deck in case FD, SD, FSD and SSD and layer 4~6 show that in case SD, SFD and SSD, respectively. From layer 1~3, compared between case FD and FSD or SD and SSD, it is found that the $|\chi_D|^2$ value of windward deck(case FSD or SSD) is remarkable smaller than that of single deck(case FD or SD), but $|\chi_L|^2$ and $|\chi_M|^2$ of windward deck are close to that of single deck. And there are three peaks of $|\chi_D|^2$ curve within case FSD whilst only two remarkable peaks within case FD, which can be explained that the signature turbulence contains more eminent reduced frequencies and wide range of affected frequency as a result of the aerodynamic interference effect. Furthermore, the $|\chi_D|^2$ curves of case FSD and SSD present similar peaks, thus it can be concluded that the equivalent aerodynamic admittance of different windward decks setting a same semi-closed box deck at leeward possess the alike signature turbulence effect. From layer 4~6, it is noticed that with different decks at leeward, the $|\chi_L|^2$ and $|\chi_M|^2$ curves of windward deck are approximate to each other, but for the $|\chi_D|^2$ curve, the semi-closed box deck at leeward exerts much more complicated signature turbulence effect than the full-closed box deck does. Therefore, we can concluded that leeward deck possessed significant signature turbulence effect will make more obvious aerodynamic interference effect on the windward deck.

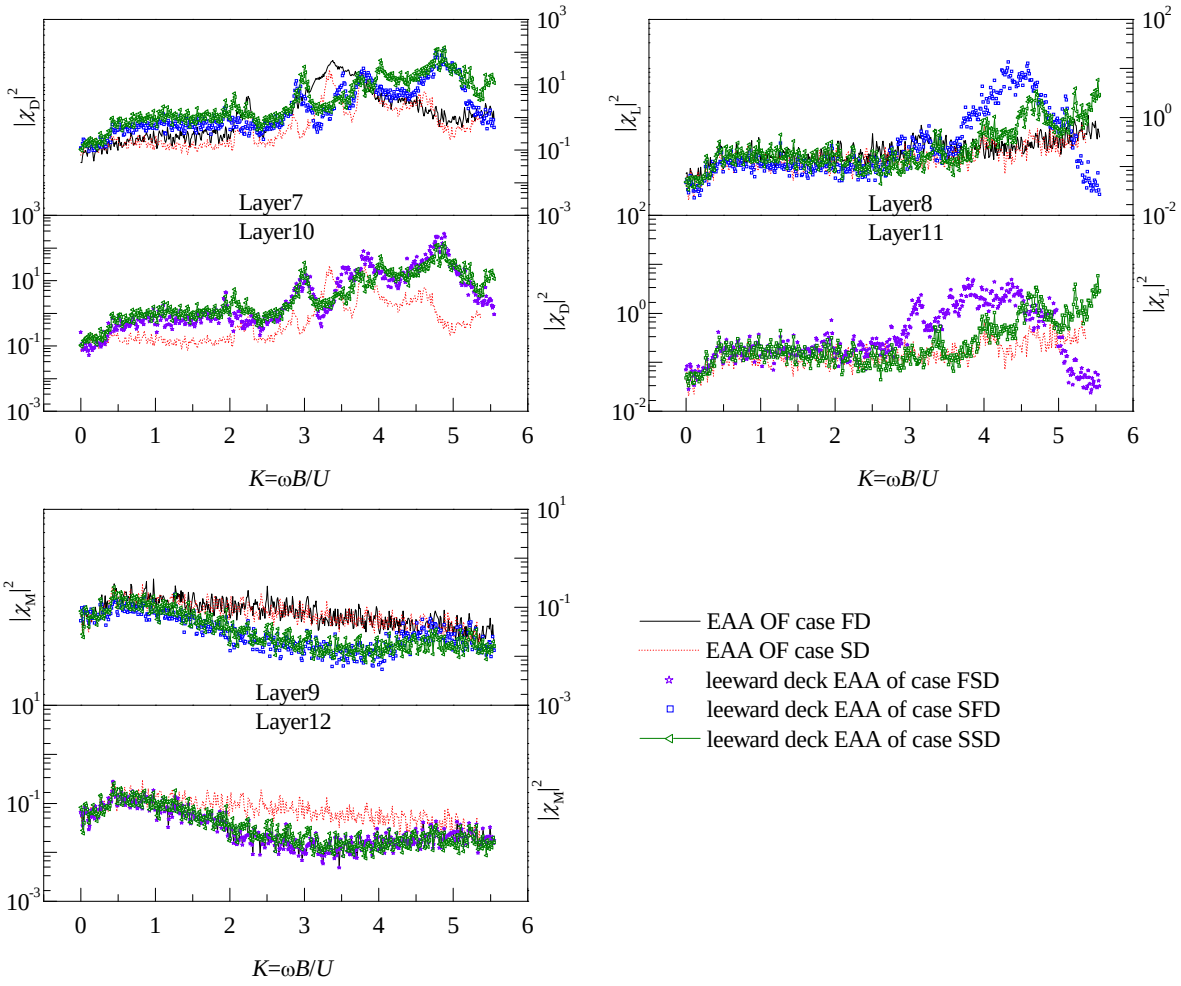

Figure 6 Comparison of equivalent aerodynamic admittances(EAA) of leeward deck between different cases

Figure 6 shows the comparison of the measured equivalent aerodynamic admittances of leeward deck with different cases. There are six layers of Figure 6 in which layer 7~9 present the measured $|\chi_D|^2$, $|\chi_L|^2$ and $|\chi_M|^2$ of leeward deck in case FD, SD, SFD and SSD and layer 10~12 show that in case SD, FSD and SSD, respectively. From layer 7~9, the equivalent aerodynamic admittances of leeward deck are remarkable different from that of single bridge

deck. For the $|\chi_L|^2$ and $|\chi_M|^2$ curves, there is no obvious peak in case FD/SD but a distinct peak at the approximation of K=5 in case SFD/SSD. For the $|\chi_D|^2$ curve, there is only one peak in case FD/SD but more than three peaks in case SFD/SSD. Consequently, the signature turbulence effect exerts a wider range of effect reduced frequency in case SFD/SSD than that in case FD/SD. Therefore, it can be further concluded that the equivalent aerodynamic admittance of bridge deck will greatly affected by the aerodynamic interference phenomenon caused by the windward deck. Moreover, compared with case SFD and SSD, because of a same bridge deck at windward, the aerodynamic interference effect on different leeward decks possess a similar behavior.

From layer 10~12, it is found that there is no obvious difference of the $|\chi_D|^2$ and $|\chi_M|^2$ curves of leeward deck between case FSD and SSD, but remarkable difference of the $|\chi_L|^2$ curve between case SD and FSD, SSD in high reduced frequency range. Because the semi- and full-closed box deck has a same width and height, the aerodynamic interference effects on the drag and torsional moment equivalent aerodynamic admittances are similar to each other. But for different bottom plates of decks, there is a remarkable difference of the lift equivalent aerodynamic admittance. The results above indicate that the same aerodynamic shape of bridge deck at windward will makes a similar aerodynamic interference effect on bridge deck at leeward, and vice versa.

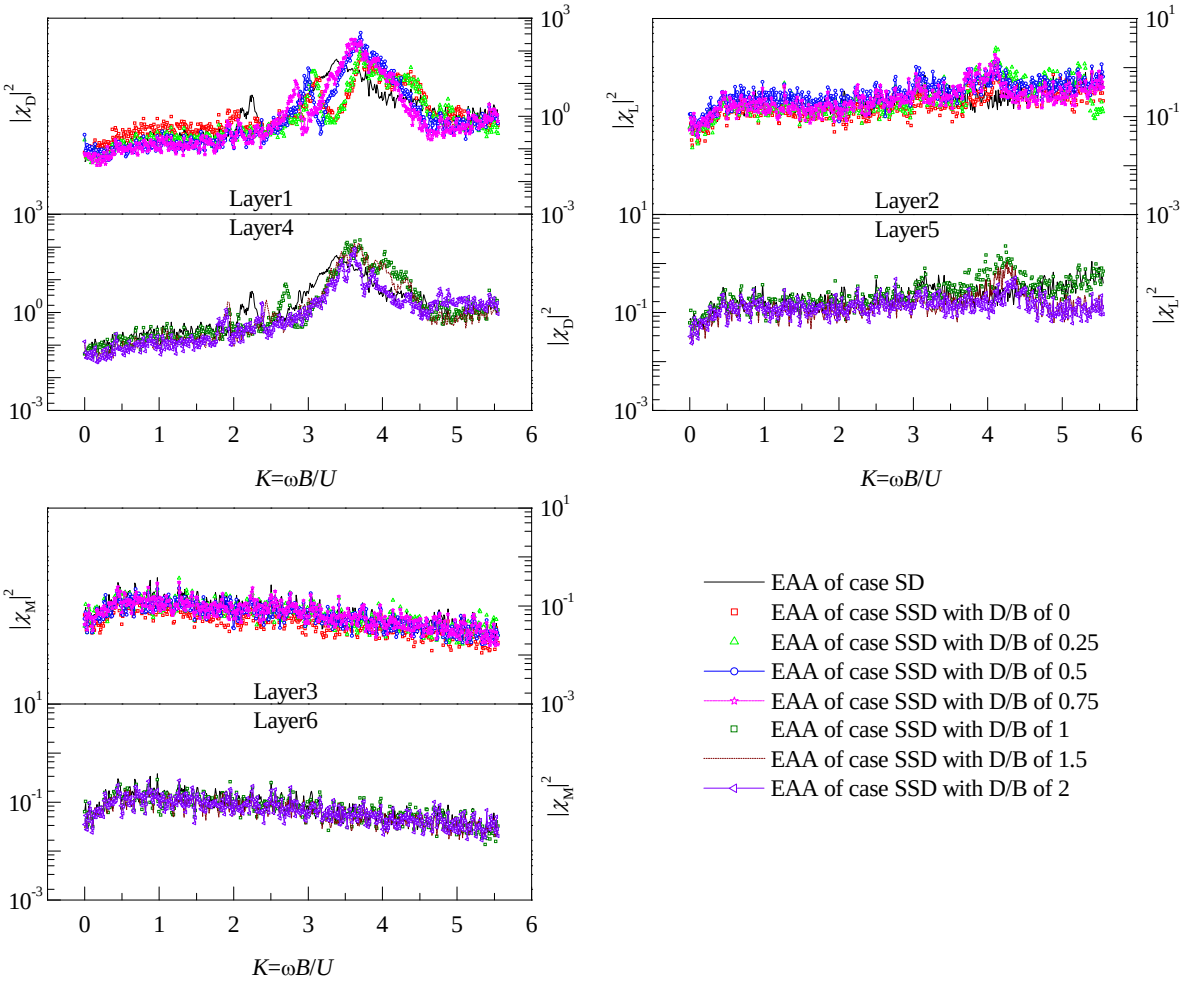

Figure 7 Comparison of equivalent aerodynamic admittances(EAA) of windward deck with different D/Bs

4.2 *Discussion of aerodynamic interference effect with different D/Bs*

Figure 7 shows the comparison of equivalent aerodynamic admittances of windward deck with different D/Bs of case SSD and that of case SD. In order to picture clearly, Figure 7 is

plotted out to six layers. Layer 1~3 present the measured results of windward deck in case SSD with D/B from 0 to 0.75 and the result of case SD, and layer 4~6 list that of leeward in case SSD with D/B from 1 to 2 and the result of case SD. From the $|\chi_D|^2$ curves in layer 1 and 4, it is interesting noticed that the drag equivalent aerodynamic admittance of windward deck with D/B of 0 is a little larger than that of other conditions. Compared with the results of case SD, the $|\chi_D|^2$ curves of case SSD are gradually approaching to that of case SD with the D/B increasing from 0 to 2. This variation indicates that the aerodynamic interference effect on the $|\chi_D|^2$ of the windward deck will become inconspicuous with the decreasing of the distance between windward and leeward deck. But in layer 2 and 5, we can found that the $|\chi_L|^2$ curves don't follow the change rule mentioned above. Meanwhile, compared with the $|\chi_L|^2$ of case SD affected by the signature turbulence inconspicuously, that of case SSD present somewhat signature turbulence effect with D/B>1. For the $|\chi_M|^2$ of case SSD in layer 3 and 6, there is no obvious difference in the comparison with case SD. Therefore, for windward deck, the drag equivalent aerodynamic admittance will get close to that of single deck gradually with the distance increasing, although it is a nonlinear change, but the lift and torsional moment equivalent aerodynamic admittances present no visible variety with the distance changing.

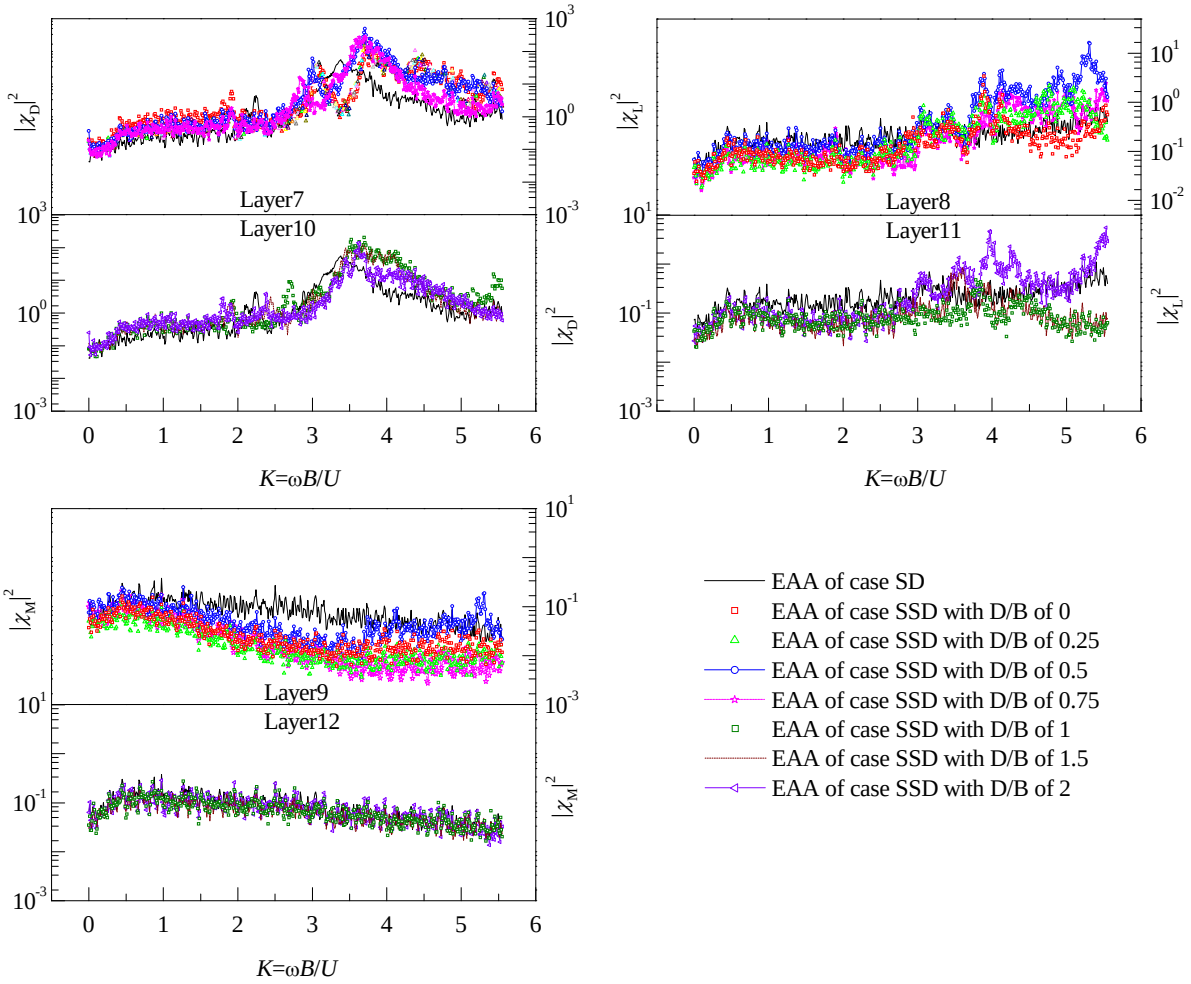

Figure 8 Comparison of equivalent aerodynamic admittances(EAA) of leeward deck with different D/Bs

Figure 8 shows the comparison of equivalent aerodynamic admittance of leeward deck with different D/Bs of case SSD and that of case SD, and is also plotted out to six layers. Layer 7~9 present the measured results of leeward deck in case SSD with D/B from 0 to 0.75 and the result of case SD, and layer 4~6 list that of leeward in case SSD with D/B from 10 to 12 and the result of case SD. From layer 7 and 10, the $|\chi_D|^2$ curves of case SSD also keep the change serially like that of windward deck with D/B increasing, but the signature turbulence

effect makes it much more nonlinear and complicated. In layer 2 and 5, due to intensely signature turbulence effect, the aerodynamic interference effect becomes disorderly and makes the $|\chi_L|^2$ curves greatly different from that of case SD. Consequently, although the distance equals zero in case SSD with D/B of 0, the signature turbulence still exerts the $|\chi_L|^2$ curves having more than two peaks at the range of K>3. In layer 9, the aerodynamic interference makes the $|\chi_M|^2$ curves of case SSD with D/B from 0 to 0.75 significant smaller than that of case SD. However in layer 12, the $|\chi_M|^2$ curves of case SSD with D/B>1 are almost equal to that of case SD which means that the aerodynamic interference effect can be ignored with the distance larger than a certain value. In general for leeward deck, with the change of distance between windward and leeward deck, the aerodynamic interference on the $|\chi_D|^2$ follows a certain variation like that of windward. presents disorderly and unsystematically on the $|\chi_L|^2$. Otherwise, the aerodynamic interference effect exerts the $|\chi_M|^2$ smaller than that of case SD with D/B<1, but can be ignored while D/B>1.

5 CONCLUDING REMARKS

The equivalent aerodynamics admittance of bridge with two separated paralleled decks are discussed in this paper. According to the discussion above, some conclusions can be drawn as follows:

The aerodynamic admittance curves don't always decrease with the reduced frequency increasing, which is different from the Sears function. Especially in high reduced frequency area, the signature turbulence effect exerts the aerodynamic admittance curves of windward deck of having some significant peaks, and makes that of leeward deck of having much more remarkable peaks. Otherwise, the measured equivalent aerodynamic admittances are generally smaller than Sears function for K<1, but much larger than Sears function at high reduced frequency due to the signature turbulence effect.

The aerodynamic interference phenomenon takes a great effect on windward and leeward deck and make their equivalent aerodynamic admittances tremendous different with that of single deck. The aerodynamic interference effect on the $|\chi_D|^2$ curve is serious than that on the $|\chi_L|^2$ and $|\chi_M|^2$ curves, and the aerodynamic interference effects on leeward deck are much more stronger than that on windward deck. Moreover, while the distance between windward and leeward deck changes, the aerodynamic interference may generate different effects on the equivalent aerodynamic admittances. For both the drag aerodynamic admittances of windward and leeward deck, the $|\chi_D|^2$ curves may approach to that of single deck gradually with the D/B increasing. For the lift and torsional moment aerodynamic admittances of windward and leeward deck, the $|\chi_L|^2$ and $|\chi_M|^2$ curves of windward deck don't behave any extraordinary difference from that of single deck, but that of leeward deck are quite different from that of single bridge especially the $|\chi_L|^2$ curves.

Effects of terrain proximity on the aeroelastic response of a bridge deck

Luigi Carassale [a], Andrea Freda [a], Michela Marrè-Brunenghi [a], Giovanni Solari [a]

[a] *Department of Civil, Environmental and Architectural Engineering, University of Genoa, Via Montallegro 1, Genoa, Italy*

ABSTRACT: Wind tunnel tests on sectional models are largely used to derive both aerodynamic forces and flutter derivatives of long-span bridge decks. The most common situation for this typology of bridges is to be far from the ground. Wind tunnel tests on sectional models are therefore generally carried out in a homogeneous and smooth flow. However, due to the possibility of channeling effects and a considerable turbulence intensity, the effects of terrain proximity deserve to be investigated if the bridge deck is close to the ground. The present paper reports the results of a wind tunnel test campaign aimed at the evaluation of wind actions and aeroelastic response of a bridge deck particularly close to the terrain. Wind tunnel tests are carried out both considering the classic configuration of isolated deck and simulating the terrain proximity with two different approaches. The results are compared.

KEYWORDS: Bridge deck, flutter, terrain proximity, wind-tunnel tests.

1 INTRODUCTION

The Marchetti Viaduct is a 290 m long arch bridge which will be built along the Milano – Novara highway, close to Ivrea, Italy. The bridge is composed by a single central arch with a trapezoidal section and the deck, which unusual width (B_p = 41 m) is coupled with a small height over the ground (H_p = 7 m, Fig. 1a). Such a configuration may emphasizes the aerodynamic interaction between the bridge and the terrain. Moreover, the noteworthy height of the side barriers, which is variable between 3 and 6.7 m, completes the picture of a project that is surely unconventional under the aerodynamic viewpoint.

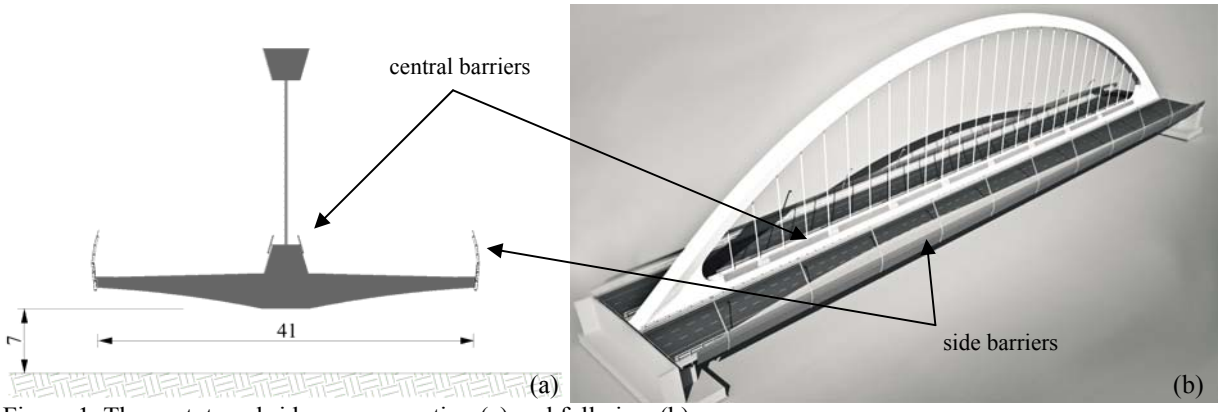

Figure 1. The prototype bridge: cross-section (a) and full view (b).

To investigate such a situation, static and aeroelastic sectional-model tests on the deck of the bridge have been conducted in the Wind Tunnel Laboratory at the Faculty of Engineering of the University of Genova, which working section is 1.7x1.35 m. Both static and aeroelastic wind

tunnel tests have been carried out considering three different arrangements: a) the deck is isolated, far from the ground, in a uniform flow; b) a rigid plate is installed under the deck, to simulate the wind channeling effect between the deck and the ground; c) the deck is placed at the scaled distance over an artificially-rough ground that generates a boundary layer coherent with the expected velocity profile for the bridge site.

The analysis of these different conditions is not traditional for sectional model tests, and the whole of these simulations provides an overview about how the effects involved by different configurations may change the aerodynamic response of the bridge.

2 WIND TUNNEL TESTS

2.1 *Experimental arrangement*

Static and aeroelastic wind tunnel tests have been carried out using the same sectional model, which has been realized in aluminium with a geometric scale equal to 1:150. The model has a length ℓ = 694 mm, and a width B = 274 mm ($\ell/B \simeq 2.5$). Static tests have been conducted separately on the sectional model of the arch but are not reported in the present paper.

The central and side barriers of the prototype are made of perforated steel plates, whose porosity changes as a function of the height over the deck. Moreover, their height changes with continuity along the length of the bridge (Fig. 1b). In the wind tunnel tests an average value of the side barriers height has been considered. Due to the impossibility of reproducing their actual geometry respecting the Reynolds number similarity, an equivalent solidity ratio of the barriers installed on the model has been selected to reproduce the head loss measured on a portion of the full-scale barrier. The head loss has been evaluated measuring the drag force acting on a portion of the real bridge barriers and on different grids suitable to be installed on the model. The grid that has been chosen to carry out the tests develops the correct drag force in the range of the velocities of interest (Fig. 2).

As introduced in Section 1, three different arrangements have been considered for wind tunnel tests. The first dealt with the isolated deck immersed in a homogeneous flow characterized by a turbulence intensity below 0.5%. This is the typical situation for testing sectional models. However, the closeness of the terrain for the real bridge may make the isolated-deck model not truly representative of the physical reality, due to the channeling of the flow between the deck and the terrain and the presence of a boundary layer characterized by high turbulence intensity. To investigate only the consequences of the channeling effects, a second setup was obtained installing a smooth, rigid plate below the model, at a distance corresponding to the height of the deck over the terrain (about 4.5 cm at 1:150 scale, Figs. 4b-6b). In this way the creation of a thick boundary layer was avoided. The real flow conditions have then been reproduced in the last setup using a suitable surface roughness to create a wind velocity profile and turbulence characteristics (Figs. 4c-6c).

The reproduced turbulent boundary layer is such that the mean wind velocity profile can be approximated by a power law with exponent α=0.27 (Fig. 3). Assuming a reference height equal to 10 m, corresponding to the average bridge deck height on the ground, the wind profile corresponds to a logarithmic law with roughness length equal to 0.2÷0.25 m, suitable for the site of prototype (i.e. countryside).

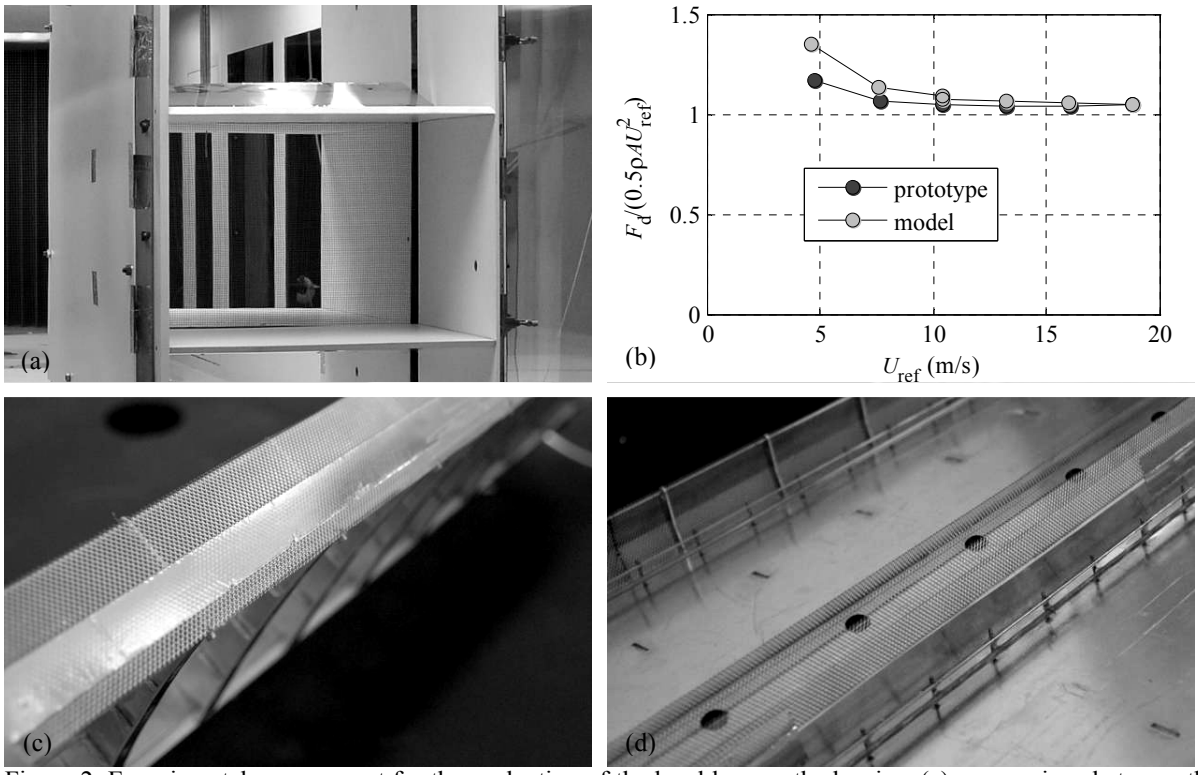

Figure 2. Experimental arrangement for the evaluation of the head loss on the barriers (a), comparison between the head loss on the prototype and the model grid (b), detail of the lateral (c) and central(d) barriers on the model.

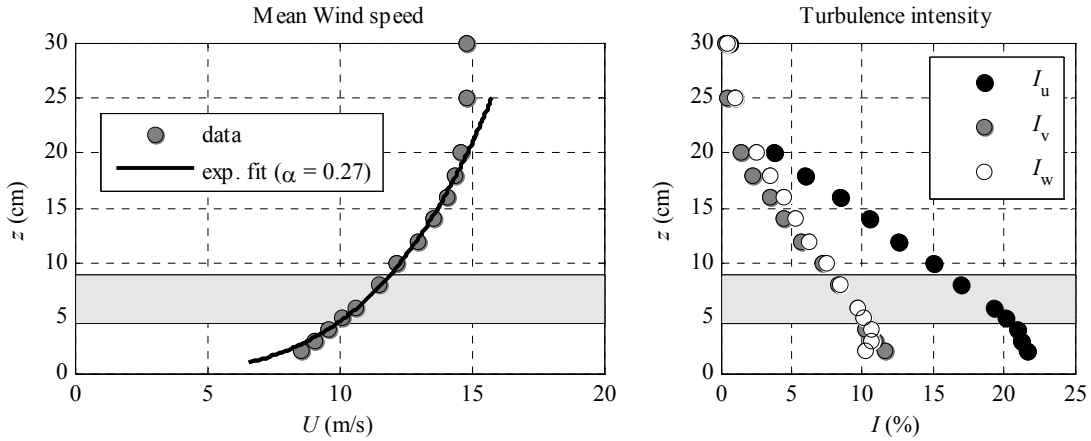

Figure 3. Main features of the boundary layer used in the third setup. The highlighted region is where the model is placed during tests.

2.2 *Static tests*

Static tests, aimed at the evaluation of the aerodynamic coefficients and wake parameters, have been carried out, with and without barriers, for a range of angles of attack between -10° and 10° in step of 1° (setups with and without plate) and with barriers between -5° and 5° in step of 1° (setup with boundary layer). Figure 4 shows the three different setups.

The drag, lift and torque aerodynamic coefficients are here defined based on the well-known expressions:

$$C_D = \frac{F_D}{0.5\rho U^2 B\ell}; \qquad C_L = \frac{F_L}{0.5\rho U^2 B\ell}; \qquad C_M = \frac{M}{0.5\rho U^2 B^2 \ell} \tag{1}$$

where F and M are the total force and the torque evaluated by measurements, ρ is the air density, U is the reference wind speed and the subscripts D, L, M stand for drag, lift and moment, respectively. The aerodynamic coefficients are constant for all practical purposes in the range of Reynolds numbers investigated during tests, i.e. $1.4 \cdot 10^5 \leq Re \leq 2.5 \cdot 10^5$ (based on the bridge width B).

Figure 4. Setups for static tests: isolated deck (a), deck close to plate (b), deck immersed in a boundary layer (c).

Figure 5 shows the drag, lift (positive upwards) and moment coefficients (positive nose up) for all the investigated configurations. From Figure 5 it is possible to infer that the barriers, the plate and the presence of a boundary layer influence significantly the aerodynamic coefficients. In particular, for the isolated deck, the introduction of the barriers enhances the dependency of the drag coefficient on the angle of attack, and tends to significantly reduce the values and the slope of both lift and moment coefficients; it also produces a stall at -5°.

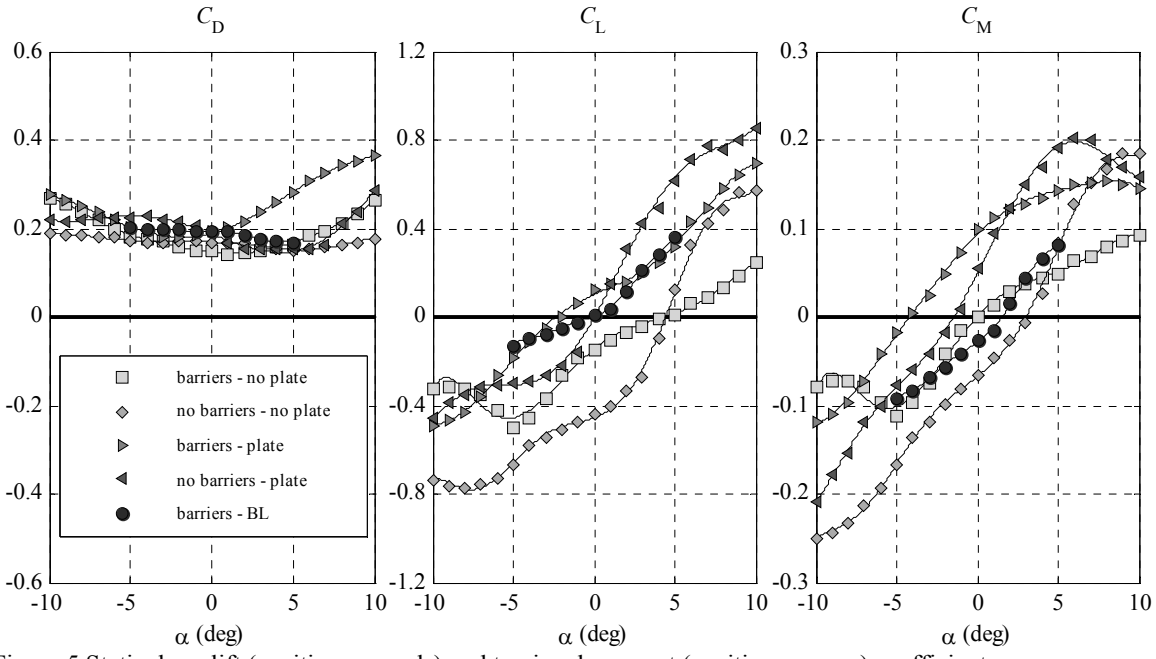

Figure 5 Static drag, lift (positive upwards) and torsional moment (positive nose up) coefficients.

The introduction of the plate to simulate the channeling effect due to the terrain mainly produces an increment of the drag coefficient for large angles of attack, and a shift of lift and moment coefficients (upwards for lift and nose-up for moment). The introduction of the plate

also anticipates the torsional stall for positive angle of incidence. The aerodynamic coefficients evaluated in presence of the turbulent boundary are obtained assuming as reference wind speed the averaged value where the deck is positioned (Fig. 3). The values of the actions evaluated in such a configuration are in between those evaluated in isolated conditions and with the plate. In particular, at zero angle of attack, the lift force becomes negligible as in the case with plate but without barriers.

2.3 *Aeroelastic tests*

Wind tunnel tests on the aeroelastic model have been carried out aimed at the evaluation of the flutter derivatives in the same configurations of static tests, but without changing the angle of attack. A classic 2 d.o.f. arrangement (i.e. heaving and pitching motion) has been considered. Figure 6 illustrates the wind tunnel setups. The aeroelastic derivatives have been extracted from the records of the free-decaying oscillatory motion from imposed initial conditions [1]. For each experimental setup and each wind velocity at least four repetitions have been carried out. Moreover, two sets of springs of different stiffness have been used to better explore different ranges of the reduced wind velocity. Table 1 shows the values of the spring stiffness k_s, the model mass and its moment of inertia, M and I respectively, the heaving and pitching natural frequencies f_h and f_α, and the corresponding damping ratios ξ_h and ξ_α.

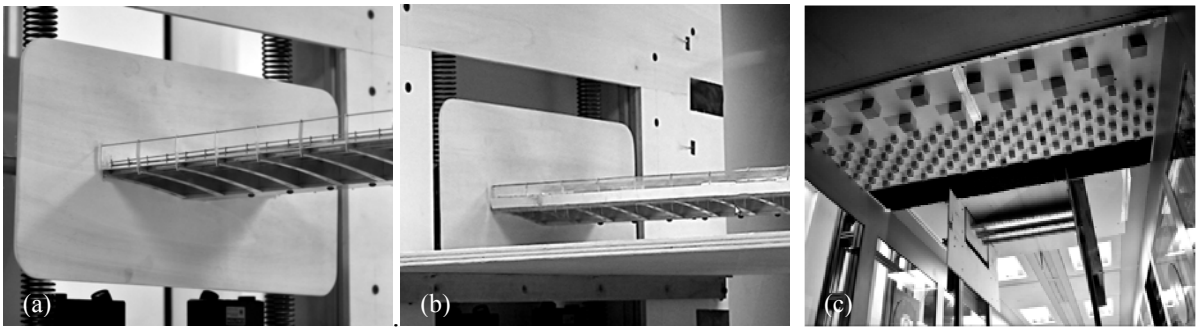

Figure 6. Experimental setups for aeroelastic tests: isolated deck (a), deck close to the plate (b) and deck immersed in the BL (c).

Table 1. Mechanical parameters for aeroelastic models.

Setup	k_s (kN/m)	M (kg)	I (kg m^2)	f_h (Hz)	f_α (Hz)	ξ_h (10^{-3})	ξ_α (10^{-3})
no barriers	1.21	5.52	6.41 10^{-2}	6.66	11.63	0.8	0.9
	7.54	5.99	6.92 10^{-2}	15.94	29.94	0.3	1.0
with barriers	1.21	5.60	6.49 10^{-2}	6.62	11.55	1.0	1.0
	7.54	6.08	7.03 10^{-2}	15.85	27.77	0.6	1.4

The estimation of the mechanical parameters during the tests has been made applying the algorithm proposed in [2]. The subsequent evaluation of the flutter derivatives has then been made applying the model proposed in [3], and considering $b = B/2$ as reference dimension.

The aeroelastic derivatives have been evaluated for reduced wind velocities up to U/(fB) = 16 and 9 (heaving motion and pitching motion respectively). As an example, Figure 7 shows, for the isolated deck without barriers, the aeroelastic derivatives H_1^*, A_1^* and A_2^* that plays an important role for torsional flutter (the direct derivative A_2^*) as well as for the coupled flutter (H_1^*, A_1^* and A_2^*) [4]. Small markers indicate the values obtained from single trials, large markers the mean values and lines the interpolating splines used for the subsequent stability analyses.

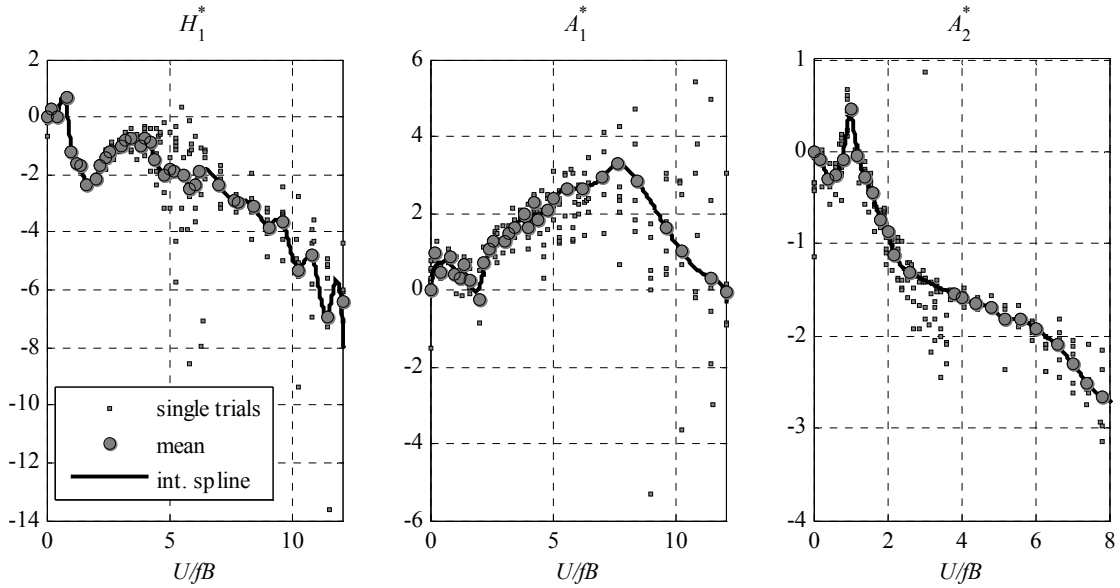

Figure 7. Flutter derivatives H_1^* A_1^* and A_2^* for the isolated deck (without barriers).

Figure 8 shows the standard deviation σ of the steady vibrations amplitude measured on the aeroelastic model (with barriers) as a function of the reduced velocity. It can be observed that the introduction of the plate deeply changed the torsional aeroelastic response of the model.

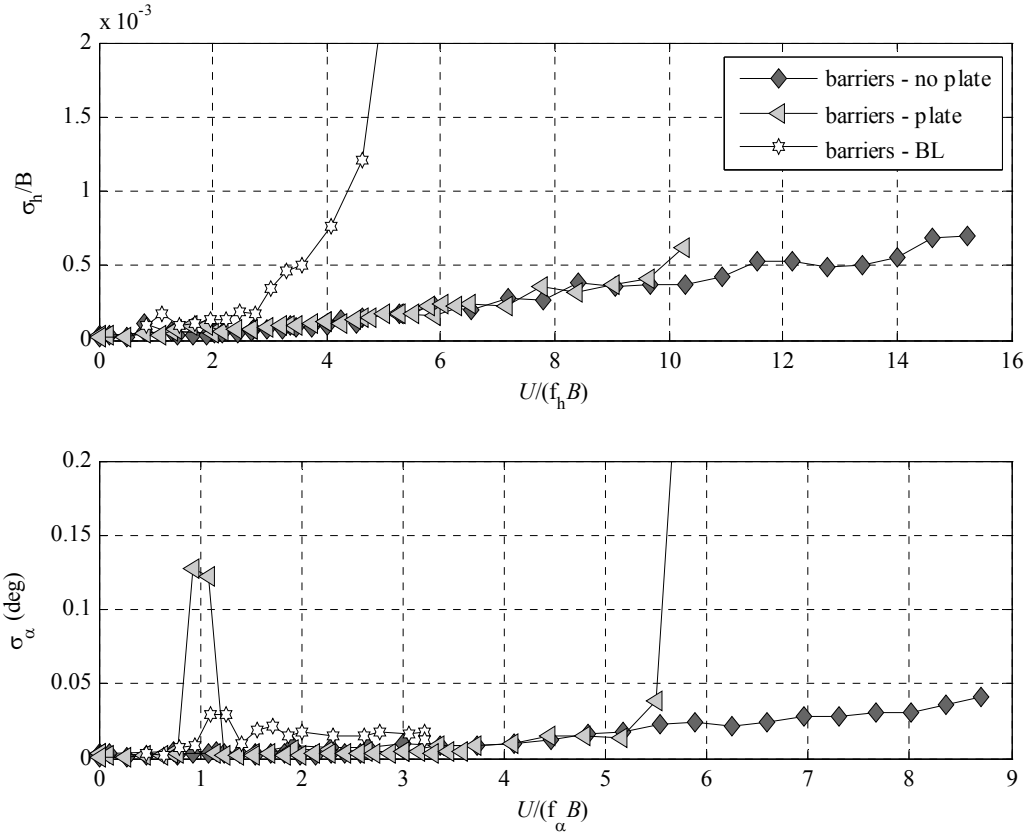

Figure 8. Amplitude of displacement of the bridge deck with barriers.

In particular, a significant vortex-induced vibration appeared at a reduced velocity roughly equal to 1, and the occurrence of diverging motion was anticipated at a reduced velocity equal to 5.5. On the other hand, the simulation of the terrain through a turbulent boundary layer reduced the torsional aeroelastic response, but significantly enhanced the heaving motion at lower reduced velocities.

3 DATA ANALYSIS AND DISCUSSION OF RESULTS

The aeroelastic derivatives obtained from wind tunnel tests have been used to carry out the stability analysis of the prototype bridge considering three modes of vibrations, namely the mode 2 (heaving, antisymmetric, 0.48 Hz) and the modes 6 and 7 (pitching, almost antisymmetric, 0.96 and 0.99 Hz, respectively). The introduction of a third mode, with respect to the classic formulation, has been made necessary due to the noteworthy similarity (both in mode shape and frequency) existing between modes 6 and 7. The other natural modes do not provide any significant contribution to the flutter mechanism.

Figure 9 shows the dependency on wind speed of the natural frequencies and damping ratios for the aforementioned prototype modes, considering the deck in isolated conditions, with and without the side barriers, and close to the plate (with barriers). From Figure 9 it can be inferred that the presence of the barriers does not affect significantly the evolution of the eigenfrequencies, but it anticipates the critical velocity from 233 to 217 m/s, as well as it shift the instability from the mode 2 (plunge, without wind) to the mode 6 (torsion, without wind).

The use of the plate to simulate channeling effects causes a significant reduction of the critical velocity for flutter, which is initiated by mode 6 as in the previous case. On the contrary, when simulating the terrain with a turbulent boundary layer (case not reported in Figure 9), no negative damping regions were found in the examined range of velocities.

Figure 9 also shows a region characterized by negative damping on pitching modes around 40 m/s. Such a region is due to a positive value of the aerodynamic derivative A_2^* (e.g. Fig. 7). This phenomenon, as already pointed out in [4], is characterized by an onset wind velocity nearly equal to the resonance velocity of Karman vortex shedding on the torsional mode, but in the present contest the response amplitude was limited as in classic vortex shedding, and such a region does not contribute to flutter instability. Confirmation of this fact is found in positive values of H_1^* in a range of reduced velocities for heaving motion corresponding to those of pitching motion (Fig. 7).

The aerodynamic coefficients derived through static tests have been used to evaluate the buffeting response of the bridge through a quasi-steady formulation, which is not reported in the present paper, and to check the applicability to the present case of the quasi-steady theory at high reduced velocities. Since the quasi-steady formulations can be referred to as a special case of unsteady forces when the frequency-dependent fluid memory effect is negligible, it is possible to correlate the static aerodynamic coefficients to the aeroelastic derivatives when the reduced frequencies tend to zero (i.e. high reduced wind velocities).

Based on the correlations between aeroelastic derivatives and quasi-steady aerodynamic force coefficients proposed in [5], Figure 10 shows the 6 aeroelastic derivatives that can be correlated to quasi-steady theory assuming a 2 d.o.f. heaving-pitching motion model. In Figure 10 the bridge deck is considered with barriers in the three different setups. The aeroelastic derivatives are plotted versus the reduced velocity; markers indicate results of aeroelastic tests, while values derived from aerodynamic coefficients (not dependent on frequency) are represented with horizontal lines of the same color.

It is necessary to point out that correlations between the flutter derivatives and the aerodynamic coefficients involves also an arbitrary length, often called characteristic radius,

whose definition is related to the contribution of the angular velocity of the body to the effective angle of incidence of the flow. The use the characteristic radius, hereinafter referred to as R_0, has been inspired by the use of the three-quarter chord point in airfoil flutter analysis, ands several values have been proposed in the literature based on the shape of the body, see [6] and [7] for references.

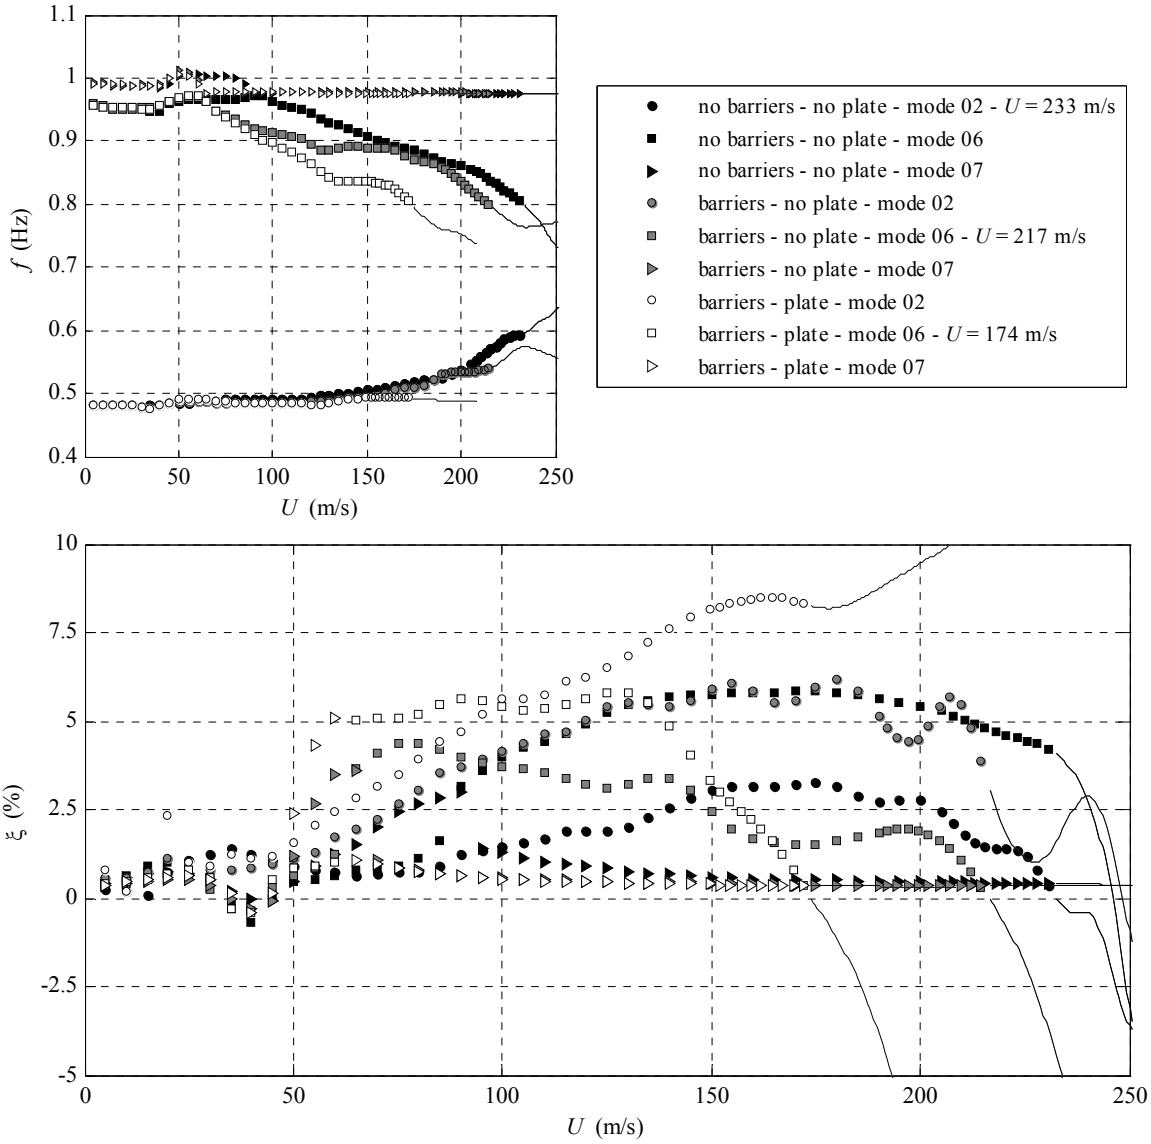

Figure 9. Isolated deck with and without barriers and deck with barriers close to plate: eigenfrequencies and damping ratios versus velocity.

The choice of the value of the characteristic radius is not obvious. In the present context, the linkage between the aeroelastic derivatives and the aerodynamic coefficients has been used to derive it, being involved in the relationships between H_2^* and $C_D + C_L'$ and between A_2^* and C_M'. Specifically, it has been evaluated by imposing the equivalence at higher reduced velocities on the term A_2^*. For the setups with installed barriers (Fig. 8), R_0 has been found always negative, varying from -0.3B to -2B (i.e. the reference point for velocity induced by the angular

velocity is aft of the pivot). Such a case is not common, but can be found in the literature (e.g. [8]).

To apply the quasi-steady theory, points represented in Figure 10 should tend to lines when the reduced velocity tends to the highest values. On the contrary, the comparison between experimental values of aeroelastic derivatives and values obtained from aerodynamic coefficients is far from being satisfactory in any case, confirming that the application of the quasi-steady theory to cases where torsional motion plays a fundamental role is questionable (e.g. [9]).

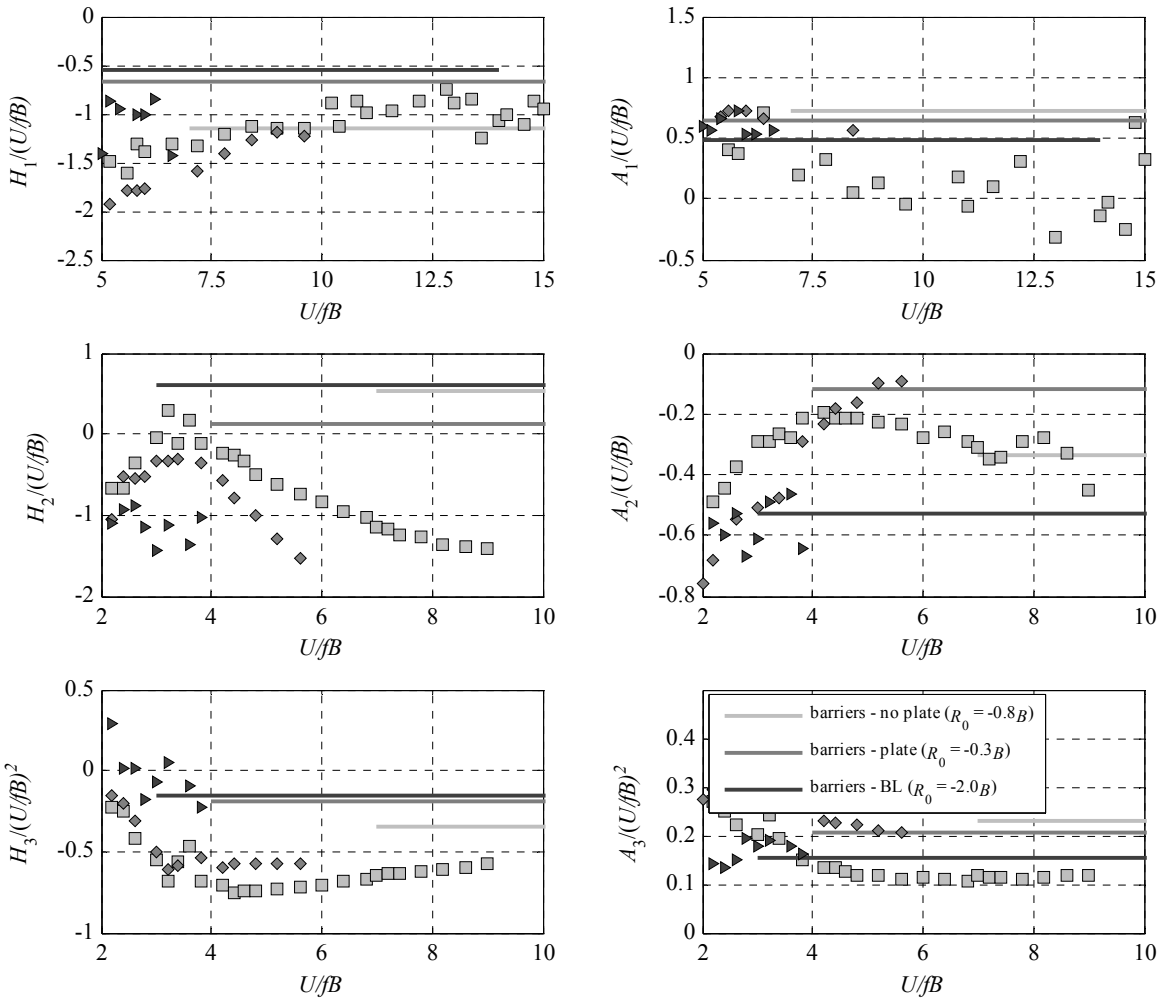

Figure 10. Aeroelastic derivatives derived from aeroelastic setups (markers) and based on aerodynamic coefficients from static tests (lines). The same color identifies the same experimental arrangement.

4 CONCLUSIONS AND PERSPECTIVES

Static and aeroelastic sectional wind tunnel tests have been carried out aimed at investigating the aerodynamic characteristics of a long-span bridge deck very close to the ground. Besides the classic configuration of isolated deck in uniform flow, the terrain proximity has been simulated with two different approaches, also considering the effects due to the barriers installed on the

bridge. The results highlight that the presence of the terrain and its modeling, as the presence of the barriers, implies deeply different aerodynamic behaviors.

It has been observed that the stability analyses carried out based on data derived considering the isolated deck do not lead to conservative values of the onset velocity for aeroelastic phenomena. Such an aspect points out that when channeling effects and the presence of a relevant boundary layer are not negligible, as for bridge decks close to the terrain, an investigation of the aerodynamic characteristics including the modeling of the boundary conditions is appropriate. Further researches are necessary to understand if some general trend can be derived, though.

Experimental results also confirm that the application of the quasi-steady theory to estimate the onset of instability is more than questionable for elongated bluff shapes.

Research on combination coefficient of cross and torsional wind forces for high-rise buildings based on the copula method

Yalin Yan [a], Yi Tang [a], Xinyang Jin [a]

[a] *China Academy of Building Research, 30# East Road North 3rd Ring, Beijing, China*

Abstract: Through wind tunnel tests on 5 models whose side ratio ranked from 1:1~1:5 in different wind fields, based on the distribution induced by Copula method and Empirical distribution, the combination coefficients of the equivalent static cross wind force and torsional wind force were determined. By analysis, the time series of wind forces and responses in different directions shows that the random data nearly subject to normal distribution, while the Gumbel distribution is not so suitable for estimation for the random variable. And through calculation, the combinations are found between 0.5~0.7 while the cross direction is the leading, and 0.7~0.9 while the torsional direction is the leading. It is something like the combination coefficient defined in AIJ code.

Keyword: combination coefficient, copula method, normal distribution, AIJ code, wind tunnel test, Gaussian distribution

1 INTRODUCTION

Since Davenport gave a description for equivalent static wind load (ESWL) method, research on wind loads on buildings has been developing fast. Homels, Solari, Tumura, Kareem etc have done a lot of work on the alongwind, crosswind, and torsional wind load. In China, Ming Gu, Yin Zhou, YongQuan, Shuguo Liang also studied the mechanism of the wind on structures based on large amount of wind tunnel tests. Based on the test data and the real time pressure data of the actual structures, the actual responses of the structures are calculated through random vibration theory or collected by tests. However, it usually costs a lot of time and a lot of money and time to get the data. So the ESWL method has been discussed a lot. Usually, in the wind field the structures are loaded simultaneously from different directions, defined as along wind direction, cross wind direction and torsional direction. As a matter of factor, for simplicity it considers only along-wind load in many cases. One reason is the along wind direction is usually the proceeding direction for high-rise structures, that is, wind loads in other directions are negligible; another reason is that there is no suitable way to exactly combine loads in different directions. However, it may undervalue effects of wind for some structures. Isyumov (1982) suggested the square root of square sum (SRSS) method for the acceleration, so his method was based on the whole relative wind loads in alongwind and crosswind directions. Solari et al. (1998) erected an ellipse for the real loads in the alongwind and crosswind directions, and also he took the SRSS method. And in the AIJ code, the combination for different directions is defined, it considers the along wind and crosswind combination for rigid structures, and for the stiff structures along wind-crosswind combination, alongwind-torsional combination and crosswind-torsional combination are all considered. The combinations are based on the project experiences. So it is practical and reflects the real projects. However the

AIJ method is not so powerful for wind fields in other countries and there is not a reflection in theory. Gianni Bartoli(2011) suggested a new method based on the joint distribution of several random variables base on the copula method, which describes the combination of different directions with the aim function Z=X+Y. The conclusion is nearly the same as the AIJ method. At one aspect the method provides a probability analysis for the combination, whereas it didn't give the explanation for the aim function, and its analysis is based on the loads self and reflects little about the responses, so it is more fit for the rigid structures rather than the stiff.

There is less discussion about the combinations of different wind direction wind loads In China. The reason may be that it is more effective to analyze an actual project with the random vibration method if the structure is large, and there is no need to combine different direction actions while the scale is not so large. However, as the climate changes a lot, the structure's responses may be undervalued if the combinations are not considered. So this paper gives a description for the combination of different wind directions in China wind fields with a joint distribution probability density function.

Firstly, a combination model is created for the research on combination of different loads and the combination coefficient is defined. Then it introduces the way to get the joint distribution probability density function with the Copula function. And based to the wind tunnel tests on 5 models whose side ratio ranked from 1:1~1:5 in different wind fields in China, the combination of cross wind direction load and torsional direction load is discussed, it also proves that the displacement responses of the structures can be considered as subjected to Gaussian distribution. At last it makes a comparison between the combination coefficient calculated in this paper and AIJ code.

2 DATA MODEL FOR THE COMBINATION

The wind in the structures would be concentrated to six components. And in high-rise buildings, the proceeding components are in the direction of along wind, crosswind, and torsion. Wind data model one direction the is created with a random variable in this direction, and an estimated value that reflects some probability may calculated and used as the design value for projects, such as the along wind equivalent static wind load calculated in the code. However the variables in different directions may be not so relative that the estimation values in different directions would not take the same as the single direction if the probability is the same. So the combination are simply expressed as the formula as (1)

$$R = R_{Dir1} \text{"+"} \gamma R_{Dir2} \tag{1}$$

Where the '+' means liner combination. R represents the response. And Dir1 and Dir2 represent two orthogonal directions. According to some papers and the tests(Gianni Bartoli,2011) of the models, the relation of X and Y direction is found to be little enough to neglect. So the combination coefficients between X and Z directions and Y and Z directions are to be researched.

Define $Z = R_{Dir2} R_{Dir1}$, thus Z represents the response relationship between Direction1 and Direction2, for in statistic theory the product of two random variables represents the joint relationships.

The Chinese Code (2001) defines the calculation method the ESWL in the along wind direction, it defines the gust factor as 2.5, which implies the exceeding probability is 2.5% in a year. In that case, the two variables model should be defined the same as the single variable model. It is expressed as equation (2).

$$P(Z \le z_\alpha) = \int_{-\infty}^{\infty} \int_{-\infty}^{z_\alpha / r_2} f(r_1, r_2) dr_1 dr_2 = 97.5\% \tag{2}$$

Compare (2) with (1), it is easy to find relationship between z and responses in two directions as (3).

$$z_\alpha = \gamma r_{1\alpha} r_{2\alpha} \tag{3}$$

That is, the combination coefficient γ should be defined as (4)

$$\gamma = \frac{z_\alpha}{r_{1\alpha} r_{2\alpha}} \tag{4}$$

3 METHOD TO DETERMINE JOINT PROBABILITY DENSITY DISTRIBUTION FUNCTION

Conclusion can be got from the equation (2) that if $f(r_1, r_2)$ is certain then z_α can be defined. And another deduction is that if we know the distribution of $f(r_1, r_2)$, then we may make certain the distribution parameters. As a matter of fact, it is difficult to define the distribution for a two-dimensional distribution, but fortunately to simulate a one-dimension distribution is easier. As the one-dimension distribution for marginal density function is sure, a copula method will be used to combine two marginal density functions as a two-dimensional distribution function. The copula method should be introduced first.

2.1 Introductions to bivariate Copula

Copula-based approaches have been used for different statistical problems in many fields, such as economics, finance and hydrology. It combines two PDF through a tie function called copula function. The formula is can be described as (5).

$$F(x_1, x_2, \cdots, x_n) = C\left(F(x_1), F(x_2), \cdots, F(x_n)\right) \tag{5}$$

Where $F(x_1, x_2, \cdots, x_n)$ is the joint Cumulative distribution functions(CDF) of random variables($x_1, x_2, \cdots, x_n$) ; $F(x_i)$ is the CDF of random variable x_i (I=1,2,$\cdots$,n) and C is the copula function.

There exist some types of copula functions, which can be classified as ellipse copula and Archimedean copula. The usually used copula functions are listed. (6) is the Gaussian copula function and (7) is Gumbel copula function.

Gaussian copula

$$C(u_1, \cdots, u_n; \rho) = \Phi_\rho\left(\phi^{-1}(u_1), \cdots, \phi^{-1}(u_n)\right) \tag{6}$$

Here, $\Phi_\rho(\square)$ means the standard multivariate Gaussian CDF and $\phi(\square)$ is the Gaussian CDF

Gumbel copula

$$C(u_1, u_2; \theta) = \exp\left\{-\left[(-\ln u_1)^\theta + (-\ln u_2)^\theta\right]^{1/\theta}\right\} \tag{7}$$

Gaussian copula function is somewhat a simple method, for the joint PDF of the two variables which subject to Guassian distribution is just the bivariate Gaussian PDF. Gussian distribution reflects the strong relation in the middle part of the two variables. And Gumbel copula function reflects a strong relation in the tail.
Relationship between random variables is reflected by the parameters in the above formulae. It is very important to find the right copula function and parameter values to model the distribution of the wind-induced responses in two directions. However there is no fixed method to choose the copula, thus the parameters form parametric tests and two steps methods are adopted.

2.2 parametric tests

As there are parameters in different copula functions and in marginal functions, it is necessary to do parametric test for the CDF. The usually used method is the two step method, that is, firstly test the parameter for the marginal functions and then for copula functions.

In first step, maximum likelihood estimation was done. Formula(8) will be formulated to estimate the parameter v_i .

$$\hat{v}_i = \arg\max \sum_{i=1}^{T} \ln f_i\left(x_i; v_i\right) \tag{8}$$

Where $f_i\left(x_i; v_i\right)$ is the PDF for x_i ; $\hat{v}_i$ is the estimated value.

And in the second step,

$$\hat{\theta} = \arg\max \sum_{i}^{T} \ln c\left(F_1\left(x_1; \hat{v}_1\right), \cdots, F_1\left(x_{n1}; \hat{v}_n\right); \theta\right) \tag{9}$$

Where $c\left(u_1, u_2; \theta\right) = \dfrac{\partial C\left(u_1, u_2; \theta\right)}{\partial u_1 \partial u_2}$, T is the number of variables, in this paper, T=2.

The way is also named the inference functions for margins method.

2.3 copula choose method

As different copula functions are determined, the bivariate CDF is determined. For there are different CDF for different copula, it is necessary to find the most suitable one. One method to choose the suitable copula function is the KS (Kolmogorov-Smimov) check.

2.4 Determination of the bivariate joint probability density function

The marginal probability density function is simulated from the response data calculated using the original pressure data based on tunnel tests. And when the marginal functions and the copula function is determined, the CDF of the bivariables are determined. It will be calculated using the formula listed below.

$$f\left(x_1, x_2\right) = c\left(u_1, u_2; \theta\right) f_1\left(x_1\right) f_2\left(x_2\right) \tag{10}$$

Where $f_1(x_1)$, $f_2(x_2)$ are marginal distributions of x_1, x_2.

By the copula method and equation (11), the bivariate joint probability density function for Gaussian copula method is following.

$$f(x,y)=\frac{1}{2\pi\sigma_1\sigma_2\sqrt{1-\rho^2}}e^{-\frac{1}{2(1-\rho^2)}\left[\frac{(x-\mu_1)^2}{\sigma_1^2}-\frac{2\rho(x-\mu_1)(y-\mu_2)}{\sigma_1\sigma_2}+\frac{(y-\mu_2)^2}{\sigma_2^2}\right]} \tag{11}$$

3 WIND TUNNEL TESTS AND ANALYSIS

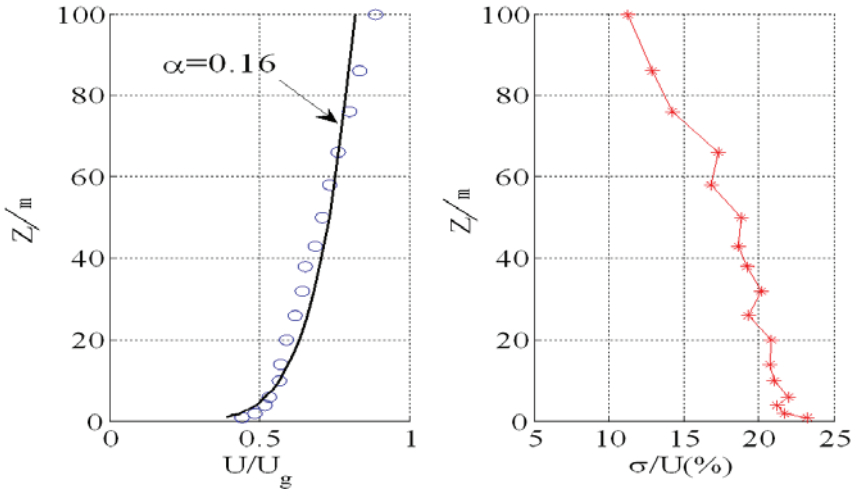

Fig 1 average wind speed and turbulence simulation in wind tunnel for field B

3.1 The basic test data

The tests were carried out in the wind tunnel in China Academy of Building Research. According to the Chinese Code, 'Load code for the design of building structures' GB50009-2001, wind fields A, B, C were simulated. Fig1 descripts the simulation of average wind speed and turbulence in wind tunnel for field B, where Z means the height from the ground. U_g means gradient velocity. U , σ means average wind speed and wind speed variance corresponding to z.

The models for test were made of ABS plates, and satisfy the similarity criteria and demand of rigidity and strength. Table1 shows the models data.

Table 1 the dimensions and test point's layout of the test models

Num.	Section	Height(H) (mm)	Breadth(B) (mm)	Depth(D) (mm)	Total number of test points (layer numbers×layer points numbers)
R1		600	100	400	216(9×24)
R2		600	100	300	216(9×24)
R3		600	100	200	216(9×24)
R4		600	100	150	324(9×36)
S4		600	100	100	180 (9×20)

3.2 The analysis of data

3.2.1 Responses time series in different directions

The responses time series in different directions are calculated in frequency domain, and translated into time domain by inverse Fourier translation (IFT). The equations for the movement of the high-rise buildings are as formula (14).

$$M\ddot{X}(t)+C\dot{X}(t)+KX(t)=F(t) \tag{12}$$

Where M is mass matrix, C is damper matrix and K is the stiffness matrix. F(t) is the force time series, and can be calculated by the sum of product of point pressures and area for the points. (14) can be translated into frequency domain.

$$M\ddot{X}(w)+C\dot{X}(w)+KX(w)=F(w) \tag{13}$$

Thus,

$$X(w)=H(iw)F(w) \tag{14}$$

Here,

$$H(iw)=\frac{1}{M^{*}w_n^2}\frac{1}{-\left(\frac{w}{w_n}\right)^2+i\left(\frac{w}{w_n}\right)+1} \tag{15}$$

w_n is the self-excited frequency of the structures.

$X(t)$ is then got from the IFT translation as formula.

$$X(t)=\frac{1}{2\pi}\int_{-\infty}^{+\infty}X(w)e^{iwt}dw \tag{16}$$

During computation, the modes are assumed to be separate and the first three modes are assumed to vibrate in along wind direction, cross wind direction and torsion direction. The periods follow the ratio as 0.77:0.85:1.

3.2.2 Marginal PDF determination

As for different directions of different models, the skewness and kurtosis of the wind forces were calculated and listed in Table2. Where x, y and represent along wind direction, cross wind direction and torsional direction. The K-S normality test results were also shown in Table 2.

Table 2 Standard variance, Skewness, Kurtosis and Normality test for displacement response

	B	0.108	0.089	0.076	-0.065	-0.064	-0.043
	C	0.165	0.144	0.112	-0.088	-0.095	-0.055
R3	A	0.213	0.297	0.121	-0.123	-0.172	-0.070
	B	0.144	0.167	0.075	-0.083	-0.096	-0.043
	C	0.183	0.225	0.105	-0.105	-0.130	-0.061

R4	A	0.224	0.482	0.094	-0.129	-0.278	-0.054
	B	0.165	0.272	0.061	-0.095	-0.157	-0.035
	C	0.216	0.324	0.084	-0.125	-0.187	-0.048
S4	A	0.234	0.571	0.041	-0.135	-0.330	-0.024
	B	0.186	0.390	0.033	-0.108	-0.225	-0.019
	C	0.254	0.485	0.050	-0.147	-0.280	-0.029

As table2 shows, almost half of the wind forces are following Gaussian distribution through KS check. And there still exists a half which is not Gaussian distribution. So a Gumbel distribution was list out to check. Thus we get the Gumbel distribution parameters as Table 3.

Compare the Gumbel distribution and Gaussian distribution, Fig 2 is the comparison for the model S4 in filed C in x direction, where the label 'experience' represents data distribution acquired from the collected data directly, and 'Gaussian' and 'Gumbel' represent data distribution simulated as Gaussian distribution and Gumbel distribution. It is obvious that the data fit Gaussian distribution better than Gumbel distribution. And repeat the work, it finds that for all data that is not so good for Gaussian distribution in Table 3 is more accurate than Gumbel distribution. The Guassian distrution is then used for the marginal distributions.

3.2.3 Joint distribution and the combination coefficients

Use method mentioned in part 2, the joint PDF is regressed. Taking the simplicity and accuracy into account, the Gaussian copula is adopted for a strong relation between data located in the middle part of the marginal distribution, and Gumbel copula for that located in the tail. Thus the parameters for the both copula functions are listed in Table 3.

In order to check the data, the 'direct method'(Gianni Bartoli,2011) is used. Thus, the coefficients calculated by formula (4) are listed in table4

Table 4 Gumbel Parameter and Gaussian Parameter from calculation

Model Mark	Wind field	Gumbel Parameter $1/\theta$			Gaussian Parameter ρ		
		XY	$X\theta$	$Y\theta$	XY	$X\theta$	$Y\theta$
R1	A	1.01	1.10	1.01	0.00	0.18	0.02
	B	1.02	1.12	1.02	0.04	0.20	0.05
	C	1.04	1.10	1.08	0.07	0.13	0.15
R2	A	1.13	1.09	1.19	0.23	0.19	0.27
	B	1.05	1.10	1.16	0.15	0.17	0.23
	C	1.06	1.00	1.09	0.12	0.04	0.15
R3	A	1.00	1.02	1.48	0.04	0.03	0.52
	B	1.01	1.00	1.45	0.07	0.01	0.49
	C	1.02	1.08	1.38	0.08	0.11	0.46
R4	A	1.00	1.02	1.28	0.03	0.04	0.38
	B	1.04	1.03	1.36	0.09	0.09	0.44
	C	1.02	1.03	1.52	0.08	0.03	0.56

S4	A	1.00	1.02	1.56	0.02	0.02	0.56
	B	1.00	1.06	1.54	0.01	0.07	0.57
	C	1.02	1.06	1.51	0.08	0.08	0.54

Thus, using formula(4), the combination coefficients were computed and shown as table5.

Table 5 combination coefficients from different methods

Model Mark	Wind field	Gumbel Copula		Gauss Copula		Direct method	
		Y leading	Z leading	Y leading	Z leading	Y leading	Z leading
R3	A	0.230	0.807	0.604	0.923	0.90	0.82
	B	0.254	0.785	0.569	0.903	0.74	0.66
	C	0.264	0.764	0.545	0.882	0.78	0.95
R4	A	0.595	0.659	0.624	0.704	0.76	0.71
	B	0.704	0.729	0.683	0.727	0.71	0.84
	C	0.706	0.742	0.738	0.795	0.58	0.85
S4	A	0.126	0.914	0.586	0.970	0.74	0.95
	B	0.141	0.900	0.606	0.966	0.79	0.91
	C	0.133	0.882	0.581	0.957	0.68	0.94

From table 5, it is apparent the combination coefficients calculated by the Gaussian Copula method are more accurate than that by Gumbel method. In one sense it certificates Gaussian Copula method is more fit for the determination of joint probability density. Also from the table, if Y is the leading direction the combination coefficient is 0.54~0.74, and if Z is the leading direction the combination coefficient is 0.7~0.9. The result is different from the AIJ code. In AIJ code the combination coefficient is the same no matter which direction is the leading direction, and it does not give a constant exceeding probability. However if the leading direction is Y direction, then the combination coefficient of AIJ lies between 0.54~0.78 while the frequencies ratio is about 0.9, just the same as the result.

4 CONCLUSIONS

Through wind tunnel tests on 5 models whose side ratio ranked from 1:1~1:5 in different wind fields, based on the distribution induced by copula method and empirical distribution, the combination coefficients of the equivalent static cross wind force and torsional wind force were determined. By analysis, the time series of wind forces and responses in different directions shows that the random data nearly subject to normal distribution, while the Gumbel distribution is not so good for estimation for the random variable. And through calculation, if the frequency ratio is 0.85, the combinations are found between 0.5~0.7 while the cross direction is the leading, and 0.7~0.9 while the torsional direction is the leading. It is something like the combination coefficient defined in AIJ code.

Along-wind aerodynamic damping of high-rise buildings

Cao Huilan [a], Quan Yong [a], Gu Ming [a], Wu Di [a]

[a] *State Key Laboratory of Disaster Reduction in Civil Engineering, Bridge Building, Tongji University, No. 1239 Siping Road, Shanghai, China*

ABSTRACT: Along-wind aerodynamic damping ratios are identified from wind-induced responses of 46 aeroelastic models in simulated turbulent flow using the random decrement technique (RDT). Their validity is examined through comparison with previous research achievements and the results evaluated by quasi-steady theory. Based on the identified results, characteristics of along-wind aerodynamic damping of isolated high-rise buildings are studied. The effects of density ratio, generalized stiffness, structural damping ratio, aspect ratio, side ratio, roughness exposure, aerodynamically modified cross-sections and tapering on aerodynamic damping ratio of high-rise buildings are investigated. Results indicate that: aerodynamic damping ratio increases monotonically with reduced wind velocity; structural damping ratio, density ratio, side ratio, reduced wind velocity and aspect ratio are very important parameters for along-wind aerodynamic damping ratio, while no clear effect of generalized stiffness on aerodynamic damping ratio is observed. Aerodynamic damping ratio increases as corner-cut ratio or taper ratio increases; low corner-cut ratios significantly decrease aerodynamic damping; however, modifications of building corners and tapering are not always effective at reducing the aerodynamic damping of tall buildings. According to the database, an empirical aerodynamic damping function for high-rise buildings is proposed.

KEYWORDS: high-rise building; wind-induced vibration; aerodynamic damping; aeroelastic model; wind tunnel test; along-wind.

1 INTRODUCTION

Since structural damping ratio of high-rise building is always small and predominant frequency of aerodynamic force under strong wind is close to the natural frequency of structure, wind load would be one of the control loads in design of high-rise building for significant wind-induced response. In addition, coupling effect between incident turbulent flow and structure may generate negative aerodynamic damping, which would decrease total damping, and furthermore cause larger response. Generally, along-wind, across-wind and torsional structure motion all could induce aerodynamic damping. And aerodynamic damping in along-wind attracts researchers' attention most early.

Aerodynamic damping in along-wind can generally be estimated with satisfactory accuracy by adopting the quasi-steady theory. Based on it, Davenport (1979) [1] found ζ_a=0.0175 with $V/(f_0B)$=10, M/ρ_aB^2=182 and C_D~2. Holmes (1996, 2001) [2,3] estimated the aerodynamic damping in along-wind based on the assumption that the aerodynamic drag force is proportional to the square of the difference between the mean oncoming wind speed and the speed of the moving structure. Gabbai and Simiu (2010) [4] presented a methodology for estimating aerodynamic damping in which the relative wind speed with respect to the moving structure is modeled, more accurately, as the difference between the total oncoming wind speed and the speed of the moving structure. In addition, the structural motion is assumed to be proportional to the relative oncoming wind speed raised to powers larger than two. In theory, this methodology is more accurate than quasi-steady method and the method proposed by Holmes, but more complex.

There are also many researchers study along-wind aerodynamic damping of high-rise buildings through wind tunnel test. Marukawa (1996) [5] evaluated the aerodynamic damping of rectangular tall buildings from wind tunnel tests of aeroelastic model. Random decrement technique is used to analyze effects of side ratio, aspect ratio and structural damping ratio on along-wind aerodynamic damping. Cooper (1997) [6] studied the impact of motion amplitude on along-wind aerodynamic damping by forced vibration test. Besides, the aerodynamic damping obtained from aeroelastic response measurements was compared with those predicted by quasi-steady theory. The results indicated that aerodynamic damping ratios in this test are independent of motion amplitude. Quan (2002, 2004, 2005) [7,8,9] and Gu (2004) [10] proposed a formula for aerodynamic damping as a function of reduced velocity, roughness exposure and structural damping using RDT method. Zou (2003) [11] investigated the aerodynamic damping of an isolated rectangular high-rise building with side ratio of 2:1 at three reduced wind velocities. But up to now, existing researches only focus on one or a few influence factors and are far from systemization. Moreover, the research achievements are lack of comparison with each other and the theoretical results.

Generally, the use of aerodynamically modified cross-sections, such as slotted corners, chamfered corners and tapering, is an effective means to reduce the wind-induced response. However, modifications of building corners might not be entirely effective, as adverse effects may also occur (Kareem et al., 1999; Kim and Kawai, 1999) [12,13]. Kim and You (2002) [14] investigated the taper-ratio effect for reducing wind-induced excitations in along- and across-wind directions based on the force-balance test using rigid models with taper ratios of 5%, 10%, and 15%, and one basic model of a square cross-section without taper. They discovered that the tapering is more effective in reducing wind-induced excitations in the suburban flow environment than in the urban flow environment. They also showed that tapering reduces the across-wind responses more than the along-wind responses. And, compared with a basic model without a taper, the tapering is not always effective at reducing the wind-induced excitations of tall buildings. However, the literatures mentioned above could not systematically indicate the variation of wind-induced response of high buildings and aerodynamic damping. Huang (2003) [15] studied effects of modified cross-sections (corner-cut ratio of 10%) on along- and across-wind aerodynamic damping. Results showed that aerodynamic damping of high buildings with slotted corner and chamfered corner are much less than that of square high buildings, and in the view of engineering application, the aerodynamic damping in along- and across-wind all could be neglected for buildings with corner-cut ratio of 10%. However, up to the present, relevant researches all focus on rectangular building (Davenport, 1979; Marukawa, 1996; Quan, 2002, 2004, 2005; Gu, 2004; Zou, 2003 etc.). And whether theoretically or experimentally, quite limit studies are about the influence of corner-cut and tapering on aerodynamic damping. Therefore, further researches are needed to consider about these factors.

Along-wind aerodynamic damping ratios are identified from wind-induced response of 46 aeroelastic models in simulated turbulent flow. The effects of density ratio, generalized stiffness, structural damping ratio, aspect ratio, side ratio, roughness exposure and aerodynamically modified cross-sections and tapering on aerodynamic damping ratio of high-rise buildings are investigated. According to the database, an empirical aerodynamic damping function for high-rise buildings is proposed.

2 OUTLINE OF THE WIND TUNNEL TESTS

2.1 *Simulation of wind characteristics*

The test is carried out in TJ-1 Boundary Layer Wind Tunnel in Tongji University, whose working section is 1.8m in width, 1.8m in height and 18m in length, and the wind speed ranges from 3

to 32 m/s. Four kinds of wind conditions, corresponding to exposure category A, B, C and D in the Chinese code [16] are simulated in the wind tunnel at a length scale of 1/800. The exponents of the mean wind profiles for the exposure category A, B, C and D are 0.12, 0.16, 0.22 and 0.30, and the corresponding gradient heights are 300, 350, 400, 450m, respectively. The wind characteristics are achieved by a combination of turbulence generating spires, a barrier at the entrance of the wind tunnel, and roughness elements along the wind tunnel floor upstream of the model. The longitudinal turbulence intensities at the height of building (480m) are separately 9.23%、9.36%、9.52% and 9.78%, while the values at the height of roughness length are 18.52%、22.11%、27.07% and 27.50%. As profile of turbulence integral scale is difficult to be accurately simulated, the values at the 2/3 height of building for the exposure category A, B, C and D are respectively 229m, 231m, 285m, 274m. Figure 1 shows the simulated mean wind speed profiles and longitudinal component profiles of turbulence intensity, as wind speed profiles provided by Chinese code and turbulence intensity profile given by AIJ (2004) [17].

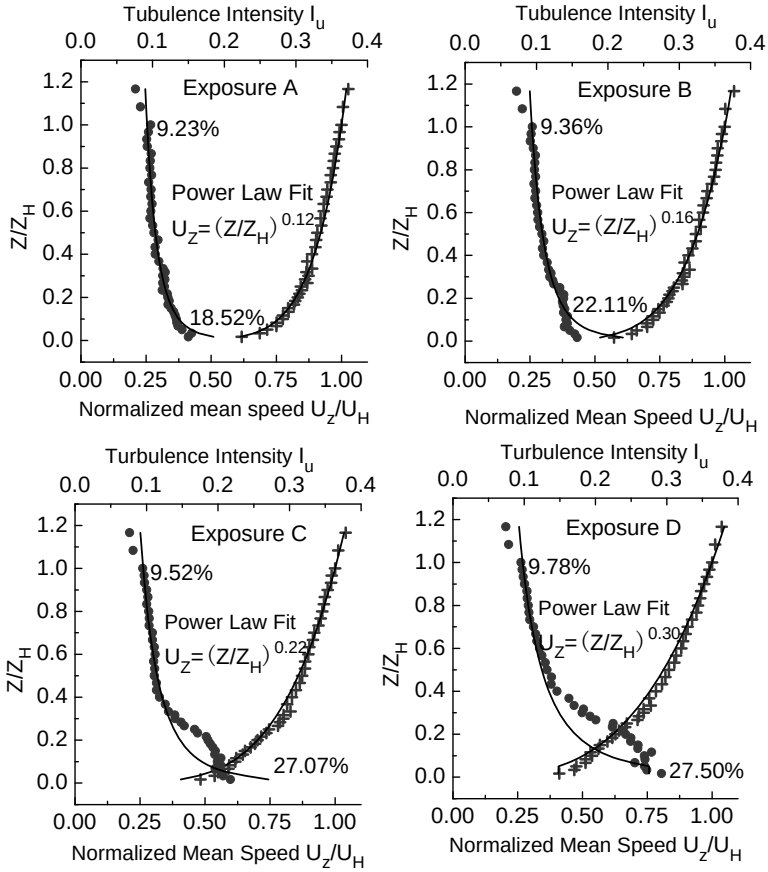

Figure 1 Profiles of wind velocity and longitudinal turbulence intensity

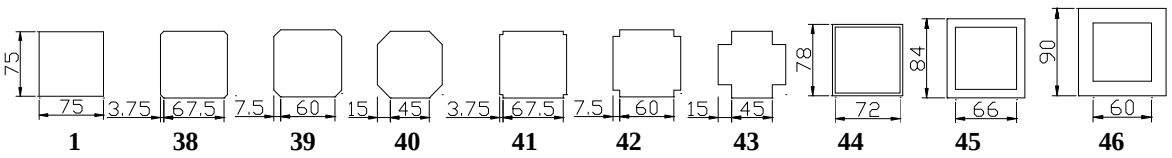

Figure 2 Model cross-sections (*mm*)

2.2 *Building models*

Length and velocity scale are separately 1/800 and 1/8. Dimensions of standard model are $0.075m \times 0.075m \times 0.6m$, with frequency of $13Hz$, density of $213Kg/m^3$ and generalized mass of $0.24Kg$. Corresponding to real structure, these parameters represent building with size of $60m \times 60m \times 480m$, natural frequency of 13 Hz, and density of $213Kg/m^3$. Generalized stiffness is selected to be 1600 Kg/s^2 according to natural frequency. In addition, structural damping ratio of standard model is taken as 1%, while density of air is $1.227Kg/m^3$.

Wind-induced responses of 46 high-rise buildings are measured from aeroelastic model wind tunnel test. The structure characteristic parameters are shown as Table 1. As to the other cases, the heights of models keep the same, and cross sections are changed according to aspect ratios and side ratios. The maximum block ratio of model to test section of wind tunnel is 2.22%. Case 38 to 46, cross sections are changed in accordance with corner-cut and taper ratios, considering one type of aerodynamically modification each case, as shown in Figure 2. The base is used to model the elastic parameters of buildings, as structural damping ratios are simulated by width of damping plates and their depth dipped into oil, while springs are used to achieve stiffness. In order to avoid energy transmission in the two orthogonal directions, one degree of freedom in horizontal direction is fixed. All of the models are built with base plates, hollow aluminum alloy as the cores, foamed plastics, light wood plates of 1mm thickness as their "clothes" and balancing weight. Two piezoelectric accelerometers with sampling frequency of $1000Hz$ are placed at the two ends inside windward surface, as sampling time set as 7 minutes.

Table 1 Wind tunnel test cases for high-rise buildings

Case	Model Height $H(mm)$	Roughness Exposure	Side Ratio B/D	Aspect Ratio $H/(BD)^{0.5}$	Structural Damping ζ_s (%)	Structure Density ρ_s (Kg/m^3)	Generalized Stiffness K (Kg/s^2)	Corner-cut or Taper Ratio

3 TEST RESULTS

The generalized formula with four variables proposed by Tamura et al (1996) [18] is used to estimate damping from random acceleration responses.

$$a(\tau) = Ae^{-\zeta\omega\tau}\left(\cos\sqrt{1-\zeta^2}\,\omega_0\tau + B\sin\sqrt{1-\zeta^2}\,\omega_0\tau\right) \tag{1}$$

Firstly, amplitude dependent structural damping ratio is derived from free acceleration response. Then, RMS of wind-induced acceleration response after band-pass filtering is taken as the initial amplitude of RDT to calculate total damping ratio. Afterwards, structural damping ratio corresponding to this amplitude is derived through interpolation. The aerodynamic damping ratio ζ_a is

calculated by subtracting the value of structural damping ratio ζ_s from the value of total damping ratioζ, i.e. $\zeta_a = \zeta - \zeta_s$. Following research mainly focuses on the study of aerodynamic damping variation with density ratio, generalized stiffness, structural damping, aspect ratio, side ratio, roughness exposure, aerodynamically modified cross-sections and tapering.

3.1 *Verification of result*

Marukawa (1996) studied the effects of side ratio in the range of 0.33-3, aspect ratio from 4 to 6, and structural damping ratio of 0.5% to 2% on along-wind aerodynamic damping, and compared the results with that evaluated by quasi-steady theory. Here, the drag coefficient was derived from the mean displacement assuming that the wind force is distributed in proportion to the velocity pressure. Quan (2002, 2004) discussed impacts of exposure category (A、B、C、D) and structural damping on along-wind aerodynamic damping, and made comparison with Marukawa (1996). The validity of research results in this paper is examined through comparison with previous research achievements and the results evaluated by quasi-steady theory as shown in Figure 3, corresponding structure characters shown in Table 2.

As shown in Table 2 and Figure 3, there are certain differences between research results with different roughness exposures and model parameters. But in general, the results show a good agreement with previous research achievements and that derived by quasi-steady theory, especially with the result evaluated by quasi-steady theory.

Table 2 Structure parameters for tests

	Aspect Ratio $H/(BD)^{0.5}$	Side Ratio B/D	Roughness Exposure (α、I_h)	Model Height H (mm)	Length Scale	Structural Damping ζ_s	Structure Density ρ_s (Kg/m^3)
Standard Model	8	1	A、B、C、D	600	1/800	0.88%	213
Marukawa (1996)	6	1	α=0.167, I_h=10.7%	480	1/500	1%	200
Quan (2002)	6	1	A	600	1/500	0.6%	180
Quasi-steady Theory	$\zeta_a = \frac{1}{4\pi}\frac{\rho_a B^2}{M}\frac{V_H}{f_0 B}C_D$, as reduced velocity defined as $V_H/f_0(BD)^{0.5}$, derives $\zeta_a = = \frac{1}{4\pi}\frac{\rho_a}{\rho_s}\frac{B}{D}\frac{V_H}{f_0\sqrt{BD}}C_D$ (According to Marukawa (1996), for B/D =1, C_D=1.05; as to the Chinese code, for B/D =1, C_D=1.3)						

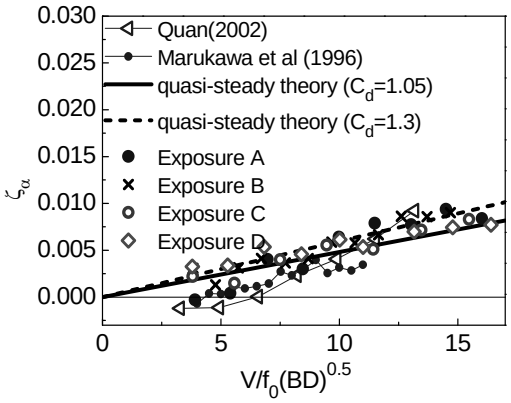

Figure 3 Comparison with research achievements and theoretical result

3.2 *Characteristics of aerodynamic damping*

3.2.1 *Effect of roughness exposure*

Figure 3 indicates the variation of aerodynamic damping ratio with reduced velocity $V_H/f_0(BD)^{0.5}$ in simulated turbulence wind environments A、B、C、D. The aerodynamic damping ratio in the along-wind in Figure 3 represents positive damping at reduced velocities of 4 or more, and it increases monotonically with reduced wind velocity. At low reduced wind velocities, aerodynamic damping ratios in exposure D are bigger than that in exposure category A. Furthermore, at reduced wind velocities of more than 10, aerodynamic damping ratios are apparently bigger than other cases. That is, aerodynamic damping ratio gradually increases slower with reduced velocity for exposure category A、B、C、D. But overall, wind environment has no clear effect on along-wind aerodynamic damping, as discrepancies are within 0.003. It may be caused by the similar profiles of wind velocity (Chinese code) and turbulence intensity (AIJ2004) for this height of building. So, the influence of roughness exposure still needs further research.

3.2.2 *Effect of side ratio B/D*

Figure 4 shows the variation of aerodynamic damping ratio with reduced velocity, as aspect ratio $H/(BD)^{0.5}$=8, structural damping ratio ζ_s =1%, side ratio B/D ranges from 0.33 to 3. The corresponding values obtained by quasi-steady theory are also provided in this Figure. Here, the drag coefficients adopt the values given in Marukawa (1996). Figure 4 indicates that side ratio is an important parameter for aerodynamic damping, as aerodynamic damping increases with side ratio, exclude the case with B/D=0.33. In most cases, aerodynamic damping increases monotonically with reduced wind velocity, except that it starts to decrease at reduced velocity of 8-10 for the case with B/D=0.33. For side ratios $B/D\geq1$, aerodynamic damping increases with side ratio; for side ratios $B/D\leq1$, there is no clear variation in aerodynamic damping ratio with side ratio. As to side ratios $B/D>1$, aerodynamic damping ratios derived from experiment are bigger than that evaluated by quasi-steady theory in exposure category B; and opposite phenomena can be observed in exposure category D. As to side ratios B/D=1, 0.5, aerodynamic damping ratios derived from experiment are a little bigger than that evaluated by quasi-steady theory, as discrepancies are within 0.002 in exposure category B and much less in exposure category D. Generally, there's no big difference between each other, so along-wind aerodynamic damping can be well predicted by quasi-steady theory for these cases. But as to the case of B/D=0.33, experimental values are much bigger than theoretical values. All in all, there is a much better agreement between aerodynamic damping evaluated from wind tunnel test and the theoretical value than that obtained by Marukawa (1996). This is because, reduced velocity adopted by Marukawa (1996) is $V_H/f_0(BD)^{0.5}$, while the one used for quasi-steady theory is V_H/f_0B.

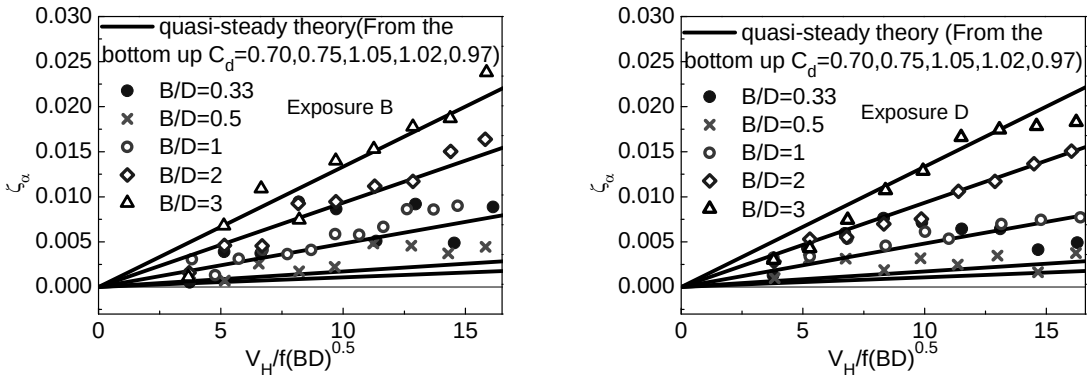

Figure 4 Effect of side ratio B/D ($H/(BD)^{0.5}$=8, ζ_s =1%)

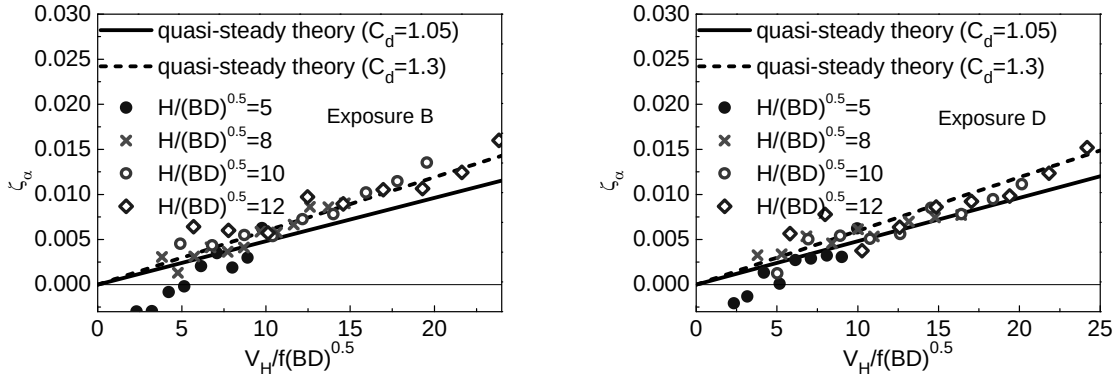

Figure 5 Effect of aspect ratio $H/(BD)^{0.5}$ (B/D=1, ζ_s=1%)

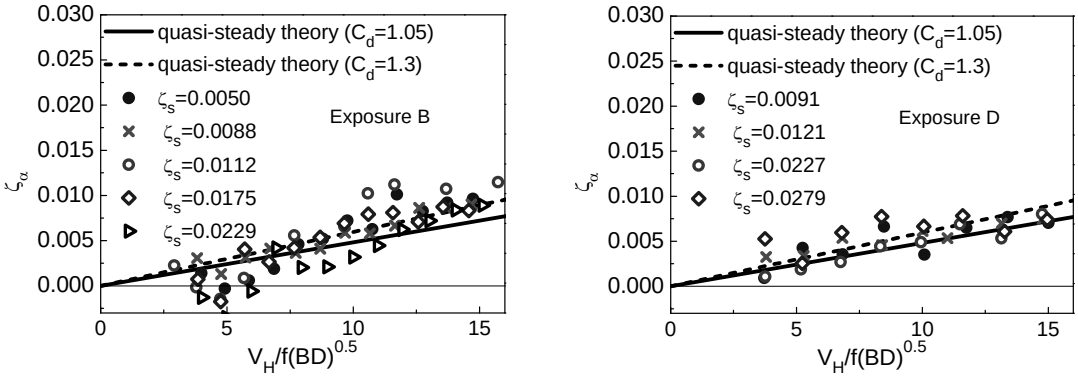

Figure 6 Effect of structural damping ζ_s (B/D=1, $H/(BD)^{0.5}$=8)

3.2.3 *Effect of aspect ratio $H/(BD)^{0.5}$*

Figure 5 shows the variation of aerodynamic damping ratio with reduced velocity, as side ratio B/D=1, structural damping ratio ζ_s =1%, aspect ratio $H/(BD)^{0.5}$ ranges from 5 to 12. Figure 5 indicates that aerodynamic damping ratio gradually increases slower with wind velocity as aspect ratio increases. At reduced wind velocitiy lower than 10, aerodynamic damping ratio increases as aspect ratio increases; while opposite trend is observed at reduced wind velocity higher than 10. Above all, the effect of aspect ratio is not so obvious, with difference not more than 0.003, and they can be relatively accurate evaluated by quasi-steady theory.

3.2.4 *Effect of structural damping ζ_s*

Figure 6 shows the variation of aerodynamic damping ratio with reduced velocity, as side ratio B/D=1, aspect ratio $H/(BD)^{0.5}$=8, structural damping ratios ζ_s ranges from 0.005 to 0.0279. At the same reduced velocity, difference of aerodynamic damping is about 0.005, which states unelectable effect of structural damping on aerodynamic damping. At low reduced wind velocity, aerodynamic damping generally decreases with structural damping; while the smaller the structural damping, the bigger the aerodynamic damping at high reduced wind velocity. The smallest aerodynamic damping ratio is observed when the structural damping ratio is 0.023. In addition, variations of aerodynamic damping for ζ_s=0.0091, 0.0121, 0.0227 in exposure category D are similar with cases of ζ_s=0.0088, 0.0112, 0.0229 in exposure category B.

3.2.5 *Effect of density ratio ρ_s/ρ_a*

Figure 7 shows the variation of aerodynamic damping ratio with reduced velocity when density ratio varies from 294 to 131. Density ratio has a clear effect on aerodynamic damping, with difference between 0.003 and 0.005 at the same reduced wind velocity. Aerodynamic damping ratio increases monotonically with density ratio. Moreover, the value derived in exposure category D is a little smaller than that in exposure category B.

3.2.6 *Effect of generalized stiffness K*

Figure 8 shows the variation of aerodynamic damping ratio with reduced velocity when generalized stiffness varies from 947 to 3027. As shown in Figure 8, no clear effect of generalized stiffness on aerodynamic damping is observed in the along-wind direction, with difference not more than 0.002. Likewise, aerodynamic damping ratio in exposure category D gradually increases slower with reduced velocity than in exposure category B. The values estimated in exposure category D are much closer to the values derived by quasi-steady theory, while much more discrepancies are observed in exposure category B.

3.2.7 *Effect of slot rate*

Figure 9 shows the variation of aerodynamic damping ratio with reduced velocity, as aspect ratios $H/(BD)^{0.5}$=8, structural damping ratio ζ_s=1%, side ratio B/D=1, slot rate ranges from 0% to 20%. The corresponding values obtained by quasi-steady theory are also provided in this Figure. Here, the drag coefficients adopt the value given in Marukawa (1996). Figure 9 indicates 5% and 10% slot rates significantly decrease aerodynamic damping, and this trend is more obvious at

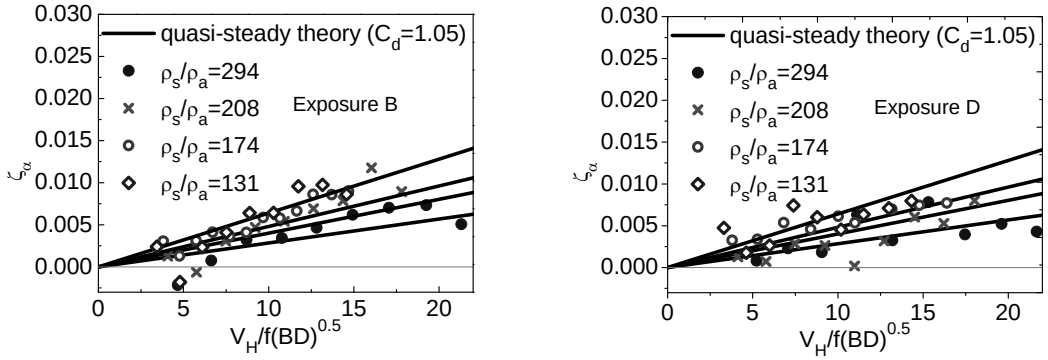

Figure 7 Effect of density ratio ρ_s/ρ_a

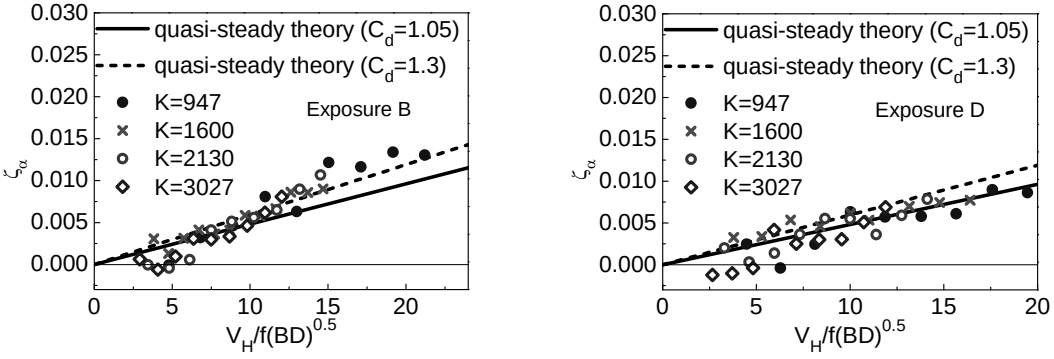

Figure 8 Effect of generalized stiffness *K*

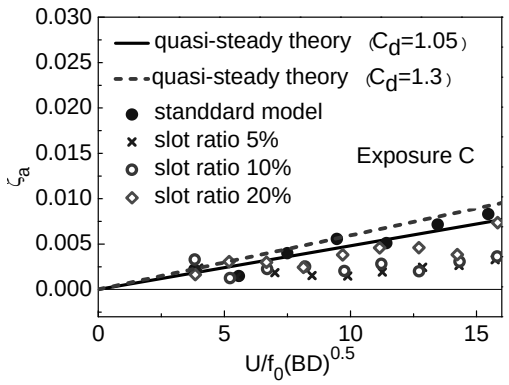

Figure 9 Effect of slot rate

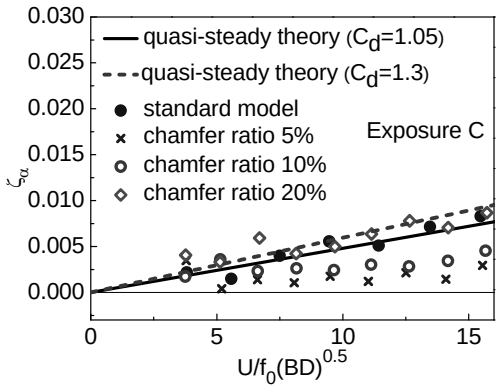

Figure 10 Effect of chamfer rate

higher reduced wind velocity. For slot rate of 20%, although it decreases in certain extend, but difference is not significant, i.e. larger slot does not lead to more decrease. Also in this case, decrease effect of aerodynamic damping strengthens as reduced wind velocity increases. In general, slot rates in certain range significantly decrease aerodynamic damping, especially for the case with slot rate of 5%.

3.2.8 *Effect of chamfer rate*

Figure 10 shows the variation of aerodynamic damping ratio with reduced velocity, as aspect ratios $H/(BD)^{0.5}$=8, structural damping ratio ζ_s=1%, side ratio B/D=1, chamfer rate ranges from 0% to 20%. The corresponding values obtained by quasi-steady theory are also provided in this Figure. As shown in Figure 10, 5% and 10% chamfer rates significantly decrease aerodynamic damping, and this trend is more obvious at higher reduced wind velocity. For chamfer rate of 20%, although it decreases in certain extend, but difference is not significant, which means larger chamfer is not always effective at reducing the aerodynamic damping of tall buildings. When chamfer rate varies from 5% to 20%, aerodynamic damping ratio increases as chamfer rate increases. As compared with cases with slotted corner, aerodynamic damping ratios of building with 5% chamfer rate are smaller than that with 5% slot rate, the opposite phenomena can be observed for chamfer rate 10% and 20%. Overall, the effects of slotted corner and chamfered corner on aerodynamic damping ratio are similar; for low corner-cut ratios, aerodynamic damping ratios are bigger with slotted corner, while for high corner-cut ratios, they are bigger with chamfered corner.

3.2.9 *Effect of tapering*

Figure 11 shows the variation of aerodynamic damping ratio with reduced velocity, as aspect ratios $H/(BD)^{0.5}$=8, structural damping ratio ζ_s=1%, side ratio B/D=1, taper rate ranges from 0% to 20%. The corresponding values obtained by quasi-steady theory are also provided in this Figure. As shown in Figure 11, taper rate of 1% reduces aerodynamic damping, but taper rate of 3% and 5% increase aerodynamic damping. When taper rate varies from 1% to 5%, aerodynamic damping ratio increases as taper rate increases. Therefore, tapering is not always effective at reducing the aerodynamic damping of tall buildings, as lower rates of tapering reduce aerodynamic damping and it will increase when taper rate exceeds 3%.

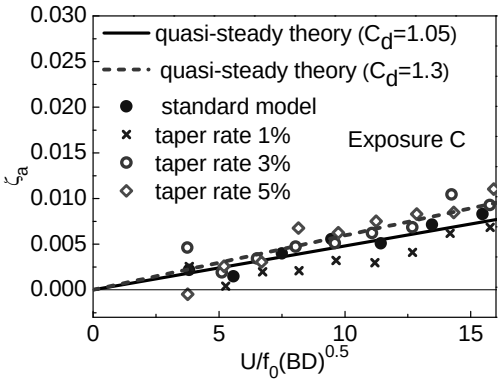

Figure 11 Effect of tapering

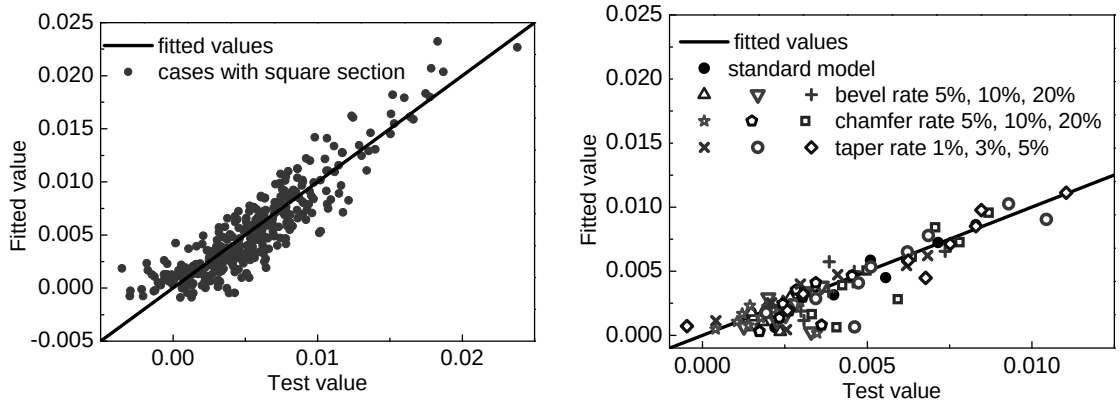

Figure 12 Comparison between fitted values and tested values for aerodynamic damping

3.3 *Formula fitting of aerodynamic damping ratio*

As described above, the aerodynamic damping ratios of high-rise building increase monotonically with reduced wind velocity. In most cases, they can be relatively accurate evaluated by quasi-steady theory. Research shows that structural damping ζ_s, density ratio ρ_s/ρ_a, side ratio B/D, reduced velocity $V_H/f_0(BD)^{0.5}$, aspect ratio $H/(BD)^{0.5}$, aerodynamically modified cross-sections and tapering are important effects for aerodynamic damping ratio in along-wind, while the influence of generalized stiffness and roughness exposure are not so significant. As quasi-steady theory only takes density ratio, side ratio, reduced velocity and drag coefficient into consideration, an empirical aerodynamic damping function for high-rise buildings, written as formula (2), is proposed according to the database after many times comparison. The conformity between aerodynamic damping ratios derived from wind tunnel test and by fitting is shown in Figure 12. Standard error for this for this empirical formula is

$$\delta_{\zeta a}=\sqrt{\frac{1}{N}\sum_{i=1}^{N}\left(\zeta_{a-calc}(i)-\zeta_{a-test}(i)\right)^2}=0.0018$$

Where, N is the number of case (415 for here); $\zeta_{a\text{-}calc}$ and $\zeta_{a\text{-}test}$ are separately the fitted values and tested values for aerodynamic damping.

$$\zeta_a = \lambda(\frac{1}{4\pi}\frac{\rho_a}{\rho_s}\frac{B}{D}\frac{\overline{U}}{f_0\sqrt{BD}}\zeta_s^{0.15}\left(\frac{H}{B}\right)^{0.5} C_D - 0.002) \tag{2}$$

Here, drag coefficient C_D adopts 1.05; λ is modification coefficient of cross section, as λ=1.0 for square building, with λ for other cases and corresponding standard error shown in Table 3.

Table 3 Fitting parameter of aerodynamic damping for corner-cut and tapering high-rise buildings

	Slot rate 5%	Slot rate 10%	Slot rate 20%	Chamfer rate 5%	Chamfer rate 10%	Chamfer rate 20%	Taper rate 1%	Taper rate 3%	Taper rate 5%
λ	0.38	0.44	0.75	0.30	0.53	1.10	0.71	1.17	1.26
$\delta_{\zeta ai}$	0.8×10^{-3}	1.2×10^{-3}	1.1×10^{-3}	1.2×10^{-3}	1.2×10^{-3}	1.7×10^{-3}	0.9×10^{-3}	1.5×10^{-3}	1.0×10^{-3}

4 CONCLUSION

46 aeroelastic model tests are conducted to study the effects of important factors on along-wind aerodynamic damping ratios using RDT method with four parameters. The influences of density ratio, generalized stiffness, structural damping ratio, aspect ratio, side ratio, roughness exposure, aerodynamically modified cross-sections and tapering on aerodynamic damping are investigated. All parameters of high-rise building, which could affect aerodynamic damping, are systematically taken into consideration. The following conclusion can be drawn:

1 Aerodynamic damping ratio gradually increases slower with reduced velocity in exposure category A、B、C、D. But overall, wind environment has no clear effect on along-wind aerodynamic damping, which may be caused by the similar profiles of wind velocity (Chinese code) and turbulence intensity (AIJ2004) for this height of building. So, the influence of roughness exposure still needs further research.
2 For side ratios $B/D\geq1$, aerodynamic damping ratio increases with side ratio; for side ratios $B/D\leq1$, there is no clear variation in aerodynamic damping ratio with side ratio. In addition, along-wind aerodynamic damping can be well predicted by quasi-steady theory.
3 Structural damping ratio and aspect ratio has great influence on aerodynamic damping. Aerodynamic damping ratio gradually increases slower with wind velocity as aspect ratio increases. At reduced wind velocity lower than 10, aerodynamic damping ratio increases as aspect ratio increases; while at reduced wind velocity higher than 10, opposite trend is observed.
4 Although density ratio and generalized stiffness all reflect in change of structural damping, the impact of density ratio is relatively significant while no clear effect of generalized stiffness can be observed.
5 The effects of slotted corner and chamfered corner on aerodynamic damping ratio are similar; aerodynamic damping ratio increases with corner-cut ratio, as corner-cut ratio of 5% and 10% significantly decrease aerodynamic damping, while there's little difference between square building and cases with corner-cut ratio of 20%.
6 Aerodynamic damping ratio increases as taper rate increases; taper rate of 1% reduces aerodynamic damping, but taper rate of 3% and 5% increase aerodynamic damping.
7 Modifications of building corners and tapering are not always effective at reducing the aerodynamic damping of tall buildings.

Structural damping ζ_s, density ratio ρ_s/ρ_a, side ratio B/D, reduced velocity $V_H/f_0(BD)^{0.5}$, aspect ratio $H/(BD)^{0.5}$, aerodynamically modified cross-sections and tapering are important effects for aerodynamic damping ratio in along-wind, while the influence of generalized stiffness is not

so significant. Through fitting of estimated aerodynamic damping ratios, an empirical aerodynamic damping function for high-rise buildings is proposed with taking effects of structural damping, aspect ratio and modification of cross section into quasi-steady theory.

ABSTRACT: The high frequency force balance is a versatile and widely used method for estimating the wind-induced response of tall buildings. Nevertheless, the estimates of the response parameters are inevitably affected by uncertainties essentially due to the lack of knowledge on the forces acting over the building height. Also, the usage the method is often hindered by the impossibility of considering more than three modes in the response assessment. In this paper a novel methodology is presented that allows to overcome the aforementioned shortcomings through the definition of a reliability framework in which the uncertainties arising from the use of the high frequency force balance are taken into account. The application to a case study building with coupled and non-linear modes shows the effectiveness of the method in providing safe estimates of the response parameters considering exclusively the base measurements.

KEYWORDS: Wind loading; Reliability models, Tall buildings, HFFB technique.

1 INTRODUCTION

The high frequency force balance (HFFB) is one of the most widely adopted techniques for the assessment of the wind-induced response of tall buildings, especially because the measurement of the base moments constitutes a relatively easy way to assess the overall action of the wind on the structure. Over the years, a number of methodologies have been proposed in the literature that are aimed at providing estimates of the structural responses commencing from the measured base moments. In most cases, this scope is attained through the identification of expressions that yield a set of correction coefficients that, applied to the three measured base moments, allow the estimation of the first three generalized forces [1, 2, 3, 4, 5]. These coefficients depend on the mode shapes of the building – therefore termed mode shape correction (MSC) coefficients – and on the pressure field acting over the building surface that, being unknown, has to be hypothesized. In the case of buildings with uncoupled fundamental modes it has been seen that these methodologies are able to provide good results in the estimation of structural response parameters [6, 7]. When the modes are coupled, in general, things become more involved and the estimates of the first three generalized forces and then of the response parameters are strongly affected by the assumptions made on the pressure field when estimating the MSC coefficients [6, 7]. It is worth underlining that, in any case, only the contribution of the fundamental modes is included in the response assessment: in general, while this is not a problem for the resonant response component, the background response can be affected by significant errors [8]. Indeed, it is common practice to use the HFFB technique only with the purpose of estimating the resonant response and not in order to obtain estimates of the background response. Different techniques that are not based on MSC coefficients, and are in general more complex from an applicative

point of view, have also been proposed [9, 10, 11]. In these cases, any number of modes can be included in the response calculation of the pressure field, but the necessity of hypothesizing the pressure field remains. Indeed, any method adopted for the assessment of the wind induced response starting from a set of base measurements is inevitably affected by what can be termed aerodynamic uncertainties [12], that is by the uncertainties generated by the lack of knowledge on the pressure field. These uncertainties propagate to the response parameter estimates, producing errors that can be significant [7], especially for tall buildings characterized by complex geometric shapes. As for the estimation of the mean response, when pressure measurements are unavailable the traditional approach consists in hypothesizing the distribution of the mean floor loads over the height of the building (linked to conventionally defined mean pressure profiles) and to calibrate it with the information at the base of the building [11]. In alternative, the method proposed in [13] exploits the definition of a power law model for the mean wind forces in order to define correction coefficients used to estimate mean values of the first three generalized forces. In any case, aerodynamic uncertainties result to be introduced also in the estimates of the mean responses.

A first step towards overcoming some of the aforementioned limitations of the HFFB technique has been proposed in [12], where the effect of the aerodynamic uncertainties on the resonant response was taken into consideration. In particular, a reliability framework was identified in which the aerodynamic uncertainties, and so their influence on the estimated response acceleration parameters, could be included.

The objective of this work is to further develop the approach proposed in [12]. This is done by firstly introducing a novel model for the probabilistic description of the mean. Secondly, a description of the correlation structure of the pressure field is carried out, which is more complete than the model presented in [12]. This allows the inclusion in the modal analysis of any number of modes, and therefore the probabilistic modeling of the total background response. To show the effectiveness of the proposed approach, a case study building characterized by a complex geometric form and non-linear coupled mode shapes is considered.

2 THE RELIABILITY FRAMEWORK

The aim of this section is to present the reliability framework in which the proposed approach for taking into account the aerodynamic uncertainties is set.

The fragility F for a generic response component R can be defined as the following conditional probability of exceedance of the response level $\widetilde{R}$ [14]:

$$F = P(R_{max} > \widetilde{R} \mid \mathbf{v}) \tag{1}$$

where $\mathbf{v} = \{U_H, \alpha\}$ is the vector of the hazard intensity with U_H the mean wind speed at the top of the building and α the wind direction while R_{max} is the peak value of the response process $R(t)$ for $t \in [0, T]$ where T is the observation period. The probability of exceedance $P_{f,R}$ can then be expressed in terms of the fragility as

$$P_{f,R} = \int_{D'} F(\mathbf{v}) \cdot p_{\mathbf{v}}(\mathbf{v}) d\mathbf{v} \tag{2}$$

where D' is the domain of all the possible hazard intensities while $p_{\mathbf{v}}$ is the probability density function of the hazard. Because $R(t)$ may be considered a stationary process, R_{max} with specified exceedance probability is given by:

$$R_{max} = \mu_R + g_R \sigma_R = \mu_R + \sqrt{g_{Rb}^2 \sigma_{Rb}^2 + g_{Rr}^2 \sigma_{Rr}^2} \tag{3}$$

where g_R is the peak value of the normalized (zero-mean and unit-variance) response process for $t \in [0, T]$, μ_R is the mean value, σ_R is the standard deviation while the subscript b and r indicate the background and resonant response component respectively. The estimates of μ_R and σ_R are traditionally considered unaffected by loading model uncertainties, resulting in a fragility only depending on g_R. Indeed, this is commonly done when choosing a deterministic model for the unknown pressure field over the building surface. On the other hand, if aerodynamic uncertainties are taken into account, the fragility can be re-written as:

$$F = 1 - \int_D p_{\mu g \sigma|\mathbf{v}}(\mu_{R,} g_R, \sigma_R) \cdot dD \tag{4}$$

where $p_{\mu g \sigma|\mathbf{v}}$ is the joint probability density function of μ_R, σ_R and g_R, conditional on the wind hazard intensity, and D is the domain where $R_{peak} < \tilde{R}$.
If the random variables μ_R, g_R and σ_R are considered independent, then

$$p_{\mu g \sigma|\mathbf{v}}(\mu_R, g_R, \sigma_R) = p_{\mu|\mathbf{v}}(\mu_R) p_{g|\mathbf{v}}(g_R) p_{\sigma|\mathbf{v}}(\sigma_R) \tag{5}$$

Therefore, to calculate the fragility it is necessary to estimate the marginal distributions $p_{\mu R}|\mathbf{v}(\mu_R)$, $p_{gR}|\mathbf{v}(g_R)$ and $p_{\sigma R}|\mathbf{v}(\sigma_R)$. The PDF $p_{gR}|\mathbf{v}(g_R)$ has been widely studied; under the hypotheses of stationary and Gaussian process, it can be expressed by the following

$$p_{gR|v}(g_R) = g_R \nu_0 T \exp\left[-1/2 g_R^2 - \nu_0 T \exp\left(-1/2 g_R^2\right)\right] \tag{6}$$

where v_0 is the mean zero-crossing rate, approximated by the first natural frequency of the building. Approaches for estimating the marginal distributions $p_{\mu R}|\mathbf{v}(\mu_R)$ and $p_{\sigma R}|\mathbf{v}(\sigma_R)$, are proposed in the following Section 3.

3 PROPOSED MODEL

3.1 *General features*

The aim of this section is to illustrate the proposed models for the propagation of the aerodynamic uncertainties in the floor loads to the structural mean and dynamic response. To reach this objective, models for the unknown floor loads (mean values and spectral structure) depending on a limited set of parameters are defined. Different values assumed by the parameters describe, although in an approximate fashion, all the possible floor load structures for every possible building and flow field. Secondly, the marginal PDFs and correlation structures for the random vectors collecting the parameters are assigned. If a large number of floor load structures would be known for buildings of different shapes and in different surrounding environments, the marginal PDFs of the governing parameters could be obtained by fitting the set of available data with the floor load model. Due to the insufficiency of this kind of data, the models for the statistical properties of the random parameters are only based on the knowledge of the physics of the problem, therefore it is of key importance that the governing parameters have a clear physical meaning.

3.2 *Model for the mean response*

With the aim of identifying the marginal PDF $p_{\mu R}|\mathbf{v}(\mu_R)$ introduced in Equation (5), in this section a probabilistic model of the unknown mean floor load distribution over the height of the building, calibrated through the five measured base reactions, is proposed. The basic idea is to use a Monte Carlo simulation to study the propagation of the uncertainties in the mean response parameters, μ_R, starting from the probabilistic description of a limited number of parameters that govern the mean floor load field.

3.2.1 *Model for the along-wind direction*

The floor loads in the along-wind direction, F_{Li}, $i = 1, \ldots, n$, where n is the number of the floors, are expressed in terms of the mean wind speed profile $U_i = U(z_i)$ and of the force coefficients in the along-wind direction c_{Li} at different heights z_i, as follows:

$$F_{L,i} = 1/2 \rho U_i^2 c_{Li} h_i L_{\alpha i} \tag{7}$$

where h_i is the height of the tributary area of the ith floor, $L_{\alpha i}$ is the width of the building orthogonal to the wind direction at height z_i and ρ is the air density. The mean wind speed profile indicated by the European Standards [15] is assumed. In this model, the vector of the random variables, $\{c_L\}$, contains the n values of the force coefficients, one for each floor:

$$\{c_L\} = \{c_{L1}, c_{L2}, \ldots c_{Ln}\} \quad \text{with} \quad c_{L,\min} \le c_{Li} \le c_{L,\max} \tag{8}$$

where $c_{L,min}$ and $c_{L,max}$ are the limits assigned to the force coefficients and can be fixed based on the knowledge of the physical phenomenon. The limits for the range of variability of the F_{Li} are consequently fixed and a range of possible values for the floor loads is obtained from Equations (7) and (8). Due to the lack of information on the actual value of the pressures over the building surface, a uniform distribution is adopted as marginal distribution for each random variable. As for the correlation structure of the random vector $\{c_L\}$, it can be observed that the degree of correlation among two force coefficients c_{Li} (at z_i) and c_{Lj} (at z_j) is in general very low if marked changes in the geometry of the building occur between the two floors at z_i and z_j. To account for this physical phenomenon, the floors of the building are grouped into n_g ideal sectors, based on the changes of geometry over the height of the building. Then, full correlation is assigned between all the force coefficients belonging to the same sector, while the coefficients of different sectors are considered uncorrelated. It should also be observed that the mean forces resulting from one realization of the random vector $\{c_L\}$ will not, in general, respect the base equilibrium conditions (shear and moment). To take this into account, only the randomly generated vectors that satisfy both the equilibrium equations (within a certain tolerance) are considered, while the others are rejected. As a result of this selection process, the marginal distributions of the c_{Li} are no longer uniform.

3.2.2 *Model for the across-wind direction*

For the across-wind direction the procedure adopted is substantially the same as for the along-wind direction. The floor load components, F_{Ci}, are defined in terms of the coefficients c_{Ci}, that can have positive or negative values. The following relation is adopted:

$$F_{C,i} = 1/2 \rho U_H^2 c_{Ci} h_i L'_{\alpha i} \tag{9}$$

where $L'_{\alpha i}$ is the width of the building parallel to the wind direction at height z_i. If the geometry of the building is symmetric with respect to a vertical plane containing the oncoming flow direction, the mean force coefficients are expected to be zero over the height of the building. Nevertheless, asymmetries in the geometry can generate non-zero mean across-wind forces. For this reason, the limiting values of c_{Ci} are set as $c_{C,max}$ and $c_{Cmin} = -c_{Cmax.}$. Considerations analogous to the along-wind case hold (the division of the buildings in sectors and the respect of the base equilibrium conditions).

3.2.3 *Model for the torsional component*

Because the torsional loads are generated by the two translational forces when their action is eccentric with respect to the vertical axis of the reference system, for the torsional component the random variables are the normalized eccentricities of the floor loads e^n_{si} ($s = x,y$) defined as:

$$e^n_{si} = e_{si} / L_{si} \tag{10}$$

where e_{si} is the eccentricity of the floor load F_{si} while L_{si} is the width of the building at the ith floor (in direction perpendicular to the s direction). At each floor, the hypothesized torsional force $F_{\theta i}$ can be calculated from:

$$F_{\theta i} = F_{yi} e^n_{xi} L_{xi} - F_{xi} e^n_{yi} L_{yi} \tag{11}$$

where the forces F_{yi} and F_{xi} are obtained by simply projecting the F_{Li} and F_{Ci}, generated as illustrated in 3.2.1 and 3.2.2, on the reference system xy. By fixing the limits for the values of the normalized eccentricities $e^n_{s,max}$ and $e^n_{s,min} = -e^n_{s,max}$ a range of possible values is obtained for the random variables. The limits for the values of the vector of the hypothesized torsional forces result from both the limits on the eccentricities and the limits obtained for the along and across-wind floor loads. Akin to what was done for the along- and across-wind coefficients, the generated aleatory vectors $\{e^n_x\}$ and $\{e^n_y\}$ are considered acceptable if the base torsional equilibrium equation is respected, otherwise they are rejected.

3.3 *Model for the dynamic response*

In this section, an approach for estimating the PDF of a response parameter standard deviation σ_R taking into account the propagation of aerodynamic uncertainties is proposed. Similarly to other methods that can be found in the literature, the proposed approach is based on the assumption of a model for the floor load spectral structure. However the method developed herein has three distinct advantages that make it particularly attractive: 1) all the components of the floor load spectral matrix $[S_F]$ are modeled: this allows to take into account any number of modes in the response estimate, without approximations on their shape; 2) the calibration of the spectra is different for each wind direction; 3) the model depends on a limited number of parameters; varying the parameter values all the possible spectral structures of the floor load can be (approximately) described. In particular, the third characteristic allows the model to be used for the estimation, through a Monte Carlo simulation, of the PDF of the response parameter standard deviation. To do this, probabilistic models have to be defined for the parameters that govern the spectral structure of the floor loads.

3.3.1 *Modeling of the floor load spectral structure*

In the proposed approach, the floor load spectrum S_{Fsphl}, i.e. the cross-spectrum between F_{sh} and F_{pl} ($s, p = x,y,\theta$ and $h,l = 1,\ldots,n$), is modeled according to the following expression:

$$S_{Fsphl}(f) = S_{FspHH}(f)\left(\frac{z_h}{H}\right)^{\gamma_s}\left(\frac{z_l}{H}\right)^{\gamma_p}\exp\left(-\frac{k_{zsp} f\left|z_h - z_l\right|}{U_H}\right) \tag{12}$$

where S_{FspHH} is the cross-spectrum between the two top floor forces in direction s and p, γ_s and γ_p are the coefficients that govern the variation of the intensity of the spectrum of the components s and p, respectively, over the height, k_{zsp} is the decay factor in the vertical direction that governs the cross-correlation between two spectra belonging to the sub-matrix $[S_{Fsp}]$ acting at different heights. Equation (12) is the extension to the case $s \neq p$ of the expression proposed in [5] for the spectra S_{Fsshl}.

The floor load spectra defined according to equation (12) depend on the values of the parameters k_{zsp}, γ_s and γ_p and also on the value of S_{FspHH}. In order to eliminate the dependency on S_{FspHH}, it is hypothesized that S_{FspHH} can be obtained by scaling with a proportionality factor, $\alpha_{sp}(f)$, the measured base moment spectrum S_{Msp} (cross-spectrum between the base moments M_s and M_p).

The proportionality factor $\alpha_{sp}(f)$ can then be determined by imposing the equilibrium at the base of the building, once the values for γ_s and k_{zsp} are chosen. In particular, it is imposed that the spectrum resulting from the integration of the spectra S_{Fsphl} over the building height coincides with the spectrum of the measured moments at the base S_{Msp}. The following equations are consequently obtained:

$$\alpha_{sp} = \left[\sum_{h=1}^{n} \sum_{l=1}^{n} \left(\frac{z_h}{H} \right)^{\gamma_s} \left(\frac{z_l}{H} \right)^{\gamma_p} \exp\left(- \frac{k_{zsp} f |z_h - z_l|}{U_H} \right) \right]^{-1} \qquad s, p = \theta \tag{13a}$$

$$\alpha_{sp} = \left[\sum_{h=1}^{n} \sum_{l=1}^{n} \left(\frac{z_h}{H} \right)^{\gamma_s} \left(\frac{z_l}{H} \right)^{\gamma_p} \exp\left(- \frac{k_{zsp} f |z_h - z_l|}{U_H} \right) z_h \right]^{-1} \qquad s = x, y \quad p = \theta \tag{13b}$$

$$\alpha_{sp} = \left[\sum_{h=1}^{n} \sum_{l=1}^{n} \left(\frac{z_h}{H} \right)^{\gamma_s} \left(\frac{z_l}{H} \right)^{\gamma_p} \exp\left(- \frac{k_{zsp} f |z_h - z_l|}{U_H} \right) z_h z_l \right]^{-1} \qquad s, p = x, y \tag{13c}$$

In this way, the dependency on S_{FspHH} is eliminated and all the spectra of the matrix $[S_F]$ can be modeled by fixing values for the 9 parameters γ_s and k_{zsp}.

3.3.2 *Response prediction*

The probabilistic approach illustrated in 3.3.1, being based on the modeling of the entire floor load spectral structure $[S_F]$, allows the assessment of any number of generalized force spectra as:

$$S_{Qij} = \{\Phi^i\}^T [S_F] \{\Phi^j\} \tag{14}$$

Therefore, any number of modes can be taken into account in the assessment of the structural response. Equation (14) will be used for the assessment of the resonant response, while to calculate the total background component of the response, R_b, the following expression will be adopted:

$$S_{Rb} = \{\Gamma_R\}^T [S_F] \{\Gamma_R\} \tag{15}$$

where S_{Rb} is the spectrum of the background response and $\{\Gamma_R\}$ is the vector of the influence coefficients of the response R.

3.3.3 *Modeling of the parameters*

In the proposed probabilistic model, the 9 parameters γ_s and k_{zsp} that govern the floor load spectrum model of Equation (12) are the components of a random vector whose marginal distribution and correlation structure have to be assigned. In this work, extending what proposed in [12], the marginal distributions of the governing parameters are obtained through the definition of analytical models describing the range of physically meaningful floor load correlation structures.

By observing that the value of k_{zss} is directly related, through the cross-power spectral densities S_{Fsshl}, to the level of correlation between the floor load F_{sh} (acting at z_h) and F_{sl} (at z_l), the distribution of k_{zss} can be chosen as to result in a uniform distribution of the correlation coefficient at a selected distance $D_{hl} = |z_h - z_l|$. The link between the correlation coefficient of the forces F_{sh} and F_{sl}, $r_{sshl} = \sigma^2_{sshl} / \sigma_{sshh}\sigma_{ssll}$, and the parameter k_{zss} can be found using Equation (12). With some simplifications it is possible to obtain:

$$r_{sshl} = \sigma^2_{sshl} / \sigma_{sshh}\sigma_{ssll} = \int_0^\infty S_{FssHH}(f)\exp(-k_{zss} f D_{hl} / U_H)df \Big/ \int_0^\infty S_{FssHH}(f)df \tag{16}$$

where σ^2_{sshh}, σ^2_{ssll} and σ^2_{sshl} are the variances and covariances of the forces $F_{sh}(t)$ and $F_{sl}(t)$. Having stated this, the marginal distribution of k_{zss} can be chosen as to result in a uniform distribution of the correlation coefficient between the floor loads at a selected distance D. In Equation (16), S_{FssHH} can be obtained by imposing the equilibrium of the moments at the base of the building. Considering for instance $s = x$, the relation

$$S_{Myy}(f) = \int_0^\infty \int_0^\infty S_{Fxxhl}(f) z_h z_l dz_h dz_l = \frac{S_{FxxHH}(f)}{H^{2\gamma_x}} \int_0^\infty \int_0^\infty z_h^{\gamma_x+1} z_l^{\gamma_x+1} \exp\left(\frac{-k_{zss} f |z_l - z_h|}{U_H}\right) dz_h dz_l \tag{17}$$

can be used to estimate S_{FxxHH} from the knowledge of the spectrum S_{Myy}. Analogous equations hold for the other components. It should be noted that the relation between the correlation coefficient and k_{zss} depends also on the value of γ_s, but this dependency is extremely weak and can therefore be neglected [17]. The choice of a uniform distribution for r_{sshl} ensures an impartial description of the unknown correlation between the forces, for which precise statistical information is extremely scarce. The proposed model for the marginal distribution of k_{zss} depends on D: it is suggested that this should be taken within the same order of magnitude of the average integral turbulence scales of the oncoming unsteady flow [12]. Considering the marginal distributions for the parameters k_{zsp}, with $s \neq p$, that govern the decay of the correlation between two floor loads acting in different directions, the simplest possibility is to assume their values as intermediate between k_{zss} and k_{zpp}. In this way, the k_{zsp} cease to be independent random variables. More in-depth studies on the nature of the cross-correlation between forces acting in different directions would be necessary in order to establish a more sophisticated model for these parameters.

Analogously to the k_{zsp}, the γ_s have a well-defined physical meaning: as their value passes from -1 to ∞ the energy of the floor loads progressively moves from the bottom to the top of the structure. Having said this, physically meaningful marginal distributions of the components γ_s can be obtained by imposing a suitable distribution of the value of the auto-spectrum S_{Fsshh} for each frequency (or of the floor load variance σ^2_{sshh}) at a fixed height $0 < z_d < H$. Exploiting indications in the literature concerning the most probable ranges of values for the floor load variances (normalized to the value at the top of the building), in [12] the authors suggested to assume for the floor load variance σ^2_{sshh} a PDF with uniform value between $\sigma^2_{sshh}(\gamma_s = 0)$ and $\sigma^2_{sshh}(\gamma_s = 0.5)$, and decreasing values outside this region. This leads to a distribution for the parameter γ_s which is well approximated by a lognormal distribution with mode = 0 and standard deviation of the associated normal distribution σ = 0.62. Further details on this model can be found in [12].

4 APPLICATION OF THE PROPOSED APPROACH TO A CASE STUDY

4.1 *Case study*

The Bank of China building, Hong Kong, is considered as a case study (Fig. 1). The footprint is square with a side of 52 m and the top floor height is 286 m. The geometry is irregular, with coupled and non-linear mode shapes (Fig. 1c): this is particularly interesting for the proposed application due to the fact that the use of the HFFB technique in presence of irregular shape and mode coupling can determine significant errors in the estimates of the floor loads [6]. Specific wind tunnel tests were carried out [16] using 126 pressure taps measuring synchronously the surface pressure for various wind directions, ranging from 0° to 360° with 10° increments, with a wind speed of 16 m/s and a sampling frequency of 250 Hz. The model length scale was 1/500.

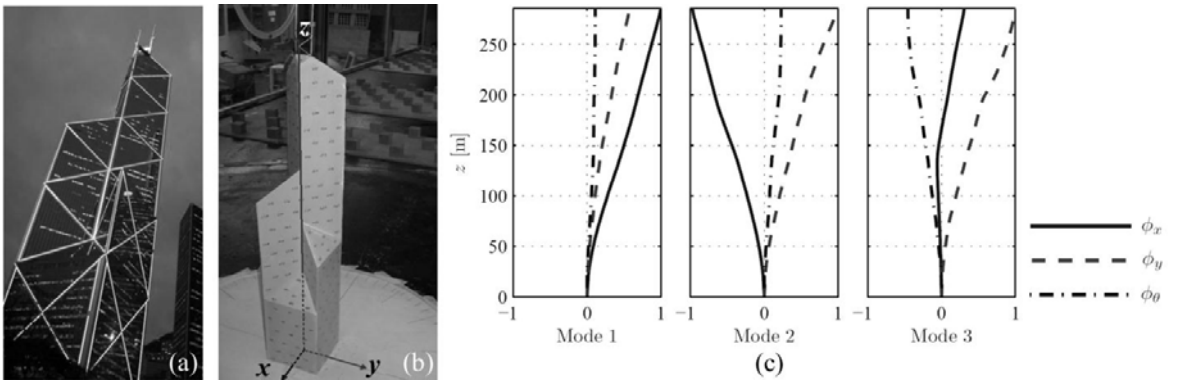

Figure 1. Bank of China building, Hong Kong (a); building model in the wind tunnel (b); mode shapes, with torsional component multiplied by 10 (c).

The pressures were then integrated to obtain virtual base moment measurements; the HFFB technique with the MSC scheme presented in [2] and the approach proposed in this paper were then applied to this virtual set of data to estimate the response parameters. The knowledge of the pressures allowed a reference solution to be determined, to which the approximated results obtained through the HFFB techniques can be compared. The response parameters which are taken into consideration are the top floor acceleration and displacement in the corner at (x_c, y_c) = (-26 m, 26 m). The results are referred to a wind speed of 55 m/s at prototype scale.

4.2 *Results*

For this application the random parameters γ_x, γ_y and γ_θ are assumed fully correlated. Also k_{zxx}, k_{zyy} and $k_{z\theta\theta}$ are assumed fully correlated, with zero correlation between the γ_s and the k_{zsp}. The following values have also been assumed: $D = H/8$, $c_{L,max} = 1.6$, $c_{L,min} = 1$, $c_{Cmax} = -c_{C,min} = 0.8$.

Figure 2 shows a complete overview of the conditional PDFs obtained for the peak values of the response. It is seen that both their mean and their standard deviation vary strongly with the wind angle, according to the directional behavior of the building. For the acceleration (Fig. 2(b)), a bigger spread is seen in the values of the standard deviation of the density functions, than for the displacements (Fig. 2(a)). This can be ascribed to the fact that the resonant response marginal distributions tend to have strong variations for different wind directions.

It is interesting to compare the proposed approach to traditional methodologies (i.e. the MSC approach) and to the reference solution. Figure 3 shows, for $\alpha = 300°$ and $U_H = 55$ m/s, the value of the fragility calculated for different intensities of the peak response. The reference solution is obtained considering the reference (deterministic) value of the standard deviation and of the mean. The solution obtained with the "traditional approach" has been determined through the use of the MSC approach of [2] for the standard deviation and with the approach proposed in [13] for the mean. In all cases the PDF for the peak factor is obtained through Equation 8. The presence of the aerodynamic uncertainties in the proposed approach causes the exceedance probability curve to be softer than the others, where only the uncertainties due to the aleatory nature of the wind loads are taken into account. For different wind directions, while the curves obtained with the traditional approach are not always close to the reference curves, and often lie on the unsafe side, for the proposed approach there is always a value of the fragility which is sufficiently low to give a conservative value of the peak response parameter. This is better seen from Figure 4, where the values of the peak response parameters are plotted for all wind angles and $F = 10\%$.

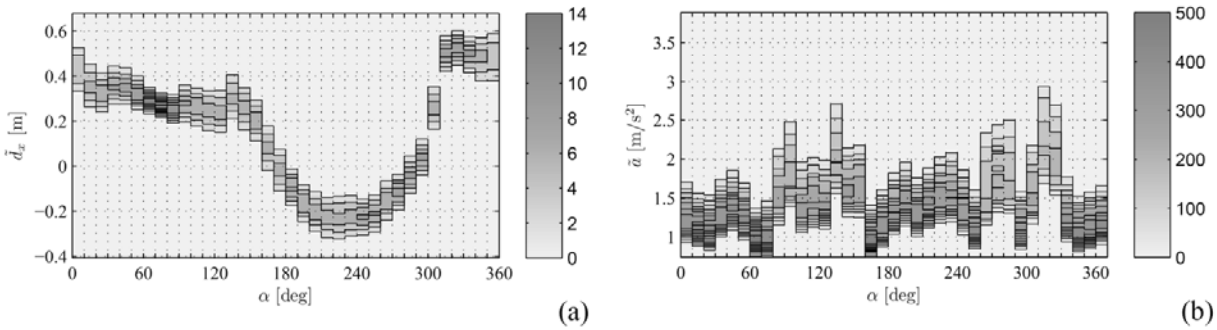

Figure 2. Estimated conditional PDFs of the peak values of the top floor *x*-displacement (a) and acceleration (b), for all wind angles and U_H = 55 m/s.

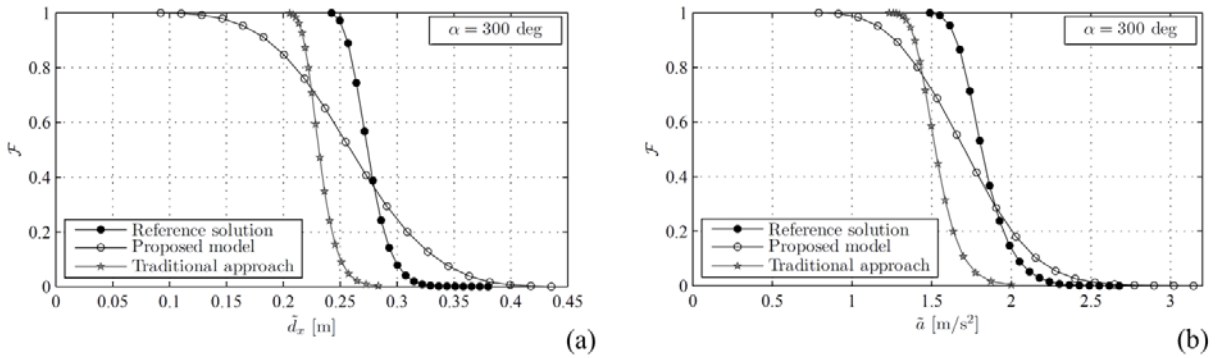

Figure 2. Fragility corresponding to different level of peak response for top floor corner *x*-displacement (a) and acceleration (b), for α = 300° and U_H = 55 m/s.

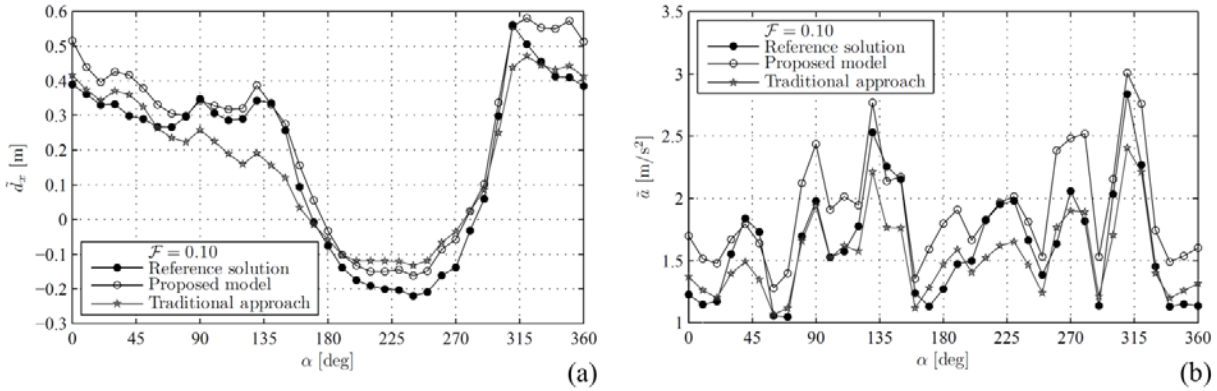

Figure 2. Value of the peak response of the top floor corner x-displacement (a) and acceleration (b) for all wind direction, U_H = 55 m/s and F = 0.10.

5 CONCLUSIONS

In this paper a new method for the estimation of the dynamic response of tall buildings based on HFFB measurements is presented. The methodology is set within a performance-based design framework and attempts to overcome the two fundamental shortcomings of the HFFB method, that is the necessity of making assumptions on the unknown floor loads spectral structure (that introduce aerodynamic uncertainties in the estimated responses) and the impossibility of taking into account higher mode contributions and mean values in the response estimates.

A novel probabilistic approach has been proposed for the assessment of the mean response. Also, for the dynamic response, a new model for the floor load spectral structure has been presented, that gives the possibility of including any number of modal contributions. Both models depend on a limited number of physically meaningful random parameters. By probabilistically modeling the random vector collecting these parameters, the propagation of the aerodynamic uncertainties to the response was achieved. A procedure for the probabilistic characterization of the random vector was presented that, being based on the physical meaning of the governing parameters, results to be independent of the mechanical and aerodynamic performance of the building under consideration. A novel fragility model incorporates both the modeled aerodynamic uncertainties and the aleatory nature of the wind load in the estimation of the peak responses.

An application of the model to a case study building with non-linear coupled modes was presented in terms of the exceedance probabilities of peak responses. A comparison to the traditional approach was made demonstrating the importance of the inclusion of aerodynamic uncertainties in the peak response estimation and the effectiveness of the proposed approach in providing safe design values for the response parameters.

The effects of freestream turbulence on wind-induced responses of tall buildings

Gang Hu, Q. S. Li

Department of Civil and Architectural Engineering, City University of Hong Kong, Tat Chee Avenue, Kowloon, Hong Kong

ABSTRACT: The turbulence characteristics of natural winds are usually described by turbulence intensity, turbulence scale, and wind velocity spectra. Turbulence intensity reflects fluctuations of wind velocity, which is affected by the degree of surface roughness of the earth. One of the most widely used scales is the integral length scale which is a representation of the average size of the most energetic turbulent eddies. In this paper, three tall buildings with different heights and typical height/width ratios are chosen to investigate the effects of turbulence integral length scale on along-wind responses of the tall buildings. Discussions on the influences of turbulence intensity to the along-wind structural responses are also presented. The results of this study indicate that as turbulence integral length scale increases, the along-wind responses of the tall buildings decrease while the along-wind responses increase obviously with the growth of turbulence intensity.

KEYWORDS: turbulence characteristics; turbulence integral length scale; turbulence intensity; tall building; along-wind response; wind spectra

1. INTRODUCTION

Wind flow in the atmospheric boundary layer of the earth is highly turbulent. As a result, wind loads acting on buildings and structures are significantly influenced by turbulence characteristics. Turbulence integral length scale and turbulence intensity are two main parameters to describe the characteristics of natural wind. Turbulence integral length scale is the measure of average size of the vortices. For wind flows, there are three turbulence integral length scales in three directions (longitudinal, lateral and vertical directions), namely, L_u^x, L_u^y, L_u^z, and they are often expressed as $L_u^y \approx 0.3-0.4L_u^x$, $L_u^z \approx 0.5-0.6L_u^x$ (Counihan 1975). Turbulence intensity is the ratio of the standard deviation of fluctuating component to the mean value of wind velocity. It is related to the surface roughness of the ground. Turbulence integral length scale and turbulence intensity can be defined as follows.

$$L_u^x = \frac{1}{\sigma_u^2}\int_0^\infty R_{u_1u_2}(x)dx \tag{1}$$

$$I_u = \sigma_u / \bar{U} \tag{2}$$

$R_{u_1u_2}(x)$ is the cross-correlation function of fluctuating wind speed component u at two points. σ_u is the standard deviation of wind speed, and $\bar{U}$ is mean wind speed. In boundary layer wind tunnel testing, how to control the value of turbulence integral length scale is a difficult problem. Varshney and Poddar (2011) conducted an investigation on controlling turbulence integral length scale values in a wind tunnel and showed that the integral length scale can be controlled using different combinations of passive devices. However, it is difficult or impossible to generate wind

flows with sufficiently large values of turbulence integral length scale in wind tunnels, even active devices are adopted.

During the past several decades, many researchers have conducted wind tunnel studies on the effects of turbulence on bluff bodies. Lee (1975a) reported that addition of turbulence to the flow causes an increase of base pressure and reduction of the drag of a two-dimensional square cylinder. His experiments showed the strength of the vortex shedding reduces as the growth of turbulence intensity. Lee (1975b) also investigated the effects of turbulence integral length scale on mean forces of square prisms and indicated that the mean drag is sensitive to the variation of turbulence scale when it is around the body size. In addition, at high values of turbulence integral length scale the drag tends to a constant value greater than that at low values. Tieleman and Akins (1990) analyzed the effects of incident turbulence on pressure distributions on rectangular prisms. Their results showed that the pressure coefficients on the side and rear faces of the prisms vary primarily with the energy associated with the small scale turbulence in the incident flow. Laneville (1990) investigated the effect of turbulence scale ratio on pressure coefficients of two dimensional square cylinders, finding that when turbulence scale ratio is larger than three, the turbulence scale effect on mean drag is evident and the magnitude of this effect is about 12%. Nakamura (1993) pointed out that turbulence intensity and turbulence integral length scale have significant effects on pressure coefficients on bluff bodies.

Besides the above studies carried out by wind tunnel experiments, other methods such as full-scale measurements, CFD and structural dynamic analysis were also applied to investigate the wind effect on tall building. It has been recognized that the most reliable evaluations of wind effects are obtained from measurements of prototype buildings. Li et al. (1998, 2004a, 2004b, 2005, 2006), Campbell et al. (2005), among others, have carried out full-scale measurements of wind effects on tall buildings. These investigations provided important validation of design procedures as well as examined structural behavior of tall buildings under wind actions. On the other hand, CFD method becomes more and more attractive to study wind effects on tall buildings (Swaddiwudhipong and Khan 2002; Huang et al. 2007; Tominaga et al. 2008; Braun and Awruch 2009; Huang et al. 2011; Hang and Li 2012) because of low cost compared with wind tunnel testing. In fact, CFD and structural dynamic analysis can overcome the limitations of generating wind flows with sufficiently large values of turbulence integral length scale. Therefore, structural dynamic analysis method is adopted in this paper to investigate the effects of freestream turbulence on wind-induced responses of tall buildings.

2. RELEVANT FACTORS AFFECTED BY TURBULENCE CHARACTERISTICS

Nakamura (1993) indicated that turbulence intensity and integral scale have remarkable effect on pressure coefficients on bluff bodies and concluded that absolute value of base pressure increases with integral scale for 3D square rod, as shown in Fig.1. The effect of turbulence intensity on drag coefficients on bluff bodies has been investigated in the past. The relation of turbulence intensity and drag coefficients (Simiu and Scanlan, 1996), as shown in Fig. 2, is employed in this study. The relationship between base pressure coefficient and drag coefficient is expressed in Eq. (3) (Petty 1979; Laneville 1990).

$$C_D = 0.9 - 0.82C_p \tag{3}$$

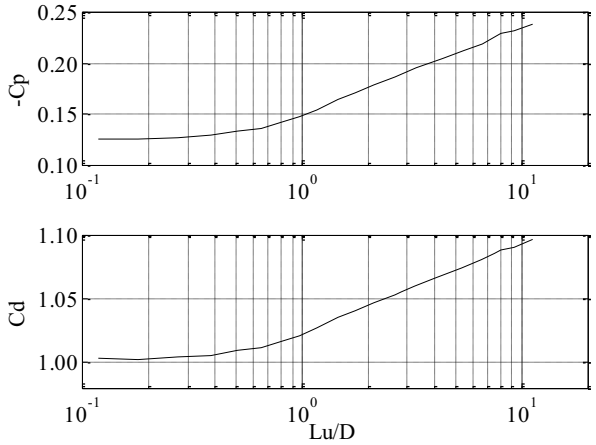

Figure 1. Pressure coefficient vs. turbulence integral scale

It can be seen from Fig. 1 that drag coefficient increases with turbulence integral scale significantly. The growth of drag coefficient will result in larger along-wind responses of

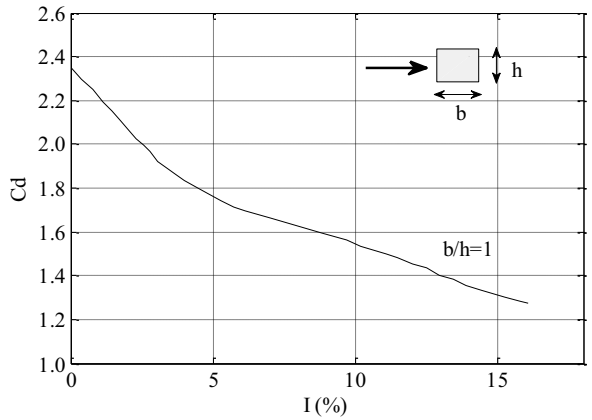

Figure 2. Drag coefficient vs. turbulence intensity (Simiu and Scanlan 1996)

tall buildings. Conversely, the increased turbulence intensity reduces the drag coefficient greatly, which will ultimately lead to the reduction of along-wind response of tall buildings.

In the computation of responses of long-span structures and high rise structures, spatial correlation of wind pressure cannot be ignored. For long-span structures, horizontal spatial correlation should be considered, and vertical spatial correlation can be neglected. On the contrary, for high rise structures, vertical spatial correlation must be taken into account, but horizontal spatial correlation may be ignored. Correlation coefficient ρ is the measurement of spatial correlation. Several empirical formulas for describing the correlation have been proposed. For example, Davenport (1967) presented a correlation function which is related to frequency n and distance between two points as follows:

$$\rho_{zz'}(z,z',n)=\exp(-C_z\frac{n\left|z-z'\right|}{\bar{v}_z})$$
$$\rho_{xx'}(x,x',n)=\exp(-C_x\frac{n\left|x-x'\right|}{\bar{v}_x}) \quad (4)$$

where C_z=7, C_x=8. These two formulas have considered several factors, such as frequency n, distances of two points and average wind speeds, but without turbulence integral scale. The following formulas include the effect of turbulence integral scale on correlation coefficient (Zhang, 2006).

$$\rho_z(z,z') = \exp(-\frac{|z-z'|}{L_z})$$
$$\rho_x(x,x') = \exp(-\frac{|x-x'|}{L_x}) \quad (5)$$

where L_z and L_x are vertical and horizontal turbulence integral scale, respectively. The relationship between correlation coefficient of two points with distance of 50m and turbulence integral scale is shown in Figure 3.

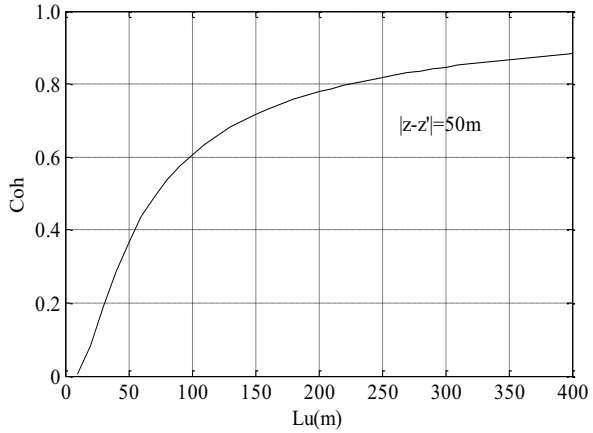

Figure 3. Correlation coefficient vs. turbulence integral scale

From Fig. 3, it can be seen that the correlation coefficient increases as turbulence integral scale increases. It is well known that the strengthening of correlation will lead to the increase of along-wind responses of tall buildings. In other words, an increase of turbulence integral scale may increase the along-wind responses.

Wind velocity spectrum varied with turbulence integral scale and turbulence intensity has significant effects on the wind-induced responses of tall buildings. There are many formulas that have been proposed to describe wind velocity spectrum. One of the widely-used wind velocity spectra was proposed by Von Karman, which is expressed as:

$$\frac{nS_u(n)}{\delta_u^2} = \frac{4\frac{nL_u}{u}}{\left[1+70.8\left(\frac{nL_u}{u}\right)^2\right]^{5/6}} \quad (6)$$

where n is the frequency; $S_u(n)$ is the power spectrum of wind velocity; δ_u is the standard deviation of fluctuating velocity; u is mean wind speed. L_u is the turbulence integral length scale. The variation of the wind velocity spectrum with turbulence integral length scale is presented in Fig. 4. In general, the fundamental frequencies of tall buildings arrange from 0.1 Hz to 2.0 Hz. Fig. 4 shows that the curves of the spectra shift to the left as turbulence integral scale increases, which means that the power of wind spectrum around fundamental frequencies reduces with the growth of integral scale. Thus, from this perspective, the increase of integral scale will result in the reduction of the along-wind responses of tall buildings.

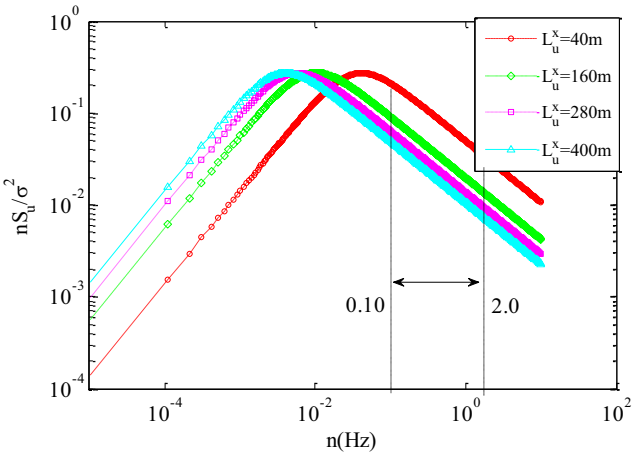

Figure 4. Von Karman spectra with different turbulence integral scales

Another form of Von Karman spectrum involved turbulence intensity is expressed as follow:

$$\frac{nS(z,n)}{v_*^2} = 0.475\beta(z)\frac{x}{(1+x^2)^{5/6}}$$
$$x = \frac{nL_x}{v}, L_x = \frac{vS(z,0)}{0.475\sigma_{vf}}, \sigma_{vf} = \beta(z)v_*^2, \beta(z) = \frac{(I\overline{v})^2}{v_*^2}, v_*^2 = K\overline{v}_{10}^2 \quad (7)$$

where L_x is turbulence integral length scale, I is turbulence intensity. In order to consider the effect of turbulence intensity on wind velocity spectrum, L_x and v_{10} are assumed as constants. The wind spectra with different turbulence intensities are plotted in Fig. 5. As turbulence intensity increases, the wind velocity spectra shift up. This illustrates the increasing power of wind spectra. Therefore, the addition of turbulence intensity will result in the growth of the along-wind responses of tall buildings.

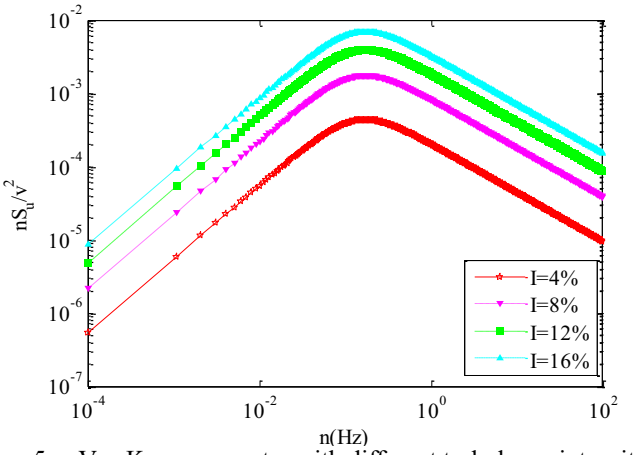

Figure 5. Von Karman spectra with different turbulence intensity

The effects of turbulence on drag coefficient, correlation coefficient and wind velocity spectrum have been discussed. The increase of turbulence integral length scale leads to the growth of drag coefficient and correlation coefficient, which will cause larger along-wind responses of tall buildings. Conversely, in the major frequency range of wind actions on tall

buildings (from 0.1 Hz to 2.0 Hz), the power of wind velocity spectrum reduces significantly as turbulence integral length scale increases, which will result in the reduction of the along-wind structural responses.

So, what on earth is the overall effect of turbulence integral length scale on the along-wind responses of tall buildings? This problem will be investigated in this paper through a detailed structural dynamic analysis. Similarly, the addition of turbulence intensity causes the decrease of drag coefficient but the increase of power of wind spectrum. The former will reduce the along-wind responses of tall building while the latter will increase the responses of tall buildings. This contradiction induces the uncertainty of the effect of turbulence intensity on the along-wind responses of tall buildings, which will also be investigated in this paper.

3. ALONG-WIND RESPONSES OF TALL BUILDINGS

A tall building can be simplified as a Multi-Degrees of Freedom (MDOF) System, the motion equation of a MDOF system subjected to random wind loads is:

$$[M]\{\ddot{y}\}+[C]\{\dot{y}\}+[K]\{y\}=\{F(t)\} \tag{8}$$

where [*M*], [*C*] and [*K*] are $N\times N$ order matrices of mass, damping and lateral condensed stiffness of the structure in along-wind direction. (*N* is the number of the total stories of a building). Since the order of the matrices defined in the above equation is high, the mode superposition method is used for evaluation of wind-induced response of a tall building. Assuming only the lowest N_k modes are considered in the computation, then the structural displacement vector $\{y\}$ is decomposed into

$$\{y\}=[\phi]\{q\}=\sum_{k=1}^{N_k}\{\phi_j\}q_k \tag{9}$$

where $[\phi]$ is the $N\times N_k$ mode shape matrix corresponding to the lowest N_k vibration modes. $\{q\}$ is the generalized displacement vector and q_k is the *k*-th component of vector $\{q\}$.

The power spectrum density (PSD) of the displacement responses at the location of the *i*-th floor (lumped mass) of the building would be

$$S_{yy}(y_{i,}\omega)=\sum_{j=1}^{N_k}\sum_{k=1}^{N_k}\phi_{ij}\phi_{ik}H_j^*(\omega)H_k(\omega)S_{f_jf_k}(\omega) \tag{10}$$

where

$$S_{f_jf_k}(\omega)=\frac{1}{M_j^*M_k^*}\sum_{i=1}^{N}\sum_{l=1}^{N}\phi_{ij}\phi_{lk}S_{F_iF_l}(\omega) \tag{11}$$

$S_{F_iF_l}(\omega)$ is the cross-PSD function of the local along-wind or across-wind load. The frequency response function $H_k(\omega)$ of the *k*-th vibration mode is

$$H_k(\omega)=(\omega_k^2-\omega^2+2i\xi_k\omega\omega_k)^{-1}, i=\sqrt{-1} \tag{12}$$

For tall building structures, the damping ratio is relatively small and the frequency response function distributes sparsely in the frequency domain, therefore the cross-correlation terms in Eq. (10) are usually neglected, which leads to the following approximate expression of Eq. (10)

$$S_{yy}(y_{i,}\omega)=\sum_{k=1}^{N_k}\phi_{ik}^2\left|H_k(\omega)\right|^2\frac{1}{(M_k^*)^2}\sum_{j=1}^{N}\sum_{l=1}^{N}\phi_{jk}\phi_{lk}S_{F_jF_l}(\omega) \tag{13}$$

The PSD of the acceleration response $\ddot{y}_i$ at the *i*-th floor (lump mass) of the building would be

$$S_{\ddot{y}\ddot{y}}(\ddot{y}_i,\omega)=\sum_{k=1}^{N_k}\omega_k^2\phi_{ik}^2\left|H_k(\omega)\right|^2\frac{1}{(M_k^*)^2}\sum_{j=1}^{N}\sum_{l=1}^{N}\phi_{jk}\phi_{lk}S_{F_jF_l}(\omega) \tag{14}$$

The RMS values of displacement response and acceleration response of a building structure would be

$$\sigma_{y_i}^2=\int_0^\infty S_{yy}(y_i,\omega)d\omega \tag{15}$$

and

$$\sigma_{\ddot{y}_i}^2=\int_0^\infty S_{\ddot{y}\ddot{y}}(\ddot{y}_i,\omega)d\omega \tag{16}$$

The along-wind load on each lumped mass can be expressed as

$$S_{F_{xi}F_{xj}}(z_i,z_j,f)=(\rho C_D)^2A_{z_i}A_{z_j}\overline{V}_{z_i}\overline{V}_{z_j}\sqrt{S_V(z_i,f)S_V(z_j,f)}Coh(z_i,z_j,f) \tag{17}$$

where $S_V(z_i, f)$ is the auto-power spectral density of the along-wind fluctuating wind speed, which can be represented by Von Karman spectrum.

4. VERIFICATION OF THE COMPUTATIONAL METHOD

For verification of the above method for calculating the along-wind responses of tall buildings, a typical rectangular building is chosen as a numerical example in this study. This rectangular tall building is a 30-storey steel structure with a cross-section area of $40m\times40m$ and $120m$ height, and the average mass density is approximate $187.5kg/m^3$. Wind tunnel test was carried out for this building to determine the wind forces on the building using pressure measurement technique, and the along-wind, across-wind and torsional responses of the building were calculated based on the model test results (Yoshida et al. 1992). The analytical model of the building for the dynamic analysis was simplified as a cantilever shear column with five lumped masses; each lumped mass has two translational degrees of freedoms (DOFs) in horizontal directions (X and Y direction) and one rotational DOF in vertical (Z) direction, as shown Fig.6. The vertical distribution of the lumped mass of this building is shown in Fig.6 (Yoshida et al., 1992). The fundamental natural frequency of this building is 0.336 Hz in the two translational directions. Damping ratio was assumed to be 1% for all the vibration modes (Wu and Li, 2008).

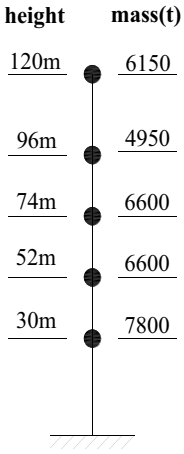

Figure 6. Simplified model of a tall building

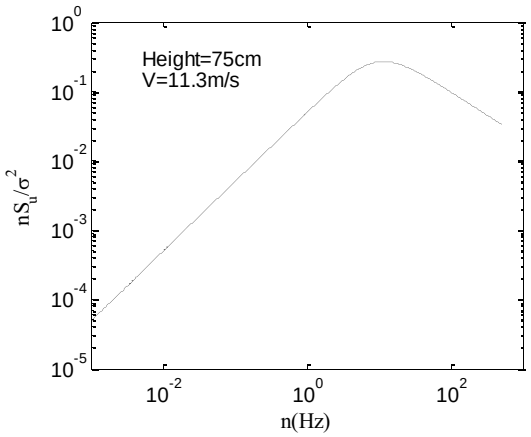

Figure 7. Power spectrum of wind speed in the wind tunnel testing

To examine the reliability of the computational method, two mean wind speeds atop the building, 20m/s and 30m/s, are chosen. The approaching wind direction is normal to one side of the square building. Comparison of the numerical predictions and wind tunnel test results are listed in table 1.

Table 1 Comparison between the numerical results and wind tunnel test results

Acceleration responses	$\sigma_{\ddot{y}}$ (gal)	
Wind speed	20m/s	30m/s
Numerical results	0.665	1.702
Wind tunnel results	0.620	1.913
Difference	7.26%	11.03%

As shown in table 1, the differences between the numerical results and wind tunnel test results are about 10%. Generally, such differences can be accepted in engineering practices, thus verifying the accuracy of the computational method.

5. EFFECTS OF TURBULENCE INTEGRAL LENGTH SCALE ON ALONG-WIND RESPONSES OF TALL BUILDINGS

To investigate the influences of turbulence integral length scale to the along-wind response of tall buildings, three square tall buildings with typical heights, 200m, 300m and 400m, are chosen as study objects, respectively. The models of the three tall buildings are simplified as cantilever shear columns with ten lumped masses; each lumped mass has two translational DOFs in horizontal directions and one rotational DOF in vertical direction. The average mass density is approximate 187.5kg/m^3, and the vertical distributions of the lumped mass of the buildings are shown in Fig. 8.

The fundamental natural frequency and mode shapes of the tall buildings can be calculated by the empirical formulas stipulated in the Chinese Load Code for The Design of Building Structures (2001). Damping ratio was assumed to be 1% for all the vibration modes. The parameters of these three buildings are listed in table 2.

Table 2 Parameters of three tall buildings

Height (H)	200*m*	300*m*	400*m*
Width (D)	40*m*	60*m*	80*m*
Fundamental frequency (f_1) (Hz)	0.200	0.133	0.100

Ten different values of turbulence integral scales at height of 30m above ground are chosen for the calculation, while L_u/D arranges from 1 to 10. In the computation, the variation of turbulence integral length scale with height was described by the empirical formula of AIJ Recommendations for Loads on Buildings (AIJ 2005). This code recommends the following formula.

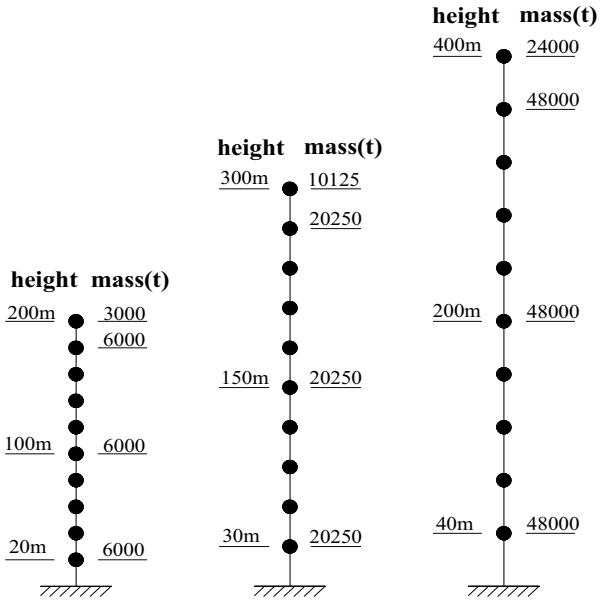

Figure 8. Three simplified models of the buildings

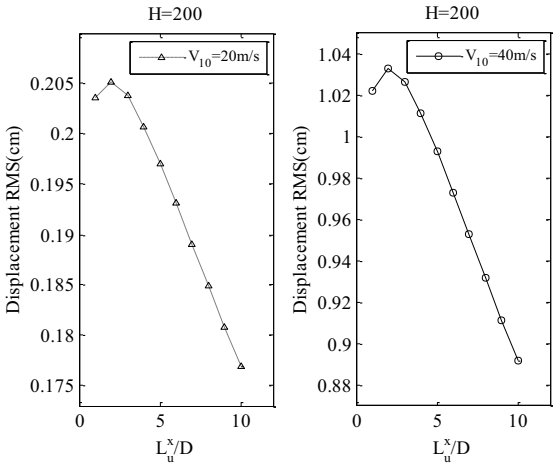
$$L_Z = \begin{cases} 100\left(\dfrac{Z}{30}\right)^{0.5} & 30\text{m}<Z \le Z_G \\ 100 & Z \le 30\text{m} \end{cases} \tag{18}$$

where Z (m) is height above ground; Z_G is a parameter determining the exposure factor. Turbulence integral length scale at one height calculated by this formula is a fixed value. However, the purpose of this paper is to discuss the variation of responses of tall buildings with various turbulence integral scales. So, different turbulence integral length scale profiles are required herein. In order to meet this requirement, the formula proposed by AIJ is modified as follows:

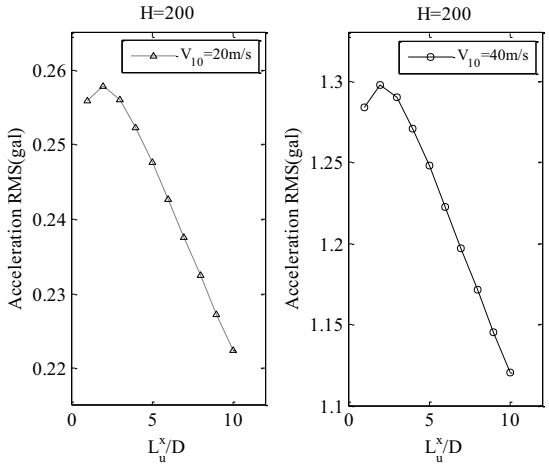
$$L_Z = L_{30}\left(\frac{Z}{30}\right)^{0.5} \tag{19}$$

where L_{30} is turbulence integral length scale at 30m. In this study, the values of L_{30}/D were selected to vary between 1 and 10, and then the integral length scale at other heights can be

calculated by this formula easily. Mean wind speeds at 10m height are supposed to be 20m/s and 40m/s, respectively. Based on the computational procedure presented previously, the along-wind responses of these three tall buildings are calculated, as shown in the following figures.

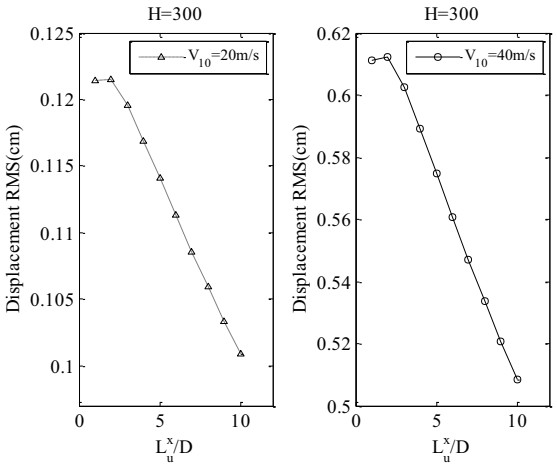


(a) Along-wind displacement responses

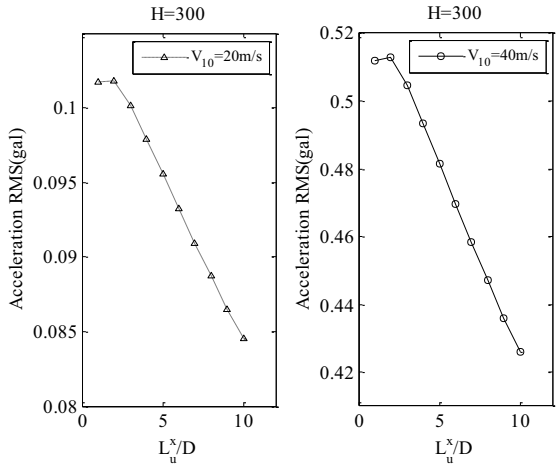


(b) Along-wind acceleration responses

Figure 9. Along-wind responses of a building (200m)

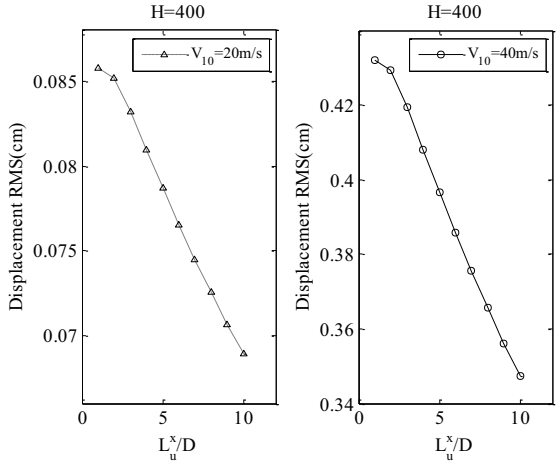


(a) Along-wind displacement responses

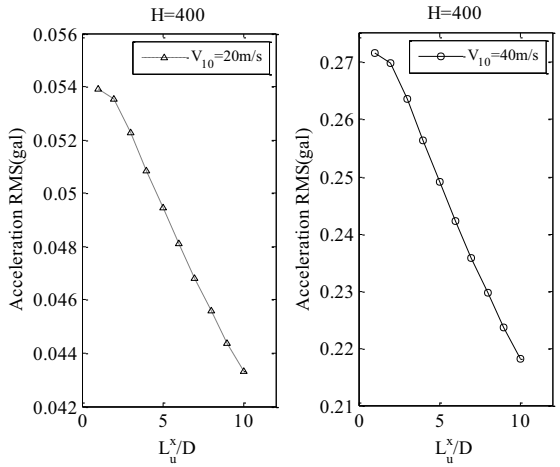


(b) Along-wind acceleration responses

Figure 10. Along-wind responses of a building (300m)



(a) Along-wind displacement responses



(b) Along-wind acceleration responses

Figure 11. Along-wind responses of a building (400m)

The above figures show the influences of turbulence integral length scale to the along-wind responses of three typical tall buildings with different heights under two wind speeds, namely,

20m/s and 40m/s. Fig. 9 presents the along-wind responses of a tall building where the building height is 200m. It can be seen from the figure that the along-wind responses increase with turbulence integral length scale when L_u/D is less than 2, then the responses reduce significantly with the increase of the integral scale when L_u/D is larger than 2. Similarly, Figs. 10-11 present the relationship between turbulence integral length scales and the along-wind responses of the tall buildings where the building heights are 300m and 400m, respectively. The effects of the integral scales on these two buildings are almost the same with those on the first building (200m). However, the uptrend of the structural responses when L_u/D is less than 2 becomes weaker gradually and eventually this uptrend is changed into downtrend as the building height increases. In conclusion, the along-wind displacement responses and acceleration responses decrease with the increase of turbulence integral length scale, although there are some uncertainties of small turbulence integral scales.

6. EFFECTS OF TURBULENCE INTENSITY ON ALONG-WIND RESPONSE OF TALL BUILDINGS

As discussed previously, the effects of turbulence intensity on drag coefficient and wind velocity spectrum are contradictory. Since these two factors have significant effects on the along-wind responses of tall buildings, it is necessary to examine the overall effects of turbulence intensity on the along-wind responses. Herein, turbulence intensities vary from 2% to 16%. Wind velocity spectrum employed in this study is Von Karman spectrum shown in Eq. (7). The relationship between turbulence intensity and drag coefficients is presented in Fig. 2. Based on the computational procedure given in section 3, the along-wind responses of the three tall buildings under wind actions with different turbulence intensities are shown in Figures 12-13 and Tables 3-4.

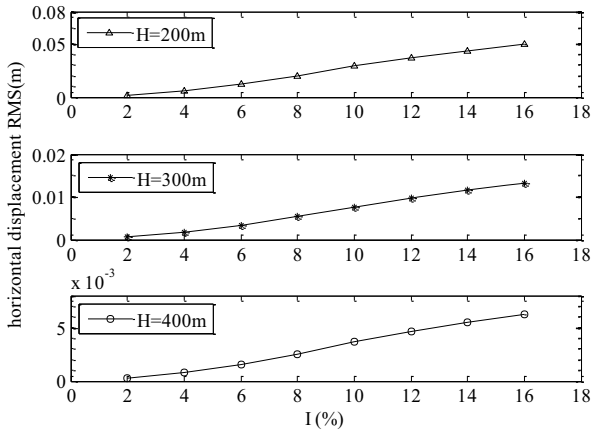


Figure 12. Along-wind displacements vs. turbulence intensities

Table 3 Along-wind displacements under different turbulence intensities

Along-wind displacements (cm)								
	Turbulence intensities							
Height(m)	2%	4%	6%	8%	10%	12%	14%	16%
200	0.2065	0.6385	1.2680	2.0230	2.8940	3.6470	4.3670	4.9740
300	0.0548	0.1694	0.3365	0.5369	0.7680	0.9679	1.1590	1.3200
400	0.0260	0.0804	0.1596	0.2547	0.3643	0.4591	0.5497	0.6261

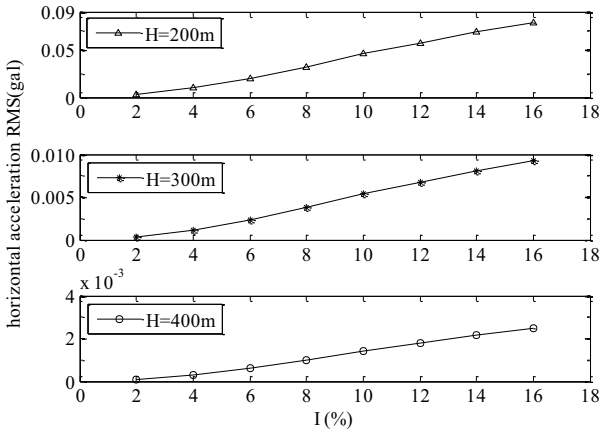

Figure 13. Along-wind accelerations vs. turbulence intensities

Table 4 Along-wind accelerations under different turbulence intensities

Along-wind acceleration (gal)								
	Turbulence intensities							
Height(m)	2%	4%	6%	8%	10%	12%	14%	16%
200	0.003261	0.01008	0.02003	0.03195	0.04571	0.0576	0.06897	0.07856
300	0.000384	0.00119	0.00236	0.00377	0.00539	0.0068	0.00813	0.00926
400	0.000103	0.00032	0.00063	0.00101	0.00144	0.0018	0.00217	0.00247

Fig. 12 shows that the along-wind displacements increase evidently as the addition of turbulence intensity. For the along-wind acceleration responses, there is the same trend as shown in Fig. 13. When turbulence intensity increases from 2% to 16%, the displacement and acceleration responses of the tall buildings raise almost 24 times. So, it is concluded that turbulence intensity has significantly effects on the along-wind responses of tall buildings.

7. CONCLUSIONS

The effects of turbulence on the along-wind responses of tall buildings have been investigated. It was found that turbulence integral length scale and turbulence intensity have significant effects on the along-wind responses of tall buildings. Some conclusions from this study are summarized below.

(1) Along-wind displacement responses and acceleration responses decrease with the increase of turbulence integral length scale, although there are some uncertainties of small turbulence integral scales.

(2) Along-wind displacement and acceleration responses increase evidently as the addition of turbulence intensity. Such effects are so remarkable that the responses rise almost 24 times when turbulence intensity increases from 2% to 16%. Consequently, the effects of turbulence intensity cannot be ignored in the determination of along-wind responses of tall buildings.

ABSTRACT: Tall buildings are particularly prone to dynamic excitations such as those from natural disasters like strong winds and earthquakes, and this has become an especially important design issue with manhattanization. One way to minimize wind-induced vibrations of tall buildings is to focus more on their shapes in the design stage. This paper investigates variations in along-wind and crosswind overturning moment coefficients, power spectral densities, and trajectories of various wind force coefficients.

KEYWORDS: Overturning moment coefficients, trajectories, power spectral densities

1 INTRODUCTION

Helical models of square cross-section have shown good performance based on both safety and habitability criteria (Tamura et.al., 2010). The effects of building plan shape on aerodynamic forces and displacement response have been studied for super-high-rise buildings with square and triangular cross-sections with corner modifications (Hayashida et.al., 1990). Aerodynamic modification of building shape, such as by changing the cross-section with height through tapering, alters the flow pattern around tall buildings, which can reduce wind-induced excitations (Kim et.al., 2002). Many researchers have tested wind pressures on buildings with irregular plans (Amin et.al., 2008), buildings with different rectangular cross-sections (Lin et al., 2005), tapered building models with taper ratios of 5% and 10%, and building models with set-back at mid-height (Kim et.al., 2010). However, there have been very few studies on the aerodynamic characteristics of triangular-cross-section tall buildings with various configurations. The objective of this study was to investigate the aerodynamic characteristics for various triangular section models.

2 EXPERIMENTAL SETUP

Wind tunnel tests were conducted in a boundary layer wind tunnel at the Wind Engineering Research Center, Tokyo Polytechnic University, Japan. The wind tunnel test section was 19m long with a cross-section 2.2m wide by 1.8m high. Equilateral triangle models with a side dimension of 0.076m and a height of 0.4m were used. All the models had the same volume, and Straight Triangle, Corner cut, Clover, 60^{o}Helical, 180^{o}Helical and 360^{o}Helical models were tested to identify their aerodynamic characteristics. These models are shown in Figure 1. The experiments were conducted for an urban (power–law exponent, α=0.27) flow. A length scale of 1/1000 and a

time scale of 1/167 were assumed. The Reynolds number was about 9.6 × 10^4. The coordinate system adopted for the calculations is shown in Figure 2.

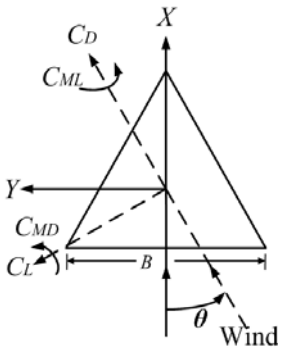

Figure 2. Coordinate system.

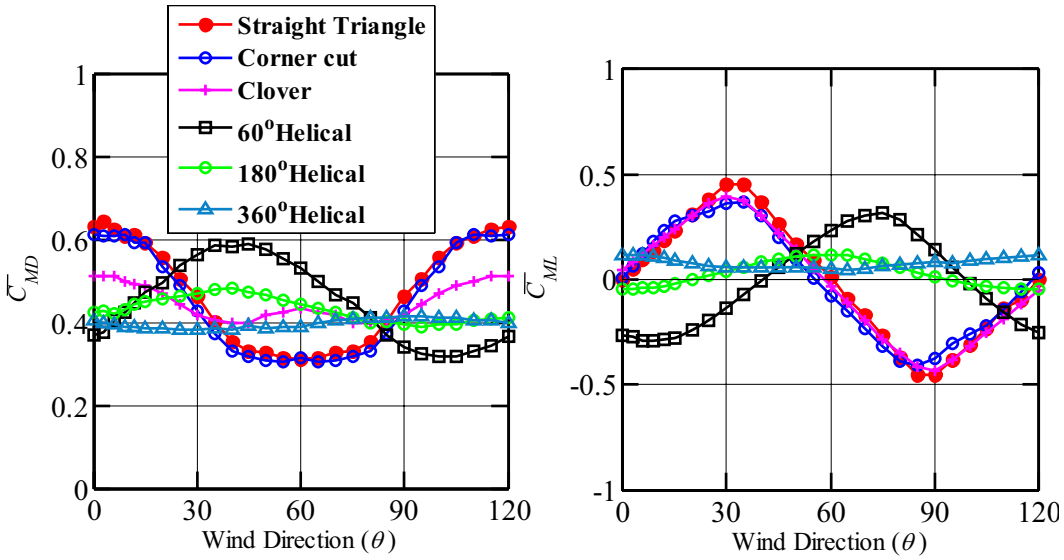
3 RESULTS AND DISCUSSIONS

3.1 *Mean overturning moment coefficients*

Overturning moment (OTM) coefficients in the along-wind and crosswind directions were calculated using the velocity pressure q_H at model height, width B and height H. Figure 3 shows the variation of mean along-wind OTM coefficient ($\overline{C}_{MD}$) and mean crosswind OTM coefficient ($\overline{C}_{ML}$) with wind direction (θ). $\overline{C}_{MD}$ values decrease and $\overline{C}_{ML}$ values increase as helical angle increases. The $\overline{C}_{MD}$ and $\overline{C}_{ML}$ values of the Corner cut model follow the same trend as the Straight Triangle model. The maximum and minimum values of $\overline{C}_{MD}$ for all the models are 0.64 and 0.3 for the Straight Triangle and Corner cut models. The maximum and minimum values of $\overline{C}_{ML}$ are 0.45 and -0.45 for the Straight Triangle model. For the 360° Helical model, the $\overline{C}_{ML}$ values are around 0.05~0.1 for all wind directions. The $\overline{C}_{ML}$ and $\overline{C}_{MD}$ values (around 0.1 and 0.4) for all the wind directions are almost constant for the 360°Helical model, as can be seen in Figure 3(b). For the Straight Triangle model, the minimum $\overline{C}_{MD}$ occurred at 60° wind direction and the curve is 'U'-shaped. Torsional moment coefficients are not discussed here in detail as these values were very small compared to the along-wind and crosswind force coefficients. They are almost 0 for the Straight Triangle, Corner cut and Clover models. The variation of mean drag and mean lift force coefficients were 1.2 and 0 for the Straight Triangle model at 0° wind direction, which is similar to the results of Kanda and Choi (1992).

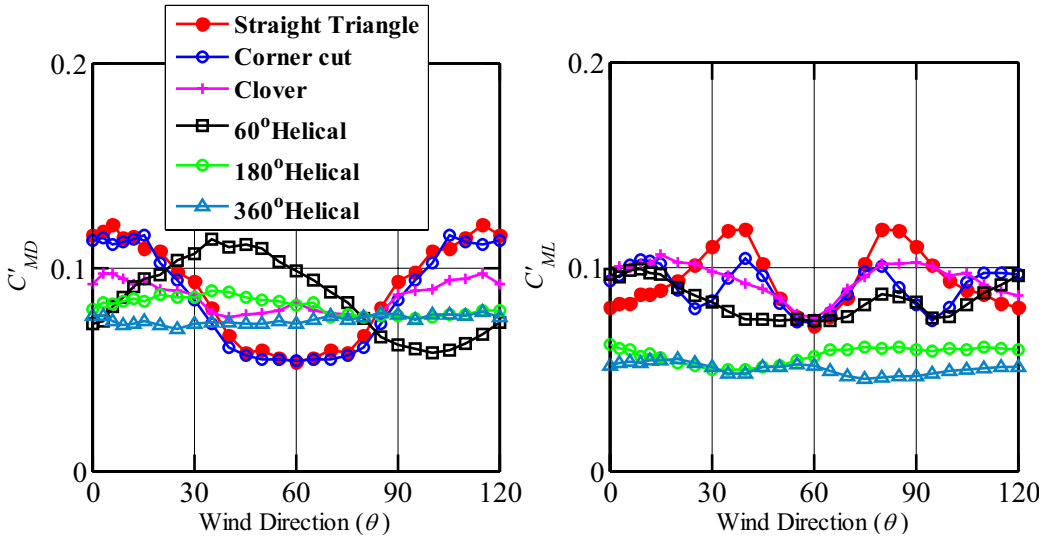


(a) Mean along-wind OTM coefficient (b) Mean crosswind OTM coefficient

Figure 3. Mean OTM coefficients.

3.2 *Fluctuating OTM coefficients*

Figure 4 shows the variation of fluctuating along-wind OTM coefficient (C'_{MD}) and fluctuating crosswind OTM coefficient (C'_{ML}) with wind direction (θ). For the 360°Helical model, the C'_{MD} values are almost 30% larger than the C'_{ML} values. The C'_{MD} and C'_{ML} values decrease as helical angle increases for the Straight Triangle model and the Helical models. The maximum and minimum values of C'_{MD} are 0.12 and 0.05 for the Straight Triangle model. The maximum and minimum values of C'_{ML} are 0.12 and 0.04 for the Straight Triangle and 360°Helical models. The maximum values of C'_{MD} and C'_{ML} are the same for the Straight Triangle model. The C'_{MD} and C'_{ML} values vary almost constantly for all wind directions for the 360°Helical model.



(a) Fluctuating along-wind OTM coefficient (b) Fluctuating crosswind OTM coefficient

Figure 4. Fluctuating OTM coefficients.

3.3 *Maximum fluctuating OTM coefficients*

Maximum fluctuating OTM coefficients in the along-wind and crosswind directions have been identified for all wind directions, as shown in Figure 5. The abscissa shows the various models. As it can be seen from Figure 5, the fluctuating OTM coefficients reduce as the helical angle increases in both the along-wind and crosswind directions. But in the along-wind direction, the maximum fluctuating OTM coefficient is almost the same as that for the Straight Triangle model. In the crosswind direction, the Clover model shows a slightly higher value than the Corner cut model.

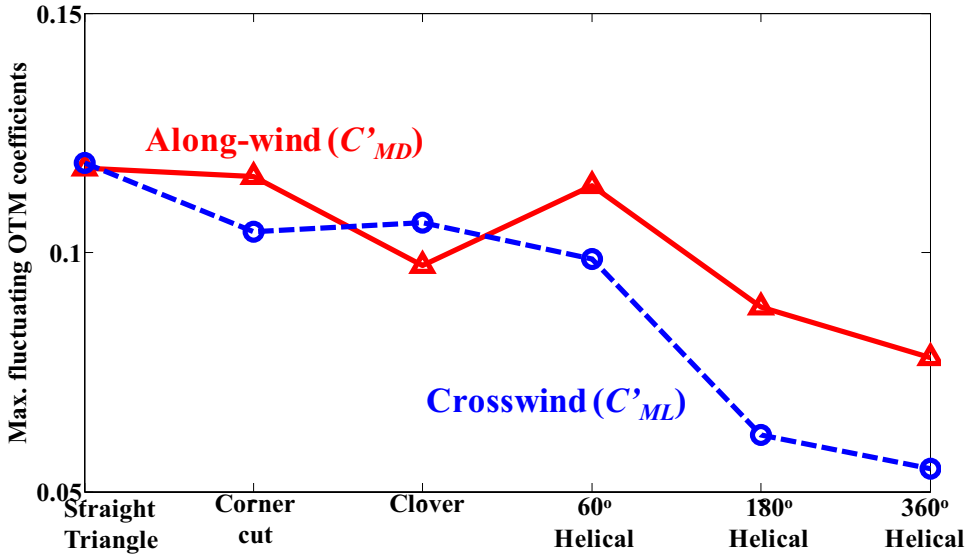


Figure 5. Maximum fluctuating OTM coefficients in along-wind and crosswind directions.

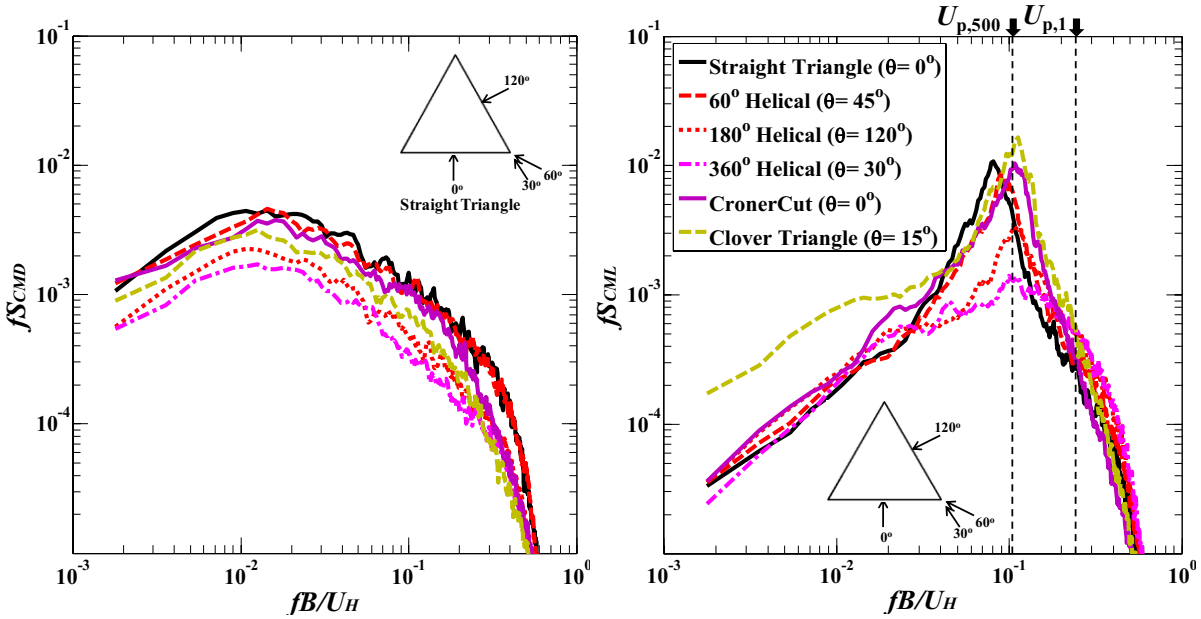
3.4 *Power spectral density for along-wind and crosswind OTM coefficients*

Figure 6(a) shows the along-wind power spectra, fS_{CMD}, for the wind directions corresponding to those where the maximum peak occurred for the crosswind spectra. Higher maximum peaks occurred for the Straight Triangle model than for all the other models. The 360°Helical model shows a smaller peak than the other models. Figure 6(b) shows the crosswind power spectra, fS_{CML}, for the wind directions at which the maximum peak occurred. The maximum peaks occurred for crosswind spectra at θ=0°, 0°, 15° 45°, 120° and 30° for the Straight Triangle, Corner cut, Clover, 60°Helical, 180°Helical and 360°Helical models. A sharp peak of crosswind spectrum is observed for the Straight Triangle, Corner cut and Clover models, but the maximum peak is observed for the Clover model. The sharp peak is reduced drastically for the Helical models as the helical angle increases, indicating that the shedding vortices are more disturbed than in the normal condition. As the helical angle increases, the peak shifts to higher reduced frequency ranges, and also the band width of the spectrum increases. But for the Corner cut and Clover models, the peak appears sharp and shifts towards slightly higher reduced frequency ranges than the Straight Triangle model.



(a) Along-wind direction (b) Crosswind direction

Figure 6. Power spectral densities of along-wind and crosswind OTM coefficients.

Figure 7 compares in detail the square root of crosswind power spectra for the design wind speeds corresponding to a 500-year return period ($U_{p,500}$) and a 1-year return period ($U_{p,1}$). Here, the first natural frequency is assumed to be f_1=0.1Hz, and the design wind speeds are assumed to be $U_{p,500}$=71m/s and $U_{p,1}$=30m/s, respectively, in the Tokyo region. Then, the corresponding spectral values were calculated. The largest values decreased as the helical angle increased corresponding to $U_{p,500}$, but the largest value is shown for the Clover model. For $U_{p,1}$, the largest values become smaller than those for the Straight Triangle model. The Corner cut model shows the smallest value of all.

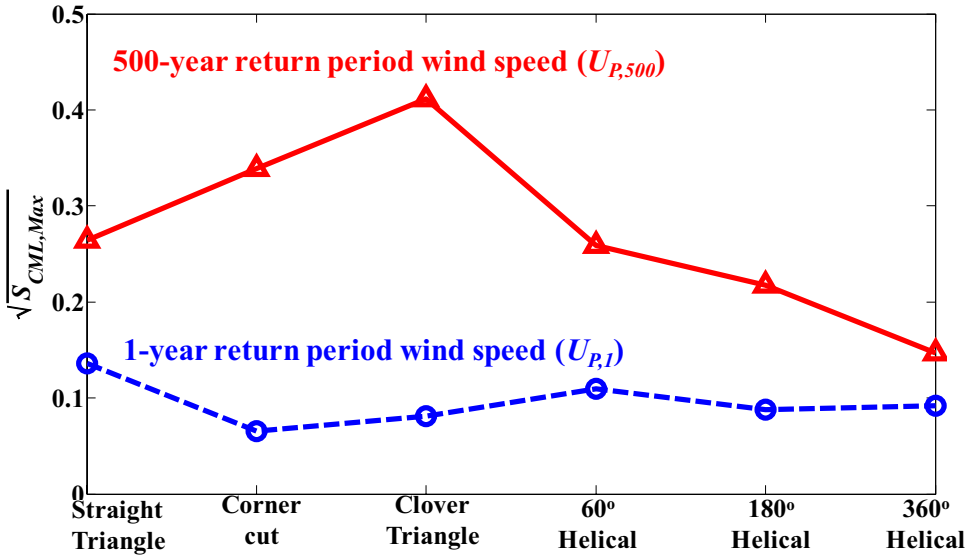


Figure 7. Peak spectral values in crosswind direction for 500-year and 1-year return periods.

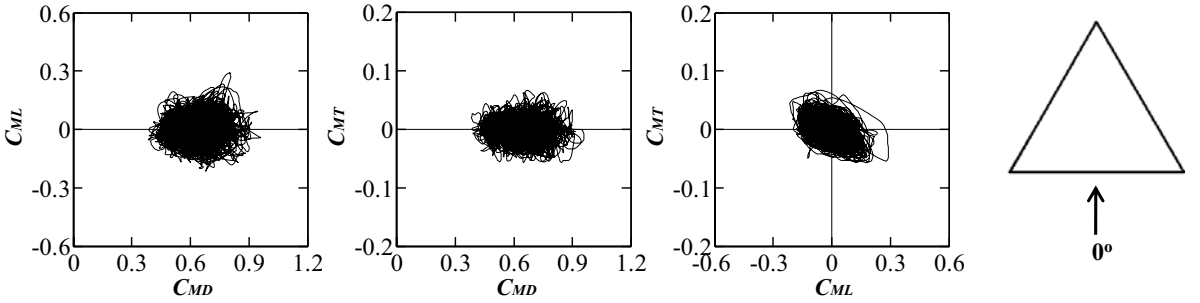
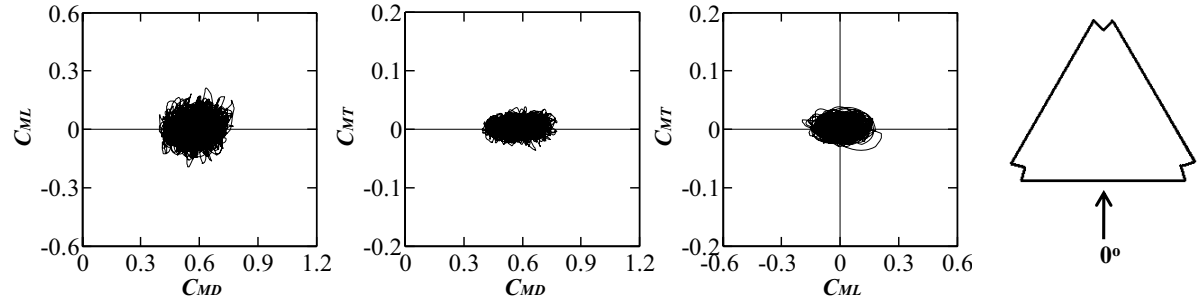
3.5 *Trajectories of OTM coefficients*

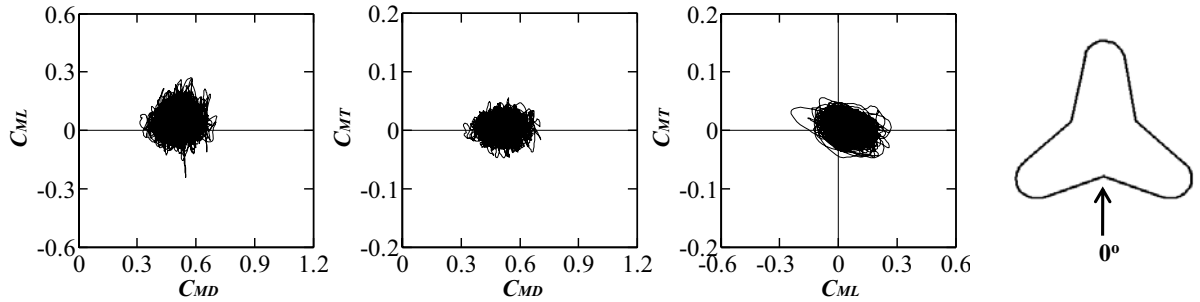
Figures 8(a)-(e) show the trajectories of various OTM's for the Straight Triangle, Corner cut, Clover, 180°Helical and 360°Helical models. The values in parentheses are the wind directions for which the trajectories were obtained. These wind directions were selected where $\overline{C}_{ML}$ is zero for easy comparison of trajectory shapes. The trajectory of C_{MD}-C_{ML} for the Straight Triangle model shows a circular shape, showing that there is no correlation between them, but sometimes we can see some correlation for C_{MD}-C_{ML} and C_{MD}-C_{MT}. The 60°Helical model shows almost the same trend as the Straight Triangle model. For the 180°Helical model, we can see a higher correlation between C_{ML}-C_{MT}. But for the 360°Helical model, the trajectory is elliptic with some inclination angle indicating high correlation for C_{MD}-C_{MT} and C_{ML}-C_{MT}. For the Corner cut model, the trajectory size reduces to less than that for the Straight Triangle model and shows some correlation between C_{MD}-C_{ML}.



(a) Straight Triangle (θ=0°)



(b) Corner cut (θ=0°)



(c) Clover (θ=0°)

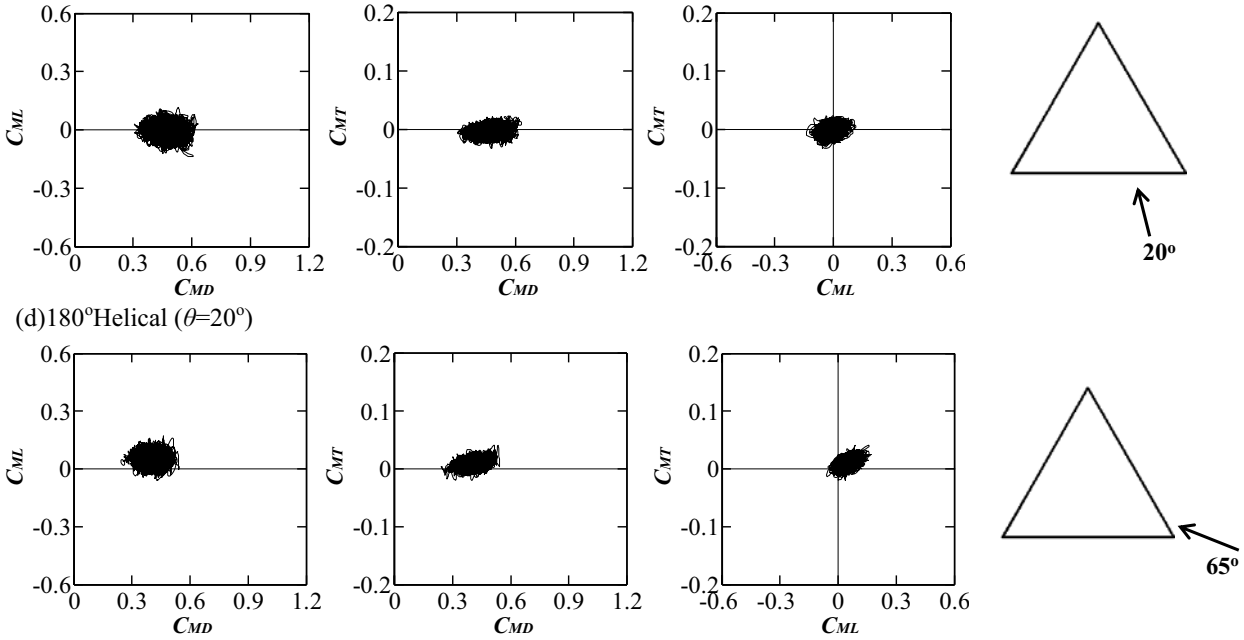


Figure 8. Trajectories of various wind force coefficients.

4 CONCLUSIONS

The aerodynamic characteristics of triangle section tall buildings with various configurations were investigated under urban flow conditions. The 360°Helical model showed lower values of C'_{ML} than all the other models. But, the Corner cut model showed a lower value than the Straight Triangle model in the crosswind direction. The maximum peak of the C_{ML} power spectra decreased as the helical angle increased, but the peak frequency shifted towards the higher reduced frequency ranges as the helical angle increased. The Clover model showed a larger peak than all the other models. The smallest crosswind spectral peak was shown for the 360°Helical model and the Corner cut model corresponding to $U_{p,500}$ and $U_{p,1}$. The 360°Helical model showed higher correlations for C_{MD}-C_{MT} and C_{ML}-C_{MT}.

Tall building response evaluation to nonstationary winds b ased on multiple simulated samples

Guoqing Huang [a], Xinzhong Chen [b]

[a]*School of Civil Engineering, Southwest Jiaotong University, Chengdu, China*
[b]*Department of Civil and Environmental Engineering, Texas Tech University, Lubbock, TX, USA,*

ABSTRACT: This paper presents a time-domain approach for estimating alongwind load effects on tall buildings using multiple wind speed time history samples, which are simulated from evolutionary spectra of nonstationary wind fluctuations using the method developed by the authors (Huang and Chen 2009). The influence of transient wind loads on various responses including time-varying mean, root-mean-square value and peak factor is also studied. Further, a simplified model is proposed to describe the nonstationary wind fluctuation as a uniformly modulated process with a modulation function as the time-varying mean. Finally, the extreme response and peak factor are quantified based on the upcrossing theory of nonstationary process.

KEYWORDS: nonstationary winds; evolutionary; time domain; tall building; response

1. INTRODUCTION

The nonstationary extreme winds are responsible for damages of many buildings and other structures in US and around the world (e.g., Choi 2004). Characterizing and modeling these extreme winds have drawn more attention from meteorological and wind engineering communities. Based on full-scale observations, Fujita (1985 and 1990) characterized downbursts with unique mean wind speed vertical profiles, rapid time varying mean wind speeds, and spatially strongly correlated wind fluctuations. The physical simulation of nonstationary winds has been conducted (e.g., Letchford and Chay 2002). Although it is difficult to gauge the downbursts on site due to its small temporal and spatial scales, and random occurrences, limited full-scale measurements were obtained by Gast and Schroeder (2003) and (Choi, 2004). More information about characterization and simulation of the downbursts can be found in literature (e.g., Holmes an Oliver 2000; Mason et al. 2009).

These nonstationary extreme winds after removing mean values can be modeled as random processes which are often characterized in terms of time-varying spectra. The evolutionary power spectra density (EPSD) functions (e.g., Priestley 1981) prevail in engineering practice, especially for applications in stochastic structural dynamics, in that EPSD functions have similar physical significance for nonstationary processes as the traditional power spectral density (PSD) functions for the stationary processes. The adequate estimation of EPSDs will be essential for characterization, modeling and simulation of these processes and their effects on structures.

With better time-frequency resolution over other tools such as Wigner-Ville method and short-time Fourier Transform, wavelets have been adopted to develop EPSD estimation of nonstationary processes for both scalar case (Spanos and Failla 2004) and vector case (Huang and Chen 2009). Huang and Chen (2009) also applied this approach to full-scale downburst winds (Gast and Schroeder 2003), and analyzed their nonstationary characteristics.

Compared to considerable research on wind effects on structures under stationary boundary layer winds, the understanding of nonstationary extreme wind effects such as thunderstorm downbursts has been less developed. Chen and Letchford (2004) studied the building responses

in the time domain using a single sample of downburst wind. Holmes et al. (2005) computed the dynamic response spectrum of single-degree-of-freedom (SDOF) structures excited by a thunderstorm wind, which is similar to the response spectrum widely used in earthquake engineering. Recently, Chen (2008) developed a frequency domain framework for quantifying tall building response caused by nonstationary winds using the evolutionary spectra. Kwon and Kareem (2009) presented a general gust-front factor framework for modeling transient wind load effects on structures. Simulation of nonstationary winds based on the estimated EPSD offers a new opportunity to evaluate the nonstationary wind effects on buildings and improve the understanding of the interaction between the nonstationary wind and the structure.

In this paper, a time domain analysis framework is employed for estimating tall building response to nonstationary winds. This framework involves estimation of EPSD of nonstationary wind speed based on the method proposed by Huang and Chen (2009), simulation of nonstationary wind time history using spectral representation method (e.g., Deodatis 1996), calculation of time history of wind load, and determination of response history by using the step-by-step integration method. From multiple response time histories, the time-dependent statistics such as RMS and extreme value of response are determined. The results are compared with those obtained from the frequency domain analysis (Chen 2008). Further, a simplified model of nonstationary wind fluctuation is proposed, and the resulting building response is addressed. The influence of transient nature of nonstationary winds on the extreme value of building response, gust response factor (GRF) and peak factor is also studied. Finally, the extreme and peak factor of building response are quantified based on the upcrosssing theory of nonstationary processes.

As compared to the time domain response analysis using single sample of wind record (e.g., Holmes et al. 2005), the analysis using multiple samples presented in this study will provide the statistical information of responses. The time domain simulation also facilitates consideration of nonlinearities of the structures and wind loads over the frequency domain analysis (Chen 2008).

2. TIME DOMAIN RESPONSE ANALYSIS FRAMEWORK

Consider the alongwind response of a tall building under a nonstationary wind. The wind speed at elevation z, $U(z,t)$, can be decomposed into the time varying mean and fluctuation as

$$U(z,t) = \bar{U}(z,t) + u'(z,t) \tag{1}$$

where $u'(z,t)$ is modeled as an evolutionary process and expressed as $u'(z,t) = \int_{-\infty}^{\infty} e^{i\omega t} d\Theta(z,\omega,t)$, in which $i = \sqrt{-1}$; ω is circular frequency; $d\Theta(z,\omega,t)$ is complex-valued zero-mean orthogonal increment random process with the following properties

$$\begin{aligned} &E[d\Theta(z,\omega,t)] = 0; \quad d\Theta(z,\omega,t) = d\Theta^*(z,-\omega,t); \\ &E[d\Theta(z_1,\omega_1,t)d\Theta^*(z_2,\omega_2,t+\tau)] = S_u(z_1,z_2,\omega_1,t)e^{i\omega\tau}\delta(z_1-z_2)\delta(\omega_1-\omega_2)d\omega_1 d\omega_2 \end{aligned} \tag{2}$$

where $E[\ldots]$ is expectation or ensemble average; * denotes the complex conjugation; $\delta(\ldots)$ is Dirac delta function; τ is time lag; $S_u(z_1,z_2,\omega_1,t)$ is the cross EPSD between $u'(z_1,t)$ and $u'(z_2,t)$; and $S_u(z,\omega,t) = S_u(z,z,\omega,t)$ is EPSD of $u'(z,t)$.

Following the strip theory, the alongwind force per unit height at z is quantified as the summation of the time varying mean component, $\bar{P}(z,t)$, and fluctuating component, $P'(z,t)$,

$$\bar{P}(z,t) = 0.5\rho C_D B \bar{U}^2(z,t); \quad P'(z,t) = \rho C_D B \bar{U}(z,t) \int_{-\infty}^{\infty} \chi_D(\omega) e^{i\omega t} d\Theta(z,\omega,t) \tag{3}$$

where ρ is the air density; B is the building width; C_D is the drag coefficient; $\chi_D(\omega)$ is the complex-valued aerodynamic admittance function.

For tall buildings, the wind-induced response is usually dominated by fundamental modal responses and higher mode contributions can be neglected. The time varying mean and fluctuating component of the generalized force, $Q(t)$, in the fundamental mode are computed by

$$\bar{Q}(t) = \int_0^H \bar{P}(z,t)\Phi(z)dz; \quad Q'(t) = \int_0^H P'(z,t)\Phi(z)dz \tag{4}$$

where $\Phi(z) = (z/H)^{\beta}$ is modal shape; H is building height; and β is exponent (1.0-to 1.5.

The EPSD of the $Q'(t)$ can be given as (Chen 2008)

$$S_{Q'}(\omega,t) = \int_0^H \int_0^H (\rho C_D B)^2 \bar{U}(z_1,t)\bar{U}(z_2,t)\left(z_1/H\right)^{\beta}\left(z_2/H\right)^{\beta}\left|\chi_D(\omega)\right|^2 S_u(z_1,z_2,\omega,t)dz_1dz_2 \tag{5}$$

The mean speed is assumed as $\bar{U}(z,t) = \bar{U}_0(z)d(t)$, where $\bar{U}_0(z)$ is the vertical profile and $d(t)$ is the modulation function. A power law profile, $\bar{U}_0(z) = U_{\max}\left(z/H\right)^{\alpha}$, is considered in this study, where α is the profile exponent, and $U_{\max}$ is the maximum wind speed on $\bar{U}_0(z)$, i.e., wind speed at building top. Based on the study by Chen (2008), wind profiles were found to have little influence on the fundamental feature of the building dynamic response to transient winds.

Accordingly, the mean generalized force is given by

$$\bar{Q}(t) = Q_R d^2(t)/(1+2\alpha+\beta); \quad Q_R = 0.5\rho C_D BHU_{\max}^2 \tag{6}$$

The EPSD of fluctuation, $u'(z,t)$, is assumed to be same, i.e., $S_u(z,\omega,t) = S_u(\omega,t)$.

The coherence function between $u'(z_1,t)$ and $u'(z_2,t)$ is assumed as

$$\mathrm{Coh}(z_1,z_2,\omega) = S_u(z_1,z_2,\omega,t)/S_u(\omega,t) = \exp[-k_z\omega\left|z_1-z_2\right|/(2\pi U_{\max})] \tag{7}$$

where k_z is the decay factor.

The EPSD of the generalized force given by Eq. 5 can be reduced to

$$S_{Q'}(\omega,t) = 4Q_R^2 S_u(\omega,t)d^2(t)\left|\chi_D(\omega)\right|^2\left|J_z(\omega)\right|^2/U_{\max}^2 \tag{8}$$

where joint acceptance $\left|J_z(\omega)\right|^2 = (1+\alpha+\beta)^{-1}[1+k_z\omega H/(2\pi U_H)/(2.5+\beta)]^{-1}$ (Chen 2008).

For the purpose of simulating the time histories of the generalized force and building response, the EPSD of the generalized force is further approximated as

$$S_{Q'}(\omega,t) = 4Q_R^2 S_u(\omega,t)d^2(t)\left|\chi_D(\omega_1)\right|^2\left|J_z(\omega_1)\right|^2/U_{\max}^2 \tag{9}$$

where $\omega_1 = 2\pi f_1$ is the fundamental natural frequency of the building.

As compared to Eq. 8, although this approximation results in a different EPSD of the generalized force on other frequencies it leads to the almost same building response due to the property of the narrow band process of the building response around the building natural frequency. According to Eq. 9 and assuming the variation rate of $d(t)$ is relatively slow, the time history of the generalized force $Q'(t)$ can be directly related to $u_0'(t)$ by

$$Q'(t) = 2Q_R u_0'(t)d(t)\left|\chi_D(\omega_1)\right|\left|J_z(\omega_1)\right|/U_{\max} \tag{10}$$

where $u_0'(t)$ is a nonstationary wind fluctuation and characterized by its EPSD $S_u(\omega,t)$.

Hence, $Q'(t)$ can be generated by first simulating $u_0'(t)$ through its EPSD $S_u(\omega,t)$. It should be mentioned that a more accurate simulation of the time histories of $Q'(t)$ can be achieved based on Eq. 8 by using the rational function approximation (Chen et al. 2000).

With the knowledge of the time histories of the generalized force, the desired response can be determined using Newmark's method to solve the following equation of building motion

$$M[\ddot{q}'(t) + 2\xi\omega_1\dot{q}'(t) + \omega_1^2 q'(t)] = Q'(t) \tag{11}$$

where M, ξ, and $q'(t)$ are the fundamental generalized mass, damping ratio and displacement, respectively. In addition, the mean component of the generalized displacement can be directly computed from the quasi-static analysis as $\bar{q}(t) = \bar{Q}(t)/(M\omega_1^2)$.

The mean and dynamic components of other response, $R(t)$, are then given as

$$\bar{R}(t) = B\bar{q}(t); \quad R'(t) = Bq'(t) \tag{12}$$

where B is the modal participation coefficient.

The velocity and acceleration are of interest in habitability design and determined as

$$v(z,t) = \Phi(z)\dot{q}'(t) \approx \Phi(z)\omega_1 q'(t); \quad a(z,t) = \Phi(z)\ddot{q}'(t) \approx \Phi(z)\omega_1^2 q'(t) \tag{13}$$

Based on multiple response samples, instantaneous RMS, mean extreme values of response can be determined. In the next discussion, top displacement is normalized by $\bar{q}(t) = \bar{Q}(t)/(M\omega_1^2)$, which is the static displacement under load Q_R. The GRF and the peak factor are accordingly determined. The GRF is defined as the ratio of the mean extreme value of total response to the maximum static response. The peak factor is defined as the ratio of the mean extreme value of dynamic response to the maximum RMS response.

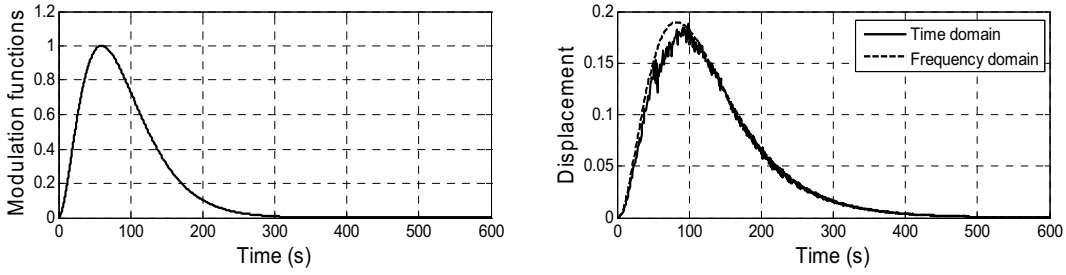
3. COMPARISON WITH FREQUENCY DOMAIN ANALYSIS

A shear building with a height of H =200 m and a square section of $B = D = 40$ m is studied. The fundamental modal frequency is given by the empirical formula $f_1 = 46/H$. The modal damping ratio is ξ =1%, and fundamental modal shape is assumed to be linear, i.e., β =1.0. The aerodynamic admittance function is given by Davenport's formula as

$$|\chi_D(\omega)|^2 = 2\lambda_y(1 - 1/\lambda_y + 1/\lambda_y e^{-\lambda_y}) \tag{14}$$

where $\lambda_y = k_y fD/U_{\max}$; k_y is decay factor and taken as 8. The power law exponent of mean wind speed profile is α =0.25. The decay factor for the coherence of wind fluctuation is $k_z = 8$.

The numerical example used by Chen (2008) for frequency domain analysis is reevaluated by the time domain approach presented here. The modulation function of the mean wind speed, $d(t)$, is shown in Figure 1(a). The mean wind speed at the building top is $U_{\max}$ = 40m/s. The wind fluctuation of this wind event is modeled as a uniformly modulated process from a stationary wind fluctuation. The stationary wind fluctuation is modeled by the von Karman spectrum with an integral length scale of 80 m and turbulence intensity of 15%.



(a) Modulation function (b) Time varying RMS of top displacement

Figure 1 Comparison with frequency domain approach

A total of 100 time history samples of the wind fluctuation are generated through Monte Carlo simulation based on the spectral representation method (e.g., Deodatis 1996). The upper cutoff frequency is 10 Hz, and frequency increment is 0.00122 Hz. The generated time history samples have a time resolution of 0.05 s and time period of 819.2s. Based on multiple samples of the response time histories, the instantaneous RMS can be computed. The static and time varying RMS values of top displacement are shown and compared in Figure 1(b).

The results show that both approaches offer almost same results for time varying RMS value of response. This comparison also demonstrates the adequacy of the approximation in the generation of the time histories of the generalized force for the response prediction. From the analysis, the GRF and peak factor are calculated as 1.75 and 1.84, respectively.

4. RESPONSE TO WINDS GENERATED BY EVOLUTIONARY SPECTRA

4.1 *Characteristics of Transient Building Response*

In this case study, the full-scale measurement of a real flank downburst wind speed at height 15 m is used (Gast and Schroeder 2003). The time-varying mean and fluctuation components are derived using the discrete wavelet transform as described in Huang and Chen (2009), where wavelet was chosen as Daubechies wavelet (e.g., Daubechies 1992) of order 3 and decomposition levels were 5. The level 5 is equivalent to a window size of 32 s for the time-varying mean component with a frequency range below 0.016 Hz. The maximum time-varying mean wind speed is 32.15 m/s. Figure 2 shows the modulation function of the mean wind speed, $d(t)$, which is defined as the time-varying mean wind speed divided by the maximum wind speed. Based on the framework for estimating EPSD proposed by Huang and Chen (2009), the normalized EPSD of the wind fluctuation is shown in Figure 3, where length scale is $L_u = 168$ m. This length scale is derived from the corresponding stationary fluctuation of original nonstationary wind speed, as shown in next section.

Based on the modulation function of the mean wind speed and the estimated EPSD, the nonstationary wind time histories with a given maximum wind speed can be generated using the spectral representation method (e.g., Deodatis 1996). A total of 100 time history samples of the wind fluctuation are generated. The corresponding building responses are calculated.

From each sample of simulated response, the extreme value of response is quantified. Then the mean and RMS of the extreme values are calculated. In addition, responses of buildings with heights $H = 100$, 150, 250 and 300 m with $B = D = 40$ m are also investigated. The building natural frequency is $f_1 = 46/H$. Figure 4 shows the mean and RMS of extreme values of top displacements of the buildings. The building response at $U_{\max} = 32.15$ m/s directly using the original one wind speed record is also conducted for comparison. As shown in Figure 4, the results computed from the original sample locate in those obtained from the simulated samples. The slight difference between the response from original sample and averaged one from the multiple simulated samples is attributed to the difference in the spectral values around the natural frequency.

Figure 5 demonstrates the original sample of the nonstationary fluctuation with $U_{\max} = 32.15$ m/s and a simulated sample of the fluctuation with $U_{\max} = 40$ m/s. The static and RMS values of the normalized building top displacement are depicted in Figure 6. The maximum normalized static response is 0.4. It is observed that the maximum value of the RMS response appears slightly later than the static response reaches its maximum value. This time lag is also reported by other authors (e.g., Solomos and Spanos 1984; Chen 2008). The maximum RMS, mean extreme value, GRF and peak factor are summarized in the Table 1 (Case 1).

Table 1. Comparison of different wind events

		Case 1	Case 2	Case 3	Case 4
Maximum RMS		0.144	0.157	0.147	0.154
Mean extreme	Time domain	0.63	0.66	0.62	0.88
	Upcrossing	0.64	0.70	0.65	0.93
GRF	Time domain	1.58	1.65	1.55	2.20
	Upcrossing	1.60	1.75	1.63	2.33
Peak factor	Time domain	1.60	1.66	1.50	3.12
	Upcrossing	1.67	1.91	1.70	3.44

Note: Case 1: time-varying mean + nonstationary fluctuation;
Case 2: time-invariant mean + nonstationary fluctuation;
Case 3: time-varying mean + simplified nonstationary fluctuation;
Case 4: time-invariant mean + stationary fluctuation.

4.2 *Influence of Time-Varying Mean Wind Speed*

To evaluate the influence of the time varying mean on the building response, the analysis using a time-invariant mean wind speed, i.e., $d(t)=1$, but same nonstationary wind fluctuation is also conducted. The previous case with time-varying mean wind speed and nonstationary wind fluctuation is referred to as "Case 1". The case discussed here is referred to as "Case 2". The time histories of total wind speed, which correspond to the wind fluctuation in Figure 5(b), is shown in Figure 7(a). The time-varying RMS values of top displacement are shown in Figure 7(b). The static top displacement is constant as 0.4. The maximum RMS, mean extreme value, GRF and peak factor are summarized in the Table 1. It is seen that the maximum value of RMS response is larger than that of Case 1. The main reason is attributed to slower fluctuation variation of the generalized force in Case 2, which needs less "build-up" time. This time is the one required to make $e^{-2\xi\omega_1 t}$ close unity (Chen 2008). Apparently, a large value of $\xi\omega_1$ requires less "build-up" time to reach the steady state response. Accordingly, the peak factor in Case 2 is also larger than that in Case 1 due to more developing time for the extreme value.

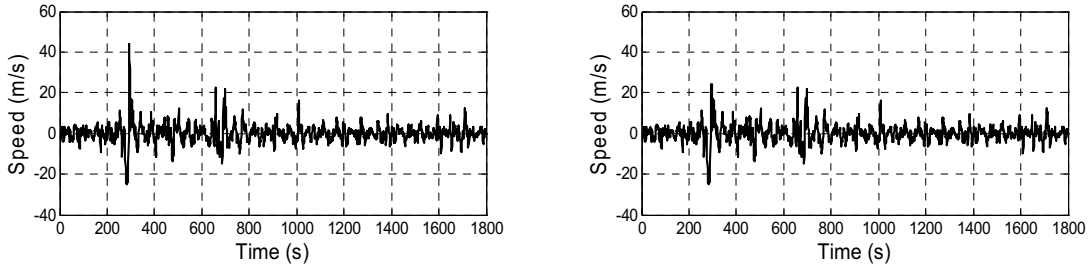
Figure 7 Wind speed and building top displacement

5. A SIMPLIFIED MODELING OF NONSTATIONARY WIND FLUCTUATION

In engineering practice, the nonstationary wind fluctuation may be approximately modeled as a uniformly modulated process with its modulation function following the mean wind speed, i.e., $\bar{U}_0(t)=d(t)U_{\max}$ and $u_0'(t)=d(t)u(t)$.



(c) $u_0'(t)=d(t)u(t)$ (d) $u(t)=u_0'(t)/d(t)$ without singular points

Figure 8 Derivation of the stationary fluctuation sample $u(t)$

The modulation function of the mean wind speed is shown in Figure 2. The wind fluctuation $u_0'(t)$ with $U_{\max}=32.15$ m/s is shown in Figure 5(a), which is derived by subtracting the time-varying mean from the original record. Based on this approximated model, stationary wind fluctuation $u(t)$ is obtained by dividing the original fluctuation sample $u_0'(t)$ with the corresponding modulation function, and then by removing few singular points, as shown in Figure 8(a) and (b). The PSD of the process $u(t)$, $S_u(f)$, is estimated and fitted with von Karman spectrum model. The length scale and turbulence intensity are 168 m and 15%, respectively. Figure 9 compared the PSD estimated from the sample and the one fitted by von

Karman spectrum. It can be seen that both have a satisfactory match around the frequency range of 0.15-0.25 Hz, which covers the fundamental frequencies of the tall buildings. The fitted spectrum is used to generate 100 samples of $u(t)$ and thus $u_0^{'}(t)$ for estimating the building response. This calculation is referred to as "Case 3".

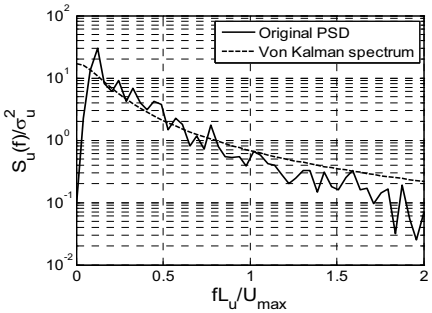


Figure 9 Comparison of normalized PSDs of stationary wind fluctuation

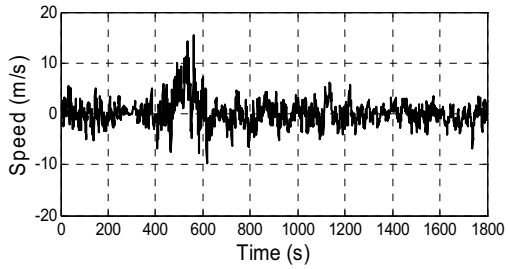

Figure 10 Sample of uniformly modulated fluctuation

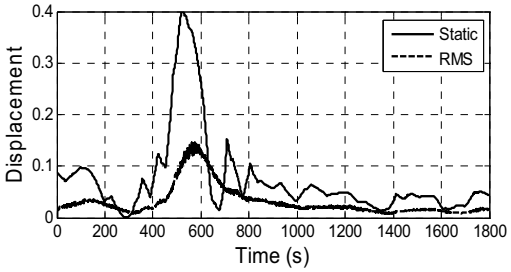

Figure 11 Static and RMS values of top displacement

Figure 10 shows one sample of the stationary fluctuation $u(t)$, and the corresponding uniformly modulated fluctuation $u_0^{'}(t) = d(t)u(t)$ with $U_{\max} = 40$ m/s. The time-varying static and RMS values of top displacement calculated from multiple samples are shown in Figure 11. The maximum RMS mean extreme, GRF and peak factor are summarized in Table 1 (Case 3).

The comparison between Cases 1 and 3 for other wind speeds is summarized in Table 2. The results in Tables 1 and 2 show that two different approaches in modeling the nonstationary downburst fluctuation have similar results in terms of the maximum RMS and the mean extreme value of the response, although they offer different time histories and time-varying RMS values. These two approaches generate different wind fluctuations and generalized forces. However, their spectra around the natural frequency are almost identical, which leads to almost equal response due to the property of the narrow-band filter of high-rise buildings. Hence, it may be practicable to model the nonstationary fluctuation as a uniformly modulated process with the modulation function of time-varying mean speed. However, for middle- and low-rise buildings, these approaches may not lead to similar responses because more frequency contents of wind loads will influence the response. In such a case, wind fluctuations generated from wavelets-based EPSD will offer more detailed time-frequency information of wind and wind load.

To further understand the transient wind load effect on the building response, the building response under stationary wind fluctuation $u(t)$ and mean wind speed of 40 m/s is also calculated. This is referred to as "Case 4". The maximum RMS, GRF and peak factor of three cases are summarized in Table 1. Compared to other three cases, the maximum RMS of Case 4 is almost identical, while the GRF and peak factor are much larger. The maximum RMS is mainly influenced by the wind fluctuation around the maximum mean wind speed. On the other hand, the extreme value as reflected by GRF and peak factor depends the time-varying RMS and the

time duration. Unlike Cases 1 to 3, Case 4 has a constant RMS and has a sufficient time to reach a larger extreme value. The influence of transient winds on the extreme response can also be well understood from the upcrossing theory, which is to be discussed in the next section.

Table 2 Comparison of Cases 1 and 3 under different wind speeds (H =200 m)

	$U_{\max}=40$ m/s		$U_{\max}=50$ m/s		$U_{\max}=60$ m/s	
	Case 1	Case 3	Case 1	Case 3	Case 1	Case 3
Maximum RMS	0.144	0.147	0.174	0.172	0.172	0.184
Mean extreme	0.63	0.62	0.68	0.65	0.68	0.68
GRF	1.58	1.55	1.70	1.63	1.70	1.70
Peak factor	1.60	1.50	1.61	1.47	1.63	1.52

6. EXTREME VALUE OF NONSTATIONARY RESPONSE BASED ON UPCROSSING RATE

The extreme value of a nonstationary Gaussian process $R(t)$ over a given time period T can also be estimated based on upcrossing theory. By "Poisson approximation of crossings", the mean upcrossing rate at level of r at any time t can be given by (e.g., Lutes and Sarkani 2004)

$$\nu(r,t)=\sigma_{\dot{R}}(t)/[2\pi\sigma_R(t)]\exp\left[-(r-\mu_R(t))^2/[2\sigma_R^2(t)]\right] \tag{15}$$

where $\mu_R(t)$ and $\sigma_R(t)$ are the time varying mean and RMS of $R(t)$, respectively; and $\sigma_{\dot{R}}(t)$ is the time varying RMS of $\dot{R}(t)$. As the building response $R(t)$ can be regarded as a narrow band process with the central frequency of the building natural frequency ω_1, $\sigma_{\dot{R}}(t)/\sigma_R(t)\approx\omega_1$.

The cumulative distribution function (CDF) of the extreme value of $R(t)$ over time period of T is given as (e.g., Lutes and Sarkani 2004)

$$Q_{\max}(r)=\exp[-\int_0^T\nu(r,t)dt]\approx\exp[-\exp(-\alpha_r(r-\hat{r}))] \tag{16}$$

The mode $\hat{r}$ and dispersion parameter $1/\alpha_r$ are determined by linearly fitting the curve $-\ln[-\ln(Q_{\max}(r))]$ as a function of r. The mean and RMS are subsequently quantified as

$$\mu_{r,\max}=\hat{r}+0.5772/\alpha_r,\quad \sigma_{r,\max}=\pi/(\sqrt{6}\alpha_r) \tag{17}$$

It is noted for a stationary process where $\nu(r,t)=\nu(r)$, the aforementioned formula reduces to that provided by Davenport (1964). The mean extreme values, corresponding GRFs and peak factors for these 4 cases are summarized in Table 1. It is seen that the results from the upcrossing approach is very close to those from the time domain simulation. It should be noted that the coefficient of variation of extreme value $\sigma_{r,\max}/\mu_{r,\max}$ for these 4 cases varies from 10% to 13%, which is close to that of the corresponding stationary case.

7. CONCLUDING REMARKS

A time domain analysis framework was presented for estimating tall building response excited by nonstationary wind events. Comparison with the frequency domain approach showed that the time domain approach offered very agreeable estimations of nonstationary response characteristics. Based on the simulated multiple samples of wind fluctuations and the calculated building responses, the transient nature in nonstationary wind was found to lead a smaller and lagged maximum RMS value and a smaller peak response due to less "build-up" time.

A simplified model was proposed to describe the nonstationary wind fluctuation as a uniformly modulated process with a modulation function as the time-varying mean. Response

analysis using this model illustrated that almost same response characteristics were obtained. This was attributed to the fact that the tall building response was dominated by the wind spectra around the natural frequency, which were almost unaffected by the approximate modeling. It should be noted that in the case of middle- and low-rise buildings, the simulation using wavelets-based EPSD will offer more detailed time-frequency information of nonstationary wind fluctuations and leads to more adequate estimation of their effects on buildings.

The approach based on the mean upcrossing rate of nonstationary process provided not only the similar extreme values of the response compared to those from the time domain simulation, but more detailed information of the influence of the instantaneous statistics on the extreme value. Compared to the corresponding stationary response, the nonstationary stationary response has a smaller peak factor and GRF due to insufficient time duration to develop extreme.

A state-space model for the wind-induced response of tall buildings with errors in the lateral loading

Luca Caracoglia

Northeastern University, 360 Huntington Avenue, Boston, Massachusetts, USA

ABSTRACT: The dynamic response of a tall building due to turbulent wind is analyzed in this study. A model is proposed to account for errors in the lateral loading, for example emerging from aerodynamic modeling assumptions, used to estimate the load in a wind tunnel test of a scaled model. The buffeting response at full scale is predicted by considering a linear structure with primary bending planes, oriented as the vertical faces, and mean loading orthogonal to one of the faces. The CAARC benchmark building is employed in the simulations. The model is based on a state-space formulation, stochastic calculus and generalized Markov-type state vector with state augmentation.

KEYWORDS: Tall buildings, stationary dynamic response, lateral loading correlation error, stochastic calculus, Reduced Fokker-Plank Equation.

1 INTRODUCTION

Risk-based methods for estimating the wind loading response of tall buildings, accounting for uncertainty in the lateral loading estimation, have been recently proposed (Bashor & Kareem[1], Chen & Huang[2], Jain *et al.*[3], Norton *et al.*[4]). Nevertheless, most methods are developed for ad-hoc problems, such as a specific building or a given structural configuration. A new generalized framework for the simulation and analysis of wind-induced response of tall buildings, in which effects of "errors" in the estimation of the lateral loading are incorporated, is currently under investigation (e.g., Smith & Caracoglia[5]). The ultimate goal of the research is to develop algorithms for performance-based assessment of peak response under severe wind excitation with an application to structural serviceability.

The fundamental hypothesis of the proposed analysis framework requires "error" propagation to be directly incorporated into the dynamics of tall and flexible buildings. Errors in loading estimation can result from aerodynamic modeling assumptions or simplifications used to enable wind tunnel experimentation. A typical example, commonly encountered in the engineering practice during the interpretation of high-frequency force-balance (HFFB) data, is the need for compensation of the idealized mode shapes, assumed in an HFFB wind tunnel test, due to imperfect planarity of lateral modes in the full-scale structure (e.g., Tse *et al.*[6]).

In this paper a preliminary numerical model is presented and discussed. Lateral buffeting loading and stationary response are investigated. Quasi-steady approximation is used to derive the lateral loading model.

Due to parametric random error propagation, the stationary response of the building may deviate from standard second-moment random vibration theory. Therefore, the error-contaminated response is directly estimated from the joint-probability of an augmented state vector, which includes several state variables: generalized modal coordinates, turbulence variables, generalized correlation length of the lateral loading. The proposed model also builds on the results of a stochastic algorithm, proposed in recent years for uncertainty simulation and dynamic analysis of slender bridges (Caracoglia[7]).

2 THEORETICAL BACKGROUND

2.1 *Fluctuating wind loading and generalized response of the CAARC building*

This section describes the derivation of the state-space model for dynamic response in the time domain. This new model is derived from the standard approach for building aerodynamics in the frequency domain (e.g., Davenport[8], Melbourne[9], Kareem[10], Piccardo & Solari[11], Kareem[12]). The dynamics of a prototype tall building is studied under the general hypothesis of linear structural behavior. The prototype structure is modeled after the CAARC benchmark building (Melbourne[9]), with rectangular floor-plan of dimensions D_x and D_y and height h. Figure 1 shows a schematic of the building geometry and wind loading; the mean wind direction and mean loading plane is orthogonal to the vertical face of width D_y (Fig. 1b). Figure 1a also coincides with the along-wind loading plane and primary bending plane for the building. Quantities $x(z,t)$ and $y(z,t)$ are used to model the dynamic displacements in the primary bending planes of the structure, as indicated in Figure 1b. Torsional effects are neglected in this study.

The CAARC building mass is assumed as uniformly distributed along the height of the structure with $m(z)$ mass per unit height; the dynamic lateral response in the two primary lateral planes is represented by modal superposition, accounting for the fundamental modes only, as: $x(z,t)=\Phi_{1x}(z)D_x\xi_{1x}(t)$ along wind (Fig. 1b), and $y(z,t)=\Phi_{1y}(z)D_x\xi_{1y}(t)$ in the transverse direction; ξ_{1x} and ξ_{1y} are dimensionless modal coordinates; $\Phi_{1x}(z)$ and $\Phi_{1y}(z)$ are dimensionless mode shapes of the first two lateral modes with frequencies n_{1x} and n_{1y}, respectively. Modal damping ratios are ζ_{1x} and ζ_{1y} with respect to critical value. The plane of bending for mode "1y" is not shown in Figure 1a since it is orthogonal to the elevation plane in the figure.

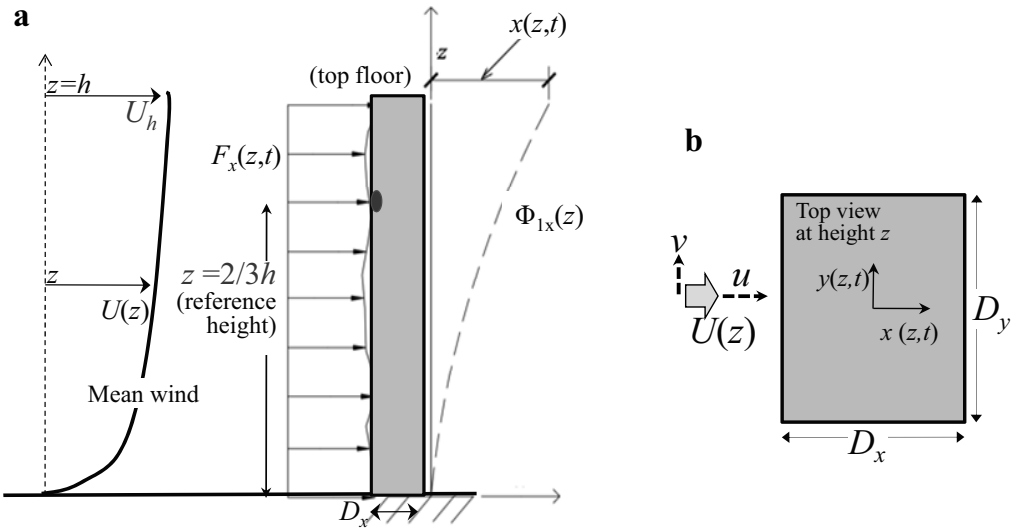

Figure 1. Schematic of the CAARC building with coordinate system and lateral wind loading: (a) lateral elevation view, (b) floor-plan view.

The fluctuating loading model operates in state space by assuming boundary layer wind with mean $U(z)$, stationary turbulence in the two directions, $u(z,t)$, $v(z,t)$ and quasi-steady aerodynamics (Fig. 1b). The along-wind and across-wind buffeting loading per unit height is written in the time domain as (Piccardo & Solari[11]):

$$F_x(z,t)=\frac{\rho D_x U^2(z)}{2}\left\{-2C_D\frac{\dot{x}(z,t)}{U(z)}+(\hat{C}_D-C_L)\frac{\dot{y}(z,t)}{U(z)}\right\}+\rho D_x U(z)C_D u(z,t) \tag{1}$$

$$F_y(z,t)=\frac{\rho D_x U^2(z)}{2}\left\{2C_L\frac{\dot{x}(z,t)}{U(z)}-(\hat{C}_L+C_D)\frac{\dot{y}(z,t)}{U(z)}\right\}+\frac{\rho D_x U(z)}{2}\left[2C_L u(z,t)+(\hat{C}_L+C_D)v(z,t)\right] \quad (2)$$

In equations above ρ=1.25 kg/m^3 is the air density. The "dot" symbol designates derivation with respect to time t. The static force coefficients per unit height are independent of z and are normalized with respect to width D_x: drag C_D per unit z and its derivative with respect to mean-wind direction $\hat{C}_D = dC_D/d\alpha$, "lift" (or transverse lateral force) C_L and $\hat{C}_L = dC_L/d\alpha$.

The mean wind velocity is referenced to the value at the top floor $z=h$ (U_h in Fig. 1a) $U(z)=U_h\Delta(z)$, with $\Delta(z)=(z/h)^g$ following a power-law velocity profile (as in Melbourne[9]). If modal superposition is employed, the previous equations can be rewritten as

$$F_x(z,t)=\frac{\rho D_x^2 U_h^{\,2}}{2}\Delta(z)\left\{-2C_D\frac{\Phi_{1x}(z)\dot{\xi}_{1x}}{U_h}+(\hat{C}_D-C_L)\frac{\Phi_{1y}(z)\dot{\xi}_{1y}}{U_h}\right\}+\rho D_x U_h\Delta(z)C_D u(z,t)$$

$$F_y(z,t)=\frac{\rho D_x^2 U_h^{\,2}}{2}\Delta(z)\left\{2C_L\frac{\Phi_{1x}(z)\dot{\xi}_{1x}}{U_h}-(\hat{C}_L+C_D)\frac{\Phi_{1y}(z)\dot{\xi}_{1y}}{U_h}\right\} \quad (3,4)$$

$$+\frac{\rho D_x U(z)\Delta(z)}{2}\left[2C_L u(z,t)+(\hat{C}_L+C_D)v(z,t)\right]$$

Modal superposition is used in Equations 3 and 4, under the hypothesis that modes "1x" and "1y" are purely planar, with mode shape $\Phi_{1x}(z)$ acting on the z-y plane and $\Phi_{1y}(z)$ on the z-x plane. Generalized forces (Q_{1x}, Q_{1y}) and modal masses (M_{1x}, M_{1y}) of "1x" and "1y" modes are:

$$Q_{1x}=\int_0^h \Phi_{1x}(z)F_x(z,t)dz, \qquad Q_{1y}=\int_0^h \Phi_{1y}(z)F_y(z,t)dz \quad (5,6)$$

$$M_{1x}=\int_0^h \left[\Phi_{1x}(z)\right]^2 m(z)dz, \qquad M_{1y}=\int_0^h \left[\Phi_{1y}(z)\right]^2 m(z)dz \quad (7,8)$$

If the dynamic response is expressed in terms of time $s=tU_h/D_x$ and dimensionless frequencies $K_{1x}=2\pi n_{1x}D_x/U_h$, $K_{1y}=2\pi n_{1y}D_x/U_h$, the generalized equations of modes "1x" and "1y" are

$$\xi_{1x}''+2(\zeta_{1x}+\mathrm{H}_{1x,1x}C_D)K_{1x}\xi_{1x}'+\mathrm{H}_{1x,1y}(C_L-\hat{C}_D)K_{1y}\xi_{1y}'+K_{1x}^2\xi_{1x}=\frac{\rho D_x^2 h C_D}{M_{1x}}\int_0^h \Delta(z)\hat{u}(z,s)\Phi_{1x}(z)\frac{dz}{h} \quad (9)$$

$$\xi_{1y}''+\left[2\zeta_{1y}+\mathrm{H}_{1y,1y}(C_D+\hat{C}_L)\right]K_{1y}\xi_{1y}'-2C_L\mathrm{H}_{1y,1x}K_{1x}\xi_{1x}'$$

$$+K_{1y}^2\xi_{1y}=\frac{\rho D_x^2 h}{M_{1y}}\left[C_L\int_0^h \Delta(z)\hat{u}(z,s)\Phi_{1y}(z)\frac{dz}{h}+(C_D+\hat{C}_L)\int_0^h \Delta(z)\hat{v}(z,s)\Phi_{1y}(z)\frac{dz}{h}\right] \quad (10)$$

In the previous equations the prime symbol designates derivation with respect to s; also, the turbulence components have been normalized as $\hat{u}=u/U_h$ and $\hat{v}=v/U_h$.

In Equations 10 and 11 fluid-structure coupling terms are introduced. These are derived from the quantities enclosed within braces in Equations 3 and 4; they become, for mode "1x" and "1y" respectively:

$$\mathrm{H}_{1x,1x}=\frac{\rho D_x^2 h}{2K_{1x}M_{1x}}\int_0^h \Delta(z)\left[\Phi_{1x}(z)\right]^2\frac{dz}{h},\qquad \mathrm{H}_{1x,1y}=\frac{\rho D_x^2 h}{2K_{1y}M_{1x}}\int_0^h \Delta(z)\Phi_{1x}(z)\Phi_{1y}(z)\frac{dz}{h} \tag{11}$$

$$\mathrm{H}_{1y,1y}=\frac{\rho D_x^2 h}{2K_{1y}M_{1y}}\int_0^h \Delta(z)\left[\Phi_{1y}(z)\right]^2\frac{dz}{h},\qquad \mathrm{H}_{1y,1x}=\frac{\rho D_x^2 h}{2K_{1x}M_{1y}}\int_0^h \Delta(z)\Phi_{1x}(z)\Phi_{1y}(z)\frac{dz}{h} \tag{12}$$

The loading terms on the right-hand side of Equations 9 and 10 are a function of along-wind and across-wind turbulence components at various z; loads may be simulated by separating the dependency on z and time s after rewriting the partially correlated turbulence-induced terms as equivalent fully correlated lateral loads, acting on a reduced "projected area", i.e., referenced to a Modal Correlation Length (MCL) in vertical direction. This principle has often been used in wind engineering and is compatible with the assumptions of the Equivalent Wind Spectrum Technique (Piccardo & Solari[11], Solari[13]). In the absence of loading errors, three MCLs are required by the model in Equations 9 and 10: $\Lambda_{1x,u}$, $\Lambda_{1y,u}$, $\Lambda_{1y,v}$. These quantities are dimensionless, normalized to the height h, and are computed by least-squares from:

$$\left[\Lambda_{1r,u}\right]^2=\int_0^h\int_0^h \Delta(z)\Delta(\upsilon)\Phi_{1r}(z)\Phi_{1r}(\upsilon)\exp\left[-\frac{2c_{z,u}n_{1r}}{U_h}\frac{|z-\upsilon|}{\Delta(z)+\Delta(\upsilon)}\right]\frac{dzd\upsilon}{h^2} \tag{13}$$

$$\left[\Lambda_{1y,v}\right]^2=\int_0^h\int_0^h \Delta(z)\Delta(\upsilon)\Phi_{1y}(z)\Phi_{1y}(\upsilon)\exp\left[-\frac{2c_{z,v}n_{1y}}{U_h}\frac{|z-\upsilon|}{\Delta(z)+\Delta(\upsilon)}\right]\frac{dzd\upsilon}{h^2} \tag{14}$$

Equation 13 is expressed in generic form with mode index "r" equal to x or y. For example, the square root of Equation 13, with $r=x$, is $0<\Lambda_{1x,u}\leq 1.0$, i.e., the MCL of the 1x-mode lateral loading (predominantly along-wind). In both Equation 13 and 14 the spatial coherence coefficients, $c_{z,u}=10$ and $c_{z,v}=6.67$, are defined in accordance with standard approaches. If Equations 13 and 14 are utilized, Equations 9 and 10 can be simplified as

$$\xi_{1x}''+2(\zeta_{1x}+\mathrm{H}_{1x,1x}C_D)K_{1x}\xi_{1x}'+K_{1y}\mathrm{H}_{1x,1y}(C_L-\hat{C}_D)\xi_{1y}'+K_{1x}^2\xi_{1x}=\frac{\rho D_x^2 h C_D}{M_{1x}}\Lambda_{1x,u}\hat{u}_{0.6h}(s) \tag{15}$$

$$\xi_{1y}''+\left[2\zeta_{1y}+\mathrm{H}_{1y,1y}(C_D+\hat{C}_L)\right]K_{1y}\xi_{1y}'-2C_L\mathrm{H}_{1y,1x}K_{1x}\xi_{1x}'$$
$$+K_{1y}^2\xi_{1y}=\frac{\rho D_x^2 h}{M_{1y}}\left[C_L\Lambda_{1y,u}\hat{u}_{0.6h}(s)+(C_D+\hat{C}_L)\Lambda_{1y,v}\hat{v}_{0.6h}(s)\right] \tag{16}$$

In Equations 15 and 16 the turbulence components are referenced to $z=0.6h\approx 2/3h$ (Solari[13]) as $\hat{u}_{0.6h}(s)=\hat{u}(z=0.6,s)$ and $\hat{v}_{0.6h}(s)=\hat{v}(z=0.6,s)$, as also schematically depicted in Figure 1a.

2.2 *Stochastic dynamics and state-space model*

The dynamic system of equations in the time domain $s=tU_h/D_x$ is transformed into a stochastic differential system of the Itô-type (Grigoriu[14]) to simulate effects of errors in the lateral loading.

In this study, random perturbation is applied to the MCL of the 1x-mode lateral loading, $\Lambda_{1x,u}$, in Equation 13 (with $r=x$), whereas quantities $\Lambda_{1y,u}$ and $\Lambda_{1y,v}$ are considered marginally affected by errors and, therefore, they are two deterministic constants. This perturbation is simulated by

replacing the deterministic quantity $\Lambda_{1x,u}$ in Equation 15 by $(\Lambda_{1x,u}+\lambda_u)$; λ_u is a zero-mean dimensionless random variable. The quantity $\Lambda_{1x,u}$, which is estimated through Equation 13, can be interpreted as the mean value of the MCL with λ_u being a measure of its error. As a result, while Equation 16 is still deterministic, Equation 15 is rewritten as

$$\xi_{1x}'' + 2(\zeta_{1x} + \mathrm{H}_{1x,1x}C_D)K_{1x}\xi_{1x}' + K_{1y}\mathrm{H}_{1x,1y}(C_L - \hat{C}_D)\xi_{1y}' + K_{1x}^2\xi_{1x} = \frac{\rho D_x^2 h C_D}{M_{1x}}\left(\Lambda_{1x,u} + \lambda_u\right)\hat{u}_{0.6h}(s) \tag{17}$$

The stochastic differential system is subsequently derived from Equations 16 and 17 in state-space form by simulating the time-dependent turbulence components $\hat{u}_{0.6h}$ and $\hat{v}_{0.6h}$ as the outputs of two auto-regressive filters as a function of s, applied to a scalar Wiener process of unit variance $W(s)$. This hypothesis enables the subsequent derivation of an Itô-type system:

$$d\hat{u}_{0.6h}(s) = -G_{1u}\hat{u}_{0.6h}(s)ds + G_{2u}dW(s) \tag{18}$$

$$d\hat{v}_{0.6h}(s) = -G_{1v}\hat{v}_{0.6h}(s)ds + G_{2v}dW(s) \tag{19}$$

In Equations 18 and 19, G_{1u}, G_{2u}, G_{1v} and G_{2v} are deterministic constants, which can be indirectly inferred from the power spectral density of turbulence (e.g., Caracoglia[7]) and are evaluated at z=0.6h. Equations 18 and 19 are written in differential form in accordance with Itô's differentiation rule.

Equations 18 and 19 are subsequently combined with Equations 16 and 17 and re-written in state-space form after augmentation (Grigoriu[14]) to obtain a stochastic differential system as a function of state vector **Z**(s). This vector is composed of physical states (generalized coordinates ξ_{1x}, ξ_{1y} and their derivatives), wind turbulence states ($\hat{u}_{0.6h}$ and $\hat{v}_{0.6h}$) and random variable λ_u. The stochastic differential equation, with $\mathbf{Z}(s)=[\xi_{1x}(s),\xi_{1y}(s),\xi'_{1x}(s),\xi'_{1y}(s),\hat{u}_{0.6h}(s),\hat{v}_{0.6h}(s),\lambda_u]^{\mathrm{T}}$ being a column vector and $s=tU_h/D_x$ a dimensionless time, is:

$$d\mathbf{Z}(s) = \mathbf{a}(\mathbf{Z}(s))ds + \sqrt{2\pi}\mathbf{d}dW(s) \tag{20}$$

In Equation 20, valid for for $s\geq 0$, **a** is a nonlinear (drift) function of **Z**(s) and $\mathbf{d} = \left[\mathbf{0}^{4\times 1}, G_{2u}, G_{2v}, 0\right]^{\mathrm{T}}$ is a scalar $n\times 1$ (diffusion) vector collecting some of the coefficients in Equations 18 and 19.

The dimension of the state vector is n=7. Initial conditions on **Z** at s=0 are irrelevant since the steady-state response (as $s\rightarrow+\infty$) is investigated. If the random state vector is relabeled as $\mathbf{Z}=[Z_1,..,Z_n]^{\mathrm{T}}$, **a**(**Z**) is

$$\mathbf{a} = \begin{bmatrix} Z_3 \\ Z_4 \\ -2K_{1x}(\zeta_{1x} + \mathrm{H}_{1x,1x}C_D)Z_3 - K_{1y}\mathrm{H}_{1x,1y}(C_L - \hat{C}_D)Z_4 - K_{1x}^2 Z_1 + \rho D_x^2 h C_D\left(M_{1x}\right)^{-1}\left(\Lambda_{1x,u} + Z_7\right)Z_5 \\ -\left[2\zeta_{1y} + \mathrm{H}_{1y,1y}(C_D + \hat{C}_L)\right]K_{1y}Z_4 - 2C_L\mathrm{H}_{1y,1x}K_{1x}Z_3 - K_{1y}^2 Z_2 + \dfrac{\rho D_x^2 h}{M_{1y}}\left[C_L\Lambda_{1y,u}Z_5 + (C_D + \hat{C}_L)\Lambda_{1y,v}Z_6\right] \\ -G_{1u}Z_5 \\ -G_{1v}Z_6 \\ 0 \end{bmatrix} \tag{21}$$

2.3 *Algorithm for assessing the joint-probability density function of the state vector*

The stationary joint-probability density function (PDF) of $\mathbf{Z}$, $p(\mathbf{z})$, can be determined from system 20 through the Reduced Fokker-Planck Equation (Grigoriu[14]) as $s\rightarrow+\infty$ and with r=4:

$$\sum_{j=1}^{n-1}\frac{\partial}{\partial z_j}\left[\mathrm{a}_j(\mathbf{z})p(\mathbf{z})\right]-\pi\sum_{j=r+1}^{n-1}\sum_{k=r+1}^{n-1}R_{jk}\frac{\partial^2 p(\mathbf{z})}{\partial z_j\partial z_k}=0 \tag{22}$$

The dependency on the time variable is irrelevant at steady-state; its explicit designation is omitted in the subsequent derivations. In Equation 22, $\mathbf{R}=\mathbf{d}^{\mathrm{T}}\mathbf{d}$ is a constant matrix with non-zero elements for $j>r$ and $k>r$. For the numerical solution of the previous equation the joint-PDF is first represented in terms of the probability potential (Lin & Cai[15]), $\varphi(\mathbf{z})$, as $p(\mathbf{z})=C_f\exp[\varphi(\mathbf{z})+\varphi_0]$ with C_f and φ_0 being two integration constants. These must satisfy the condition $\int..\int p(\mathbf{z})\mathrm{d}\mathbf{z}=1.0$. As a result, Equation 22 becomes

$$\sum_{j=1}^{n-1}\left[\mathrm{a}_j(\mathbf{z})\frac{\partial\varphi}{\partial z_j}+\frac{\partial\,\mathrm{a}_j(\mathbf{z})}{\partial z_j}\right]-\pi\sum_{j=r+1}^{n-1}\sum_{k=r+1}^{n-1}R_{jk}\left[\frac{\partial\varphi}{\partial z_j}\frac{\partial\varphi}{\partial z_k}+\frac{\partial^2\varphi}{\partial z_j\partial z_k}\right]=0 \tag{23}$$

A numerical algorithm has been developed to solve Equation 23, by adaptation of the approach proposed by Soize[16]. The numerical algorithm employs a Galerkin expansion for $\varphi(\mathbf{z})$: $\varphi(\mathbf{z})=\sum\kappa_{\boldsymbol{\beta}}h_{\boldsymbol{\beta}}(\mathbf{z})$. This expansion utilizes a basis of mutually-orthogonal Normalized Hermite Polynomials (NHP) $h_{\boldsymbol{\beta}}(z_1,..,z_j,..,z_n)=h_{\beta 1}(z_1)\times..\times h_{\beta j}(z_j)\times..\times h_{\beta n}(z_n)$ (Soize[16]). The degree of each scalar Hermite Polynomial (e.g., $h_{\beta 1}(z_1)$) is designated by its index (e.g., for $\beta_1=2$ $h_{\beta 1}(z_1)=(z_1^2-1)/\sqrt{2}$). The vector index $\boldsymbol{\beta}=(\beta_1,..,\beta_j,..,\beta_n)$ collects the degrees of each individual $h_{\beta j}$ function. The degree of each $h_{\boldsymbol{\beta}}$ is determined from $\sum\beta_j$, whereas a scalar index l=1 to $l=d_{\mathrm{NHP}}$ is used to label and group all the $\boldsymbol{\beta}$ vector indices in ascending order, based on degree and variables $z_1,..,z_n$.

The algorithm operates by exploiting the orthogonality of the NHPs with respect to the standard Gaussian vector of independent $\mathbf{z}$. The unknown coefficients of the series, $\kappa_{\boldsymbol{\beta}}$, are found by integration (Galerkin averaging) of Equation 23 with respect to the Gaussian vector over the multi-variable domain $\mathbf{z}$, after substituting $\varphi(\mathbf{z})=\sum q_{\boldsymbol{\beta}}h_{\boldsymbol{\beta}}(\mathbf{z})$.

If the series $\varphi(\mathbf{z})=\sum q_{\boldsymbol{\beta}}h_{\boldsymbol{\beta}}(\mathbf{z})$ is truncated to the first d_{NHP} terms ($\kappa_{\boldsymbol{\beta}}$), Equation 23 can be transformed into a non-linear homogeneous algebraic system of d_{NHP} equations. The expansion should preserve the features of the NHPs until the third degree to account for parametric non-Gaussian uncertainty propagation. The generic l-th scalar equation of this non-linear algebraic system is related to the generic vector index $\boldsymbol{\gamma}$ in the expansion, and is

$$\sum_{\boldsymbol{\beta}=(1,...,0)}\left(E_{\boldsymbol{\gamma}\boldsymbol{\beta}}-\pi E_{\boldsymbol{\gamma}(\boldsymbol{\beta})^j}\right)\kappa_{\boldsymbol{\beta}}-\pi\sum_{\boldsymbol{\beta}=(1,...,0)}\sum_{\boldsymbol{\varepsilon}=(1,...,0)}\kappa_{\boldsymbol{\beta}}\kappa_{\boldsymbol{\varepsilon}}G_{(\boldsymbol{\gamma}),\boldsymbol{\beta},\boldsymbol{\varepsilon}}=0 \tag{24}$$

In the previous equation the index $\boldsymbol{\gamma}$ varies from $\boldsymbol{\gamma}$=(1,..,0) (l=1) to $\boldsymbol{\gamma}$=(0,..,1,2) (l=116= d_{NHP}); $\kappa_{\boldsymbol{\beta}}$ and $\kappa_{\boldsymbol{\varepsilon}}$ denote the generic unwknown coefficients. The $E_{\boldsymbol{\gamma}\boldsymbol{\beta}}$ terms coincide with a series of scalar terms, which are evaluated by numerical integration, whearas the scalar $E_{\boldsymbol{\gamma}(\boldsymbol{\beta})j}$ and $G_{(\boldsymbol{\gamma}),\boldsymbol{\beta},\boldsymbol{\varepsilon}}$ can be found in closed form (details omitted for brevity). Equations 23 and 24 highlight the main advantage of the algorithm, which is superior to Monte Carlo simulation for solving Equation 20, since it enables the assessment of the joint-PDF directly in closed form.

3 NUMERICAL SIMULATIONS: CAARC BUILDING

3.1 *Description of full-scale building properties*

The geometric, dynamic and aerodynamic properties of the CAARC building are derived from Melbourne[9]. Reference geometric dimensions are D_x = 30.5 m, D_y = 45.7 m and h = 183 m (Fig. 1). The mass per unit height is constant with $m(z)$=220,800 kg/m. The natural frequencies are taken as n_{1x}=0.20 Hz and n_{1y}=0.22 Hz, respectively. Mode shapes are approximately linear with height (Melbourne[9]): $\Phi_{1x}(z)=(z/h)$ and $\Phi_{1y}(z)=(z/h)$. Modal damping ratios are assumed as $\zeta_{1x} = \zeta_{1y}$ = 0.01 for both modes. The aerodynamic coefficients per unit elevation are inferred from the original experimental data (Melbourne[9]), as described in Smith & Caracoglia[5], as: C_D=1.0, $dC_D/d\alpha$ = -1.1, C_L = -0.1, $dC_L/d\alpha$ = -2.2.

Two mean wind scenarios are investigated: U_h = 20 m/s (moderate wind) and U_h = 40 m/s (high wind) evaluated at mean roof height. The MCL for U_h = 20 m/s are $\Lambda_{1x,u}=\Lambda_{1y,u}$=0.17 and $\Lambda_{1y,v}$=0.21; those for U_h = 40 m/s are $\Lambda_{1x,u}$=0.23, $\Lambda_{1y,u}$=0.22 and $\Lambda_{1y,v}$=0.25. The power spectral densities of both $\hat{u}_{0.6h}$ and $\hat{v}_{0.6h}$ components are used to determine the parameters of Equations 18 and 19; densities are based on the Harris model.

In the case of the along-wind component $\hat{u}_{0.6h}$ (Fig. 1b) the energy of the spectrum has been linked to a dimensionless form of the Harris spectrum, based on the data in Melbourne[9], evaluated at z=0.6h:

$$S_{\hat{u}_{0.6h}}(K)=\frac{\left[I_u\right]^2}{\Delta_u(0.6h)U_h}\frac{960}{\left(2+\tilde{f}\right)^{5/6}},\qquad \tilde{f}=\frac{1600K}{2\pi D_x\Delta_u(0.6h)} \tag{25, 26}$$

with reduced frequency $K=2\pi nD_x/U_h$ and turbulence intensity I_u=11% at z=0.6h. For $\hat{v}_{0.6h}$ the same expression as in Equation 25 is used with I_v replacing the quantity enclosed within brackets. However, a reduction of transverse turbulence intensity is postulated: I_v=8%. The dimensionless parameters of the autoregressive turbulence models, derived for both U_h = 20 m/s and U_h = 40 m/s, are summarized in Table 1. Details on the derivation of these parameters are omitted for brevity.

Table 1. Parameters used for $\hat{u}_{0.6h}$ and $\hat{v}_{0.6h}$ in Equations 18 and 19.

U_h (m/s)	I_u	G_{1u}	G_{2u}	I_v	G_{1v}	G_{2v}
20	11%	0.356	0.121	8%	0.356	0.091
40	11%	0.294	0.082	8%	0.294	0.009

3.2 *Hermite-Polynomial Galerkin expansion*

Figure 2 shows the dimensionless scalar coefficients $\kappa_{\boldsymbol{\beta}}$, associated with each $h_{\boldsymbol{\beta}}$ term of the Galerkin expansion of $\varphi(\mathbf{z})$ and obtained by numerically solving the nonlinear system (24). In this figure the dynamic response of the CAARC building with reference wind speed U_h=20 m/s is analyzed. The NHPs are ordered in ascending order and in accordance with vector index $\boldsymbol{\beta}$. As outlined in Section 2.3 the scalar index $1 \le l \le 116$, shown on the horizontal axis of the graph, is used to identify each term of the expansion. In the figure the $\kappa_{\boldsymbol{\beta}}$ terms are divided by first, second and third degree. For example l=1 belongs to to $\boldsymbol{\beta}$=(1,0,..,0) and $h_{(1,0,0,0,0,0,0)}=z_1$, l=7 corresponds to $\boldsymbol{\beta}$=(2,0,..,0) and $h_{(2,0,0,0,0,0,0)}=(z_1^2-1)/\sqrt{2}$), l=34 to $\boldsymbol{\beta}$=(3,0,..,0) and $h_{(3,0,0,0,0,0,0)}=(z_1^3-3z_1)/\sqrt{6}$.

In Figure 2, two cases are depicted, the difference being related to the numerical integration limits on $\mathbf{z}$, which are used by Galerkin expansion to numerically evaluate $E_{\gamma\boldsymbol{\beta}}$ in Equation 24.

"Effective" integration limits must be pre-selected a priori on a hyper-cube of the whole domain **z** in the proximity of the origin and must account for the local features of the polynomial functions defined through the NHP. Preliminary simulations have suggested as acceptable limiting values $|z_j| \leq 0.50$ for each $j=1,..,n$ or $|z_j| \leq 0.25$ (Domain "b" in Fig. 2). Since the integration to determine the $E_{\gamma\beta}$ is conducted numerically, selection of integration limits and a suitable number of integration points (5E+5) is crucial.

From the analysis of Figure 2 it can be concluded that the main features of the solution are preserved between the two cases: the continuous line is related to limits $|z_j| \leq 0.50$ and the dashed line is obtained with $|z_j| \leq 0.25$.

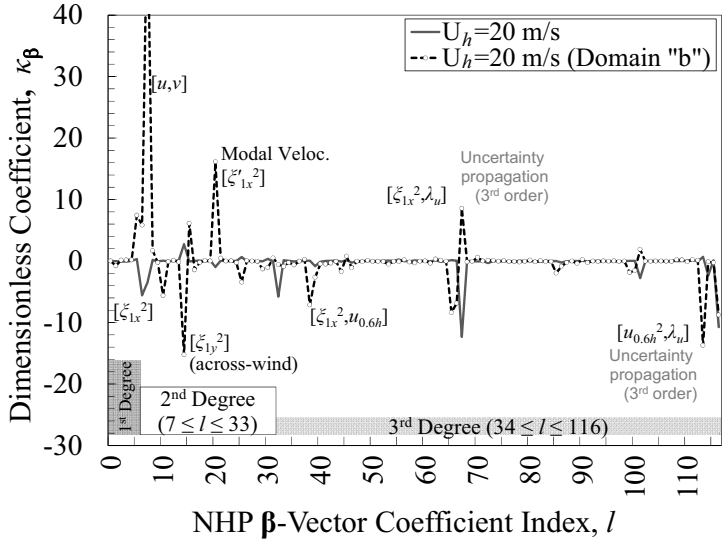

Figure 2. Normalized Hermite-Polynomials of the Galerkin expansion (U_h = 20 m/s).

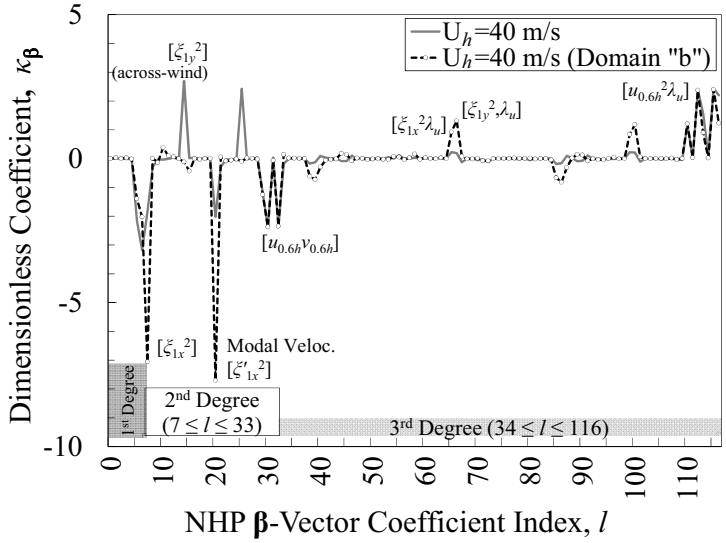

Figure 3. Normalized Hermite-Polynomials of the Galerkin expansion (U_h = 40 m/s).

A non-negligible variation in the magnitude of the κ_β parameters can be noticed in a few specific cases (e.g., l=5). Nevertheless, Figure 2 suggests that the proposed approach can replicate features typical of parametric uncertainty propagation; this observation is compatible

with the presence of non-negligible 3rd-degree polynomials in the figure, which are necessary to describe the non-Gaussian behavior in the state-space system. Figure 2 also shows that a limited number of $\kappa_{\boldsymbol{\beta}}$ terms are predominant in $\varphi(\mathbf{z})=\sum\kappa_{\boldsymbol{\beta}}h_{\boldsymbol{\beta}}(\mathbf{z})$ and, therefore, the joint-PDF; these are highlighted by indicating the corresponding state variables within brackets.

Similarly, Figure 3 depicts the numerical results obtained at large wind speed U_h=40 m/s for the same building type. The figure summarizes the results for both integration domains, i.e., limits $|z_j|\leq 0.50$ and $|z_j|\leq 0.25$ (Domain "b") imposed on each j=1,..,n. The vertical axis scale is not the same as in Figure 2.

Figure 3 tends to confirm the results at lower speed, since the same sub-set of relevant $\kappa_{\boldsymbol{\beta}}$ is observed; this fact suggests a preservation of the main features in the joint-PDF, which is numerically evaluated through $\varphi(\mathbf{z})=\sum\kappa_{\boldsymbol{\beta}}h_{\boldsymbol{\beta}}(\mathbf{z})$, if the mean wind speed U_h varies. Also, as U_h increases, the absolute value $|\kappa_{\boldsymbol{\beta}}|$ of the corresponding expansion terms (same $\boldsymbol{\beta}$) decreases. This remark is compatible with the fact that the overall load variance proportionally grows with U_h and turbulence energy.

3.3 *Integration constants of the joint-PDF*

From the discussion results in Figure 2 and Figure 3, it was inferred that the results obtained with the integration Domain "b" ($|z_j|\leq 0.25$) are preferable due to a more realistic combination of $\kappa_{\boldsymbol{\beta}}$, possibly more compatible with an actual full-scale scenario. This case is selected and analyzed in more detail in this section. The integration constants of the joint-PDF, $p(\mathbf{z})=C_f\exp[\varphi(\mathbf{z})+\varphi_0]$, C_f and φ_0, for both U_h=20 m/s and U_h=40 m/s are computed and shown in Table 2.

The quantities C_f and φ_0 depend on the random properties of λ_u, perturbing the $\Lambda_{1x,u}$. In this study, λ_u has zero mean and standard deviation $SD(\lambda_u)=0.25\Lambda_{1x,u}$ (25% of the mean value) This corresponds to $SD(\lambda_u)$=0.042 for U_h=20 m/s ($\Lambda_{1x,u}$=0.17) and $SD(\lambda_u)$=0.056 for U_h=20 m/s ($\Lambda_{1x,u}$=0.23).

The choice of employing two constants C_f and φ_0 is dictated by algorithmic efficiency. Since one condition can exclusively be imposed on the probability, $\int..\int p(\mathbf{z})d\mathbf{z}=1.0$, C_f and φ_0 are inherently dependent. In Table 2 φ_0 is initially pre-selected and C_f is subsequently determined. Even though some variability is observed in the table, the choice of an initial $\varphi_0<0$ leads to a more suitable, i.e., a finite value in C_f.

Table 2. Integration constants of $p(\mathbf{z})$, using Domain "b" solution in Figures 2 and 3

U_h (m/s)	Integr. limits	φ_0	C_f	φ_0	C_f	φ_0	C_f
20	$\lvert z_j\rvert \leq 0.25$	-1.83E+02	5.72E+00	4.76E+01	5.03E-29	0	8.37E-09
40	$\lvert z_j\rvert \leq 0.25$	-7.72E+00	1.50E-01	4.60E-01	7.20E-05	0	8.42E-05

(Note: j = 1,..,n-1)

4 CONCLUDING REMARKS

An analytically-based and numerically-implemented algorithm is proposed in this study for the simulation and analysis of modeling errors in the lateral buffeting loads for tall buildings. The model operates in time domain by employing state-space formulation and stochastic calculus techniques. The study shows that, if torsional effects are neglected, the buffeting response of a tall building can be successfully simulated. The paper demonstrates that it is possible to derive the joint probability density function of a generalized state vector, combining modal response with random turbulence and a random variable, which simulates errors in the modeling of the

correlation length of the loads. The algorithm enables the assessment of the joint-PDF directly by Galerkin expansion and is superior to "brute-force" Monte Carlo simulation, which operates by synthetically generating a series of realizations of the time-dependent response.

Buffeting response has been exclusively investigated at this stage. Preliminary results confirm the feasibility of this approach on a 183m building; sensitivity of the solution to the selection of integration domain limits has been noticed and is currently being considered for further investigation.

ABSTRACT

This current paper presents the results of computational fluids dynamics (CFD) simulations of external flow over a cubic building block. The focus is given to the investigation of the domain size dependence of such simulations. This parametric study used a systematic examination of the pressure coefficient distribution around the block with stepwise variation in domain extensions in 4 directions relative to the block. The results revealed differences between the different domain expansions in each direction and the trend of a convergence. Dimensionless parameters were introduced to link the optimum domain size to the building size. The study identified the dominant direction that influences the domain dependence the most.

1 INTRODUCTION

Bushfire is a natural phenomenon that occurs frequently in many places around the world, given favourable weather and fuel conditions, and ignition mechanisms naturally occurring, such as lightning, or man-made, such as fallen transmission lines. Most bushfires are dealt with and controlled by the various fire services at their early stages of development. However, bushfires which are difficult to control and with major fire runs, often in inaccessible areas, can develop into ragging catastrophic infernos causing widespread property damages and loss of lives, such as the recent Black Saturday Bushfire that claimed 173 lives and more than 2000 properties in Victoria, Australia on 7 February 2009 [1].

While considerable attention has been given to the principal agents of bushfire attack, including embers, radiant heat and flame contact [2], our knowledge about the characteristics of bushfire-enhanced winds and their impacts on buildings is relatively scarce. Early studies focused on the large scale, or meteorological scale interactions between wind and wild fires [3] and primarily on the effect of wind on fire spread [4]. Only recently, numerical investigations were conducted to study wind-bushfire-building interactions at the near ground level the scale comparable to building dimensions for different approach wind speeds and fire intensities [5-6]. The results demonstrated the exacerbation of wind conditions due to buoyancy effect created by a bushfire simulated as a line-like fire front. The fire-enhanced wind profile showed a significant increase in wind speed near the ground, and the speed-up effects were found to depend on the approach wind speed and the fire intensity. When the Silsoe 6 m cube was placed downstream from the fire front of a moderate intensity, the fire-enhanced wind caused a substantial increase in the positive windward wall pressures and a small decrease in the negative roof pressures, while the sidewall and leeward wall pressures remain relatively unchanged.

It is well known that the results of numerical simulations are grid dependent both in terms of grid cell size (or mesh resolution) and grid domain size [7-10]. Grid cell size sensitivity study using the particular numerical package, namely, the Fire Dynamics Simulator [11] has been investigated in a previous study [6]. Presented in the current paper is a continuous study on grid domain dependence.

1.1 *Grid dependence studies*

Murakami and Mochida [7] studied the behavior of an external flow over a cubic building. They focused on the influence of different mesh resolutions around the building, domain boundary conditions (free slip or non-slip conditions) and various wall functions (power or log law). Their investigations were carried out by comparing pressure coefficients, velocity vectors and solution or truncation errors between simulations and experiments. It was concluded that a mesh resolution in the order of $\delta x=H/24$ (or $\delta x=0.042H$), where H is the height of the cubic model, is necessary in windward building corner to avoid errors and behind the building to study the wake. Moreover, according to their results, it would be better to set the pressure rather than the velocity at domain boundary and the log law for wall condition shows better agreement with experiment.

In 1990, Baetke and Werner [12] studied external flow over a cubic building or over a square mounted rib respectively using a Reynolds averaged simulation scheme and a LES (Large Eddy

Simulation) simulation scheme. It was suggested that a mesh division of δx=19H/160 (or δx=0.12H), where H is the height of the rib, is necessary to obtain reasonable results.

More recently, He et al. [6] carried out a numerical study of wind-fire-building interactions. In their study a 6 meter cubic block was located downstream a fire bed and an external wind flow defined by $U_0(z)=U_r(z/z_r)^{\alpha}$ (where α=0.16, U_r=9.52 m/s and z_r=6 m). During this work, they began to simulate without fire and focused their study on grid dependence to find the mesh division which yields reasonably good agreement with experiments and is computationally economical. It was concluded that the optimum grid size was not necessarily the finest and the optimized grid size was δx=0.04H, similar to that found by Murakami and Mochida [7].

Yet, the domain dependence problem was often neglected. The computational domain was often set arbitrarily. It could cause serious errors because a non-appropriate domain size may overestimate or underestimate key parameters as pressure coefficient or flow velocity. He et al. [8] and Zhang et al. [9] studied particularly the domain dependence in building enclosure fire simulations. They carried out systematic investigations into the relationship between domain extension, vent opening size and the heat release rate of compartment fires. It was found that the necessary domain extension beyond the compartment boundary could be proportionally linked to the vent opening size and the heat release rate. Moreover the coefficient of proportionality depends on whether the fire is fuel controlled or ventilation controlled and the domain extension is more efficacious in the direction perpendicular to the vent opening.

Domain dependence study can be as dramatic as comparing between 2D and 3D simulations. Hostikka et al. [13] studied an external flow and fire behavior around a building block. Their primary interest is to examine the sensitivity of heat transfer (particularly radiant heat transfer) evaluation on grid dimension and grid density. They concluded that 3D domain is necessary for accurate evaluation of radiant heat transfer with grid size in the range of 0.02H<δx<0.04H.

The objective of the current study is to investigate the domain dependence problem in computational fluid dynamics studies of external flows using Fire Dynamic Simulator. The parameter of interest is the aerodynamic characteristics, or pressure coefficient distribution around a 6 m cube building block. This paper reports the first part of the study where no fire was involved.

2 METHODOLOGY

For carrying out this study, reference case was taken from He et al.'s simulation [6] using the Fire Dynamics Simulation 5 (FDS5) software. FDS5 solves numerically a form of the Navier-Stokes equations by employing Large Eddy Simulation (LES) scheme. This scheme uses a type of Smagorinsky k-ε model described in [11] to model the turbulence effect at the sub grid level and the core algorithm is a predictor-corrector scheme with second order accuracy in space and time [14].

He et al [6] have carried out a study to find the optimum grid size for a specified fire scenario. The same grid size was retained for the current study. Thus, during this investigation, multiple series of simulations with domain size extensions or contractions respectively in x, y and z directions were executed while keeping the same grid size. Each simulation has a domain size variation in only one direction to study the domain size dependence specifically in each direction. It was particularly important to take care of y direction, where the grid size is non-uniform, and keep the same mesh division around the building. So this parametric study uses a systematic examination of the results with stepwise variation in domain extension parameters. However this

stepwise variation, keeping the grid size constant, had to respect the restriction on cell numbers defined by the FDS User's Guide [10]. Thus the steps of domain size variation could not be maintained constant (Table 1). Moreover these domain extensions and contractions were described by non-dimensional parameters to allow future researchers to use the results for study with different building sizes.

The conclusion was obtained by comparing the predicted mean pressure coefficients in different cases and by identifying the parameters at which no significant difference occurs. The averaging was achieved by taking the predicted pressure during the quasi-steady period of simulation.

This domain dependence investigation was carried out firstly without involvement of fires. After finding the appropriate domain size, one more step was achieved. In order to observe the wind speed influence on the results, a simulation with variation in reference wind velocity was run. The criteria for determining the optimum domain size is that convergence is achieved in the predicted key parameter distributions, i.e. pressure coefficient distributions, within a prescribed relative error band and reasonable CPU time. The convergence is measured with two methods. On the one hand the Pearson correlation coefficient is calculated between the results of successive domain sizes simulations. On the other hand, the mean absolute pressure coefficient difference between results is also calculated.

2.1 *Domain description of the reference case*

As mentioned previously, reference case was taken from He et al.'s study [6]. The computational domain in reference case was a 40×30×18m rectangular space. A 6 meter cubic building block was located 25 meters downstream of the domain boundary. The origin of the *x*-*y*-*z* coordinate of the domain is set at the centre of the front base line of the building block as illustrate in Figure 1. Wind is blowing from left to right, along the positive *x* direction. The fire front of the bushfire, which is not involved during the first study step, is 3 m in width and runs in the entire domain in *y*-direction at the ground level. The trailing edge of this fire bed is located 20 meter upstream the left face of the building and the fire front is assumed stationary. The two domain boundaries in *y*-direction are closed and assumed slip conditions. The right and top boundaries are specified as "OPEN". All solid surfaces are specified smooth. The grid size in the reference case is 0.17, 0.24/0.42 and 0.15 m in *x*, *y* and *z* directions respectively. The grid size in *y* direction is non-uniform. A piecewise transformation was applied to achieve finer grid close to the building and relatively coarser grid further away from the building.

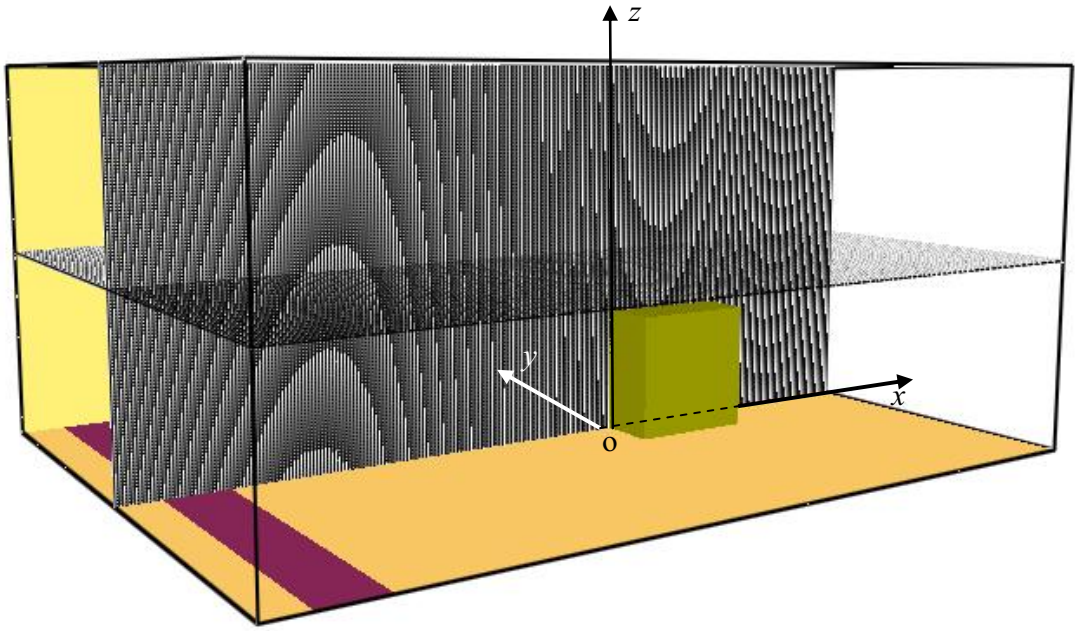

Figure 1. Computational domain and grid setup.

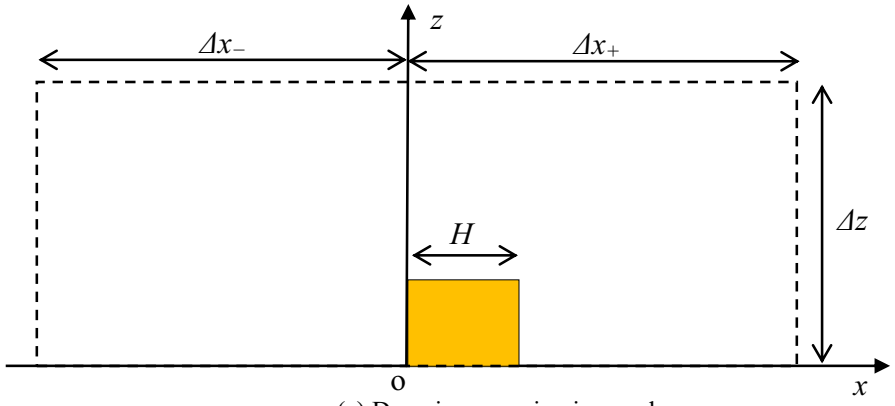
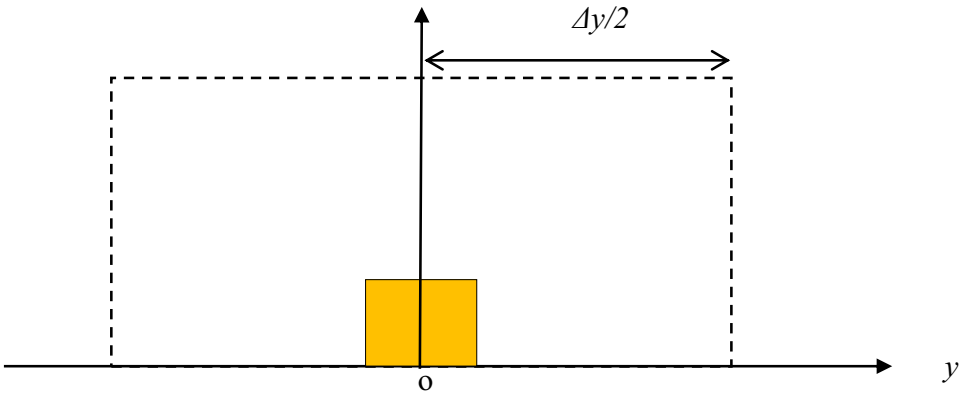
2.2 *Normalized parameters*

A group of normalize parameters are introduced to describe the dimension of the computation domain. The building block dimensions are defined as $H_x \times H_y \times H_z$. For the particular case investigated in the current study $H_x=H_y=H_z=H=6$ m. The domain expansion from the origin is denoted by Δx_+, Δx_-, Δy and Δz respectively in x_+, x_-, y and z directions. The domain expansion in y direction is symmetrical and in z is always positive. See Figure 2.



(a) Domain expansion in *x*-*z* plan



(b) Domain expansion in *y*-*z* plan

Figure 2. Illustration of computation domain and coordinate setup.

For ease in generalisation, the following non-dimensional parameters are introduced:

$$\Delta x_+^* = \Delta x_+/H; \qquad \Delta x_-^* = \Delta x_-/H; \qquad \Delta y^* = \Delta y/H; \qquad \Delta z^* = \Delta z/H \tag{1}$$

In addition, for the data presenting purpose, the non-dimensional parameter s^* is defined as $s^*=s/H$, where s is the distance measure from a reference point around the perimeter of the building block.

2.3 *Summary of simulation scenarios*

The domain expansion was undertaken in a stepwise manner in a series of simulations. From the reference case, domain expansion simulations are run. The major difficulty is to keep exactly the same grid size around the building. Moreover the number of cells in each direction has to be of the form $2^l3^m5^n$ where l, m and n are integers. So it is not possible to expand the domain arbitrarily whilst maintaining constant grid size. It is necessary to choose the domain size in function of the cell numbers permitted [10] to keep the same grid size. That explains why each domain extension in this study does not always use the same step. As regard y-direction and its non-uniform mesh division, it is not possible to keep the same grid size in the whole domain due to the piecewise linear transformation. Thus it was decided to keep the grid size unchanged close to the building. A summary of all the simulation scenarios are presented in Table 1.

Table 1. A Summary of simulation scenarios.

Simulation ID	Extensions	Domain size (m)			Grid size (m)		
		X	*Y*	*Z*	Δx	δy	δz

a. Simulation scenario A is the reference case of which the domain dimensions are Δx_+*=2.5, Δy*=5, Δz*=3 and Δx_-*≈4.2.

3 RESULT AND DISCUSSION

3.1 *Sensitivity to downstream* (Δx_+) *expansion*

Presented in Figure 3 are the predicted pressure coefficient variations along the centerline and mid height of the cube. It can be observed from Figure 3 that a significant difference in pressure coefficient distribution if the x_+ domain size is varied. This phenomenon may be attributable to pressure boundary condition at the open boundary which was prescribed downstream of the domain. As such, the simulation of wake features and flow behavior behind the building block suffers a kind of truncation or discontinuity which resulted in higher pressure coefficient distribution above and behind the cube. When Δx_+^* is increased, the pressure coefficient distribution tends to settle asymptotically. Thus the domain has to be large enough in x_+ direction to allow the simulation to take the largest wake eddies into account.

It is also noticed from Figure 3 that the variation in domain expansion in x_+ direction hardly changes the shape of the distribution curve. Indeed, the Pearson correlation coefficients between successive simulations are all above 0.999 as shown in Table 2.

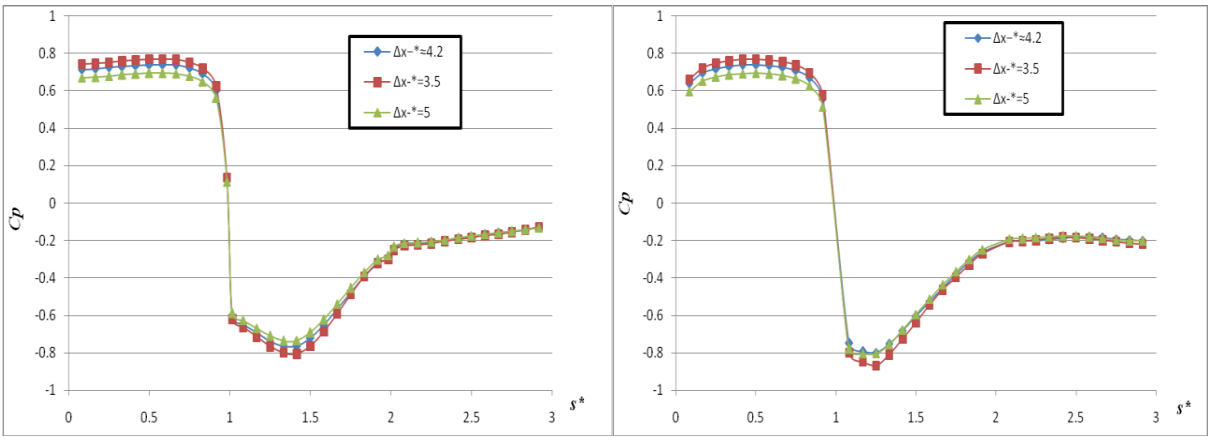
A–C	0.99994	0.99961
C–D	0.99993	0.99981
D–E	0.99998	0.99929

3.2 *Sensitivity to upstream* (Δx_-) *expansion*

For the Δx_- study only two additional simulations were run and the results are presented in Figure 4. These simulations do not reveal any significant change in comparison with simulation scenarios involving domain variations downstream of the building block. Again the correlation coefficients between successive simulations are very high, as shown in Table 3.



(a) Centerline variation. (b) Mid height variation.

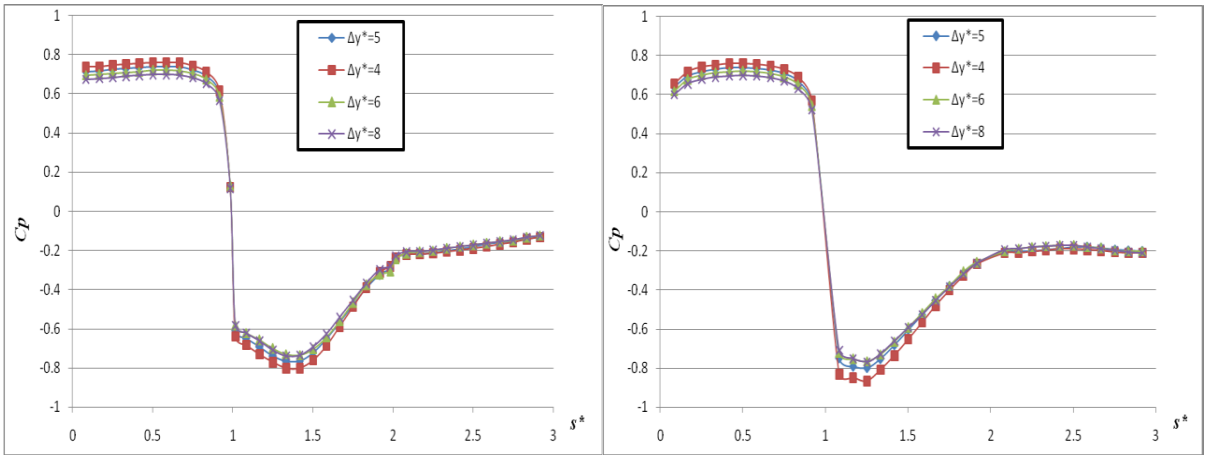
Correlation between scenarios	R	
	Centerline	Mid height
A–G	0.99994	0.99986
A–F	0.99998	0.99961

3.3 *Sensitivity to lateral* (Δy) *expansion*

In Δy variation simulation, the centerline pressure coefficient distribution does not show significant change, as revealed in Figure 5. However, in the side face, the pressure coefficient appears slightly lower when Δy^{*} is reduced. This is due to the Venturi effect between the building block and the non-slip closed boundary. Thus the domain has to be large enough to avoid this effect. It is seen from Figure 5 that the lateral dimension of Δy^{*}=5 (Case A) yielded reasonable results and any further expansion in y direction did not necessarily yield anything much different. Once more, it can be noted that the Pearson coefficient values are all higher than 0.999 and make the results reliable, as shown in Table 4.



(a) Centerline variation. (b) Mid height variation.

A–H	0.99987	0.99980
A–I	0.99991	0.99992
I–J	0.99985	0.99996

3.4 *Sensitivity to vertical (Δz) expansion*

Finally, the sensitivity to vertical domain size was studied in the last 5 scenarios in which Δz^* was varied from 2.5 to 4. The results are shown in Figure 6. Initially for relatively small vertical size Δz^*=2.5 ~3.2, the predicted pressure coefficient was almost invariant. However, when Δz^* was increased from 3.2 to 3.375, the pressure coefficient distributions exhibited on the windward face noticeable increases whilst on the roof and the side walls noticeable drops, and then remained almost invariant for Δz^*>3.375. Such a trend of variation was also revealed in the correlation analysis as shown in Table 5 where the correlation coefficient between the predicted pressure coefficient distributions of Case M and Case N attains the lowest values for both the centreline and mid height measurements.

4 CONCLUTION

A systematic examination of the mean pressure coefficient distribution in simulations with stepwise variation in each domain size has been carried out to examine the sensitivity of simulation outcome to computation domain size. As expected, the numerical simulation result of Fire Dynamics Simulator is domain dependent. In order of capture the effect of large eddies in the wake of a bluff body, sufficient domain space should be established around the bluff body. Based

on the result of the current study, a minimum domain size of 4 body length is recommended for both upstream and downstream of the body. Likewise, to avoid the "Venturi" effect, the total domain width in the lateral direction should be no less than 5 times of the body width, if the body is placed in the center location of the lateral direction. As for the vertical direction, the recommended domain height is greater than 3.5 times of the body height. The lateral and vertical domain requirement is consistent with the general requirement in wind tunnel model studies to keep the blockage ratio to be less than about 10%.

Finally, as the current study was undertaken for predominantly enclosure fire simulations, the optimum domain size is expected to be closely linked to the heat release rate or fire intensity when fires are involved. This aspect of the simulation is the subject of further studies.

ABSTRACT: The paper presents a numerical simulation of nonlinear aerodynamic forces on square section by using computational fluid dynamic (CFD) method. The square section is subjected to a forced asymptotic transverse oscillation of varying amplitude. The aerodynamic forces on the square section are computed by multiple-domain mesh technique together with unstructured dynamic meshes. The instantaneous frequencies and amplitudes of lift force are identified from its time history by continuous wavelet transform (CWT) in terms of CWT ridges. The relationship between the non-dimensional amplitude and phase angle of frequency response component of lift force and the amplitude of forced oscillation is well demonstrated. Simulated results are compared with previous data at several reduced velocities. It shows that the proposed method can identify the general nonlinear features of aerodynamic forces in association with varying excitation amplitude.

KEYWORDS: square section; nonlinear aerodynamic force; large amplitude oscillation; numerical simulation; continuous wavelet transform; lock-in region

1 INTRODUCTION

For predicting wind-induced responses of long-span cable-supported bridges, the limitation of conventional linear aerodynamic methods has been recognized and nonlinear aerodynamic forces on the bridge attract more and more attentions [1]. Chen and Kareem [2, 3] separated the aerodynamic forces into the low- and high-frequency components in accordance with the effective angle of incidence. Diana et al. [4] proposed a rheological model in the time domain to reproduce nonlinear aerodynamic forces due to large changes in the angle of attack caused by turbulence and deck motion. They further carried out wind tunnel experiments to verify the rheological model [5]. Wu and Kareem [6] utilized artificial neural network framework with embedded cellular automata scheme to capture the hysteretic nonlinear behavior of aerodynamic systems.

This paper aims at investigating the relationship between the amplitude of aerodynamic forces on and the amplitude of forced oscillation of a bluff body, in which the square cylinder is selected. The nonlinear aerodynamic forces on the square cylinder forced in harmonic oscillation have been investigated through experiments [7, 8] and computational fluid dynamic (CFD) methods [9, 10]. The continuous wavelet transform (CWT) based on the complex Morlet wavelet [11] has been successfully applied to analyse the transient vibration behaviour of structures [12] and to detect structural damage [13]. However, the combination of these two problems to find the relationship between the amplitude of aerodynamic forces on and the amplitude of forced oscillation of a square section in this paper is original. The square section is subject to a forced asymptotic transverse oscillation of varying amplitude. The aerodynamic forces on the square sec-

tion are computed by the CFD method and are further analysed by using CWT. The captured features of the aerodynamic forces are compared with previous experiment and CFD results.

2 NUMERICAL SIMULATION OF NONLINEAR AERODYNAMIC FORCES

2.1 *Dynamic mesh algorithm*

To determine nonlinear aerodynamic forces on an oscillating square section of large amplitude with uniform flow inlets, a dynamic mesh algorithm called the domain decomposition algorithm [14] is used. Two-dimensional (2D) simulation is conducted and the computational domain is shown in Figure 1. The domain called the rigid boundary layer mesh region is connected with the square section and has the same movement as the square section during its oscillation. Very fine structured quadrangular meshes are used within this region. The domain called the dynamic mesh region is modified through the interface between this region and the rigid boundary layer mesh region while the square section is subjected to a forced oscillation. The initial triangular meshes are used in the dynamic mesh region and will be adjusted according to the early work of Batina [15] during the square section oscillation. The domain called the static mesh region is meshed by relatively coarse and fixed structured rectangular meshes.

2.2 *Governing equations*

The grid velocity $\boldsymbol{V}_{\mathrm{g}}$ of the moving mesh within the rigid boundary layer region can be determined by the boundary condition of the oscillating square section. The grid velocity $\boldsymbol{V}_{\mathrm{g}}$ of the moving mesh in the dynamic mesh region can be determined by the deformed and re-meshed grids. The grid velocity $\boldsymbol{V}_{\mathrm{g}}$ of the mesh within the static region is zero.

After $\boldsymbol{V}_{\mathrm{g}}$ is determined, the Reynolds-averaged Navier-Stokes (N-S) equations for 2D incompressible unsteady fluid, which will be solved by the finite volume method, are modified and given as:

$$\oint_{\Sigma} \rho\left(\boldsymbol{V}-\boldsymbol{V}_{g}\right)\cdot \boldsymbol{n}\mathrm{d}\Sigma = 0 \tag{1a}$$

$$\frac{\mathrm{d}}{\mathrm{d}t}\oint_{\Sigma} \rho u\mathrm{d}\Omega + \oint_{\Sigma} \rho u(\boldsymbol{V}-\boldsymbol{V}_{g})\cdot \boldsymbol{n}\mathrm{d}\Sigma + \oint_{\Sigma} (p+\frac{2}{3}\rho k)\boldsymbol{i}\cdot \boldsymbol{n}\mathrm{d}\Sigma = \oint_{\Sigma} \mu_{ef}\nabla v\cdot \boldsymbol{n}\mathrm{d}\Sigma \tag{1b}$$

$$\frac{\mathrm{d}}{\mathrm{d}t}\oint_{\Sigma} \rho v\mathrm{d}\Omega + \oint_{\Sigma} \rho v(\boldsymbol{V}-\boldsymbol{V}_{g})\cdot \boldsymbol{n}\mathrm{d}\Sigma + \oint_{\Sigma} (p+\frac{2}{3}\rho k)\boldsymbol{j}\cdot \boldsymbol{n}\mathrm{d}\Sigma = \oint_{\Sigma} \mu_{ef}\nabla v\cdot \boldsymbol{n}\mathrm{d}\Sigma \tag{1c}$$

where Ω represents the control volume of quadrangular/triangular meshes whose boundary is moving; Σ is the mesh boundary (one-dimensional) surface, whose outward unit normal vector is $\boldsymbol{n}$; $\boldsymbol{V}=u\boldsymbol{i}+v\boldsymbol{j}$ is the velocity vector of the fluid; p is the fluid pressure; k is the turbulent kinetic energy; $\mu_{ef}=\mu+\mu_t$ is the total fluid viscosity; and μ is the dynamic viscosity. The turbulent viscosity μ_t is obtained through a two-equation renormalization group (RNG) k-ε turbulence model [16]. Standard values are used for the model constants: C_{μ}=0.0845, $C_{1\varepsilon}$=1.42 and $C_{2\varepsilon}$=1.68. The grid velocity of the moving mesh is also introduced into the transport equations of k and ε. Advancement in time is accomplished by the first-order implicit Euler scheme. The pressure-implicit SIMPLE algorithm is used to solve the pressure-velocity coupling. The diffusive terms are solved by a second-order central difference scheme and the convection terms are computed by means of the second-order upwind scheme. The velocity field of the steady-state solution that satisfies the continuity condition is used as the initial condition of flow velocity field.

2.3 *Forced asymptotic oscillation*

Vortex-excited oscillation is an important instability phenomenon. The shedding vortex behind a bluff body can produce a lateral periodic force. Consequently, the vortex-excited oscillation is usually considered as a forced oscillation. Large and limited amplitude oscillation may occur once reduced velocity goes into the so-called lock-in region. Therefore, the square section is defined as a rigid body and is subjected to a forced asymptotic transverse oscillation of varying amplitude in this study. The oscillating displacement of the square section is expressed as $A(t)=D_{Af}(t)\sin(2\pi ft)$ where $D_{Af}(t)$ is the forced amplitude. $D_{Af}(t)$ is given by

$$D_{Af}(t)=\begin{cases} A_0 & 0\le t\le t_1, t\ge t_4 \\ A_0 e^{2\pi\lambda f(t-t_1)} & t_1\le t\le t_2 \\ A_0 e^{2\pi\lambda f(t_2-t_1)} & t_2\le t\le t_3 \\ A_0 e^{2\pi\lambda f(t_3-t)} & t_3\le t\le t_4 \end{cases} \tag{2}$$

where A_0 represents the initial amplitude of the harmonic oscillation; λ is a constant of very small value; and f is the frequency of forced oscillation.

2.4 *Definition of aerodynamic lift coefficient*

In present study, only unsteady lift force $F_L(t)$ (positive if upward) is investigated. The corresponding lift coefficient is defined as:

$$C_L(t)=\frac{F_L(t)}{0.5\rho U^2 H} \tag{3}$$

where H is the width of square section; and U is the mean speed of incoming flow.

3 IDENTIFICATION OF NONLINEAR AERODYNAMIC LIFT FORCE USING CWT

In CFD simulation, the lift coefficient $C_L(t)$ of the square section subjected to a forced asymptotic oscillation is basically asymptotic as well. If the force coefficient varies with time at a dominant frequency, it can be expressed by

$$C_L(t)=D_L(t)\cos[\varphi_L(t)] \tag{4}$$

where $D_L(t)$ and $\varphi'_L(t)$ are limited to slowly time-varying functions, $D_L(t)\ge 0$ and $\varphi_L(t)\in[0,2\pi]$ [17]. $D_L(t)$ is defined as the instantaneous amplitude of nonlinear aerodynamic lift. The corresponding instantaneous frequency of the nonlinear aerodynamic lift is introduced as

$$\omega_L(t)=\varphi'_L(t) \tag{5}$$

where the sign ' denotes the derivative with respect to time t. The CWT method with the complex Morlet wavelet is used to identify instantaneous features of nonlinear aerodynamic lift force, and the complex Morlet wavelet is given as

$$\psi(t)=\frac{1}{\sqrt{2\pi}}e^{-0.5t^2}\cdot e^{i\omega_c t} \tag{6}$$

where $\omega_c=2\pi f_c\ge 5.0$ and f_c is the centre frequency of the mother wavelet.

By applying the CWT with the complex Morlet wavelet to Equation (4), the first term of the wavelet transform can be approximated as [18]

$$T_{CL}(a,b)\approx 0.5D_L(b)e^{i\varphi_L(b)}\hat{\psi}^*\left[a\varphi'_L(b)\right] \tag{7}$$

where a is the scale parameter; b is the shift parameter in time; and $\hat{\psi}^*(\cdot)$ stands for complex conjugate of Fourier transform of $\psi(\cdot)$. For a mono-component signal, the modulus of the wavelet

transform $T_{CL}(a,b)$ is essentially maximum in the neighborhood of a curve $a_r(b)$, called the ridge of the wavelet transform, which satisfies the following condition [18].

$$a_r(b) = \frac{\omega_c}{\varphi'(b)} \tag{8}$$

The snake penalization method proposed by Carmona et al. [18] is selected in this study to search the ridge, by which the instantaneous frequency of nonlinear aerodynamic lift can be determined through Equation (8). On the other hand, the instantaneous amplitude of nonlinear aerodynamic lift force can be found from Equation (7) in terms of the modulus. The accuracy of the above-mentioned method for the determination of instantaneous features of nonlinear aerodynamic lift force is dependent upon the time and frequency resolutions, which are merely restricted by the mother wavelet resolution. For the complex Morlet wavelet, the time and frequency resolutions at a given frequency f_i in the CWT can be expressed as [19]

$$\Delta t_i = \frac{f_c}{\sqrt{2} f_i} \qquad \Delta f_i = \frac{f_i}{2\pi\sqrt{2} f_c} \tag{9}$$

Therefore, the centre frequency f_c of the mother wavelet is a critical parameter in defining the resolution capability. In this study, the wavelet entropy method proposed by Lin and Qu [20] is applied to determine the centre frequency f_c. The subsequent investigation reveals that the nonlinear aerodynamic lift coefficient may vary with time at several frequencies although the forced oscillation is at a single frequency. Therefore, the lift coefficient shall be expressed as

$$C_L(t) = \sum_{i=1}^{m_L} D_{Li}(t)\cos\left[\varphi_{Li}(t)\right] \tag{10}$$

The amplitude $D_{Li}(t)$ as well as the derivatives $\varphi'_{Li}(t)$ also slowly vary with time. The wavelet transform, being a linear transform, of the lift coefficient by using the Morlet wavelet yields

$$T_{CL}(a,b) \approx 0.5\sum_{i=1}^{m_L} D_{Li}(b)e^{\mathrm{i}\varphi_{Li}(b)}\hat{\psi}^*\left[a\varphi'_{Li}(b)\right] \tag{11}$$

After the ridges are found using the snake penalization method, the instantaneous frequency and amplitude for each of the concerned frequency components in the lift coefficient $C_L(t)$ can be determined. Phase angle $\varphi_{Li}(b)$ can be also determined from the complex function $T_{CL}(a,b)$.

4 NUMERICAL RESULTS AND DISCUSSIONS

4.1 *Numerical model of oscillating square section*

A square section of width H=0.15m is selected as an example. The whole computational domain is sketched in Figure 1 and the corresponding parameters defining three regions as described in Section 2.1 are also designated. The height of body-fitted meshes is about 1.5mm or 2.0mm. The initial computation meshes are shown in Figure 2, in which the rigid boundary layer region has 14,712 quadrangular meshes, the dynamic mesh region has 13,398 triangular meshes, and the static mesh region has 7,898 quadrangular meshes. The initial angle of attack at the equilibrium position is set as zero. The inflow is set as uniform flow with a mean speed U and a turbulence intensity of 0.5%. The reduced velocity $V_r=U/fH$ varies from 5.0 to 12.0, in which the frequency f of forced oscillation is 4.0Hz. The Reynolds number $Re=\rho UH/\mu$ also varies from 3.1×10^4 to 7.4×10^4. The initial amplitude A_0 of harmonic oscillation is 5mm. Parameters t_1, t_2, t_3 and t_4 in Equation (2) are set as $14/f$, $59/f$, $72/f$ and $119/f$, respectively. The iteration time step is 3×10^{-4}s.

4.2 *Characteristics of flow around the fixed square section*

To demonstrate the effectiveness of RNG *k-ε* turbulence model, the unsteady flow field around the fixed square section at zero incidence of wind is simulated. In this simulation, the computational meshes are as same as the meshes shown in Figure 2. The mean speed of incoming flow is U=4.2m/s and the Reynolds number is Re=4.3×10^4. The iteration time step is 3×10^{-4}s. The computed time-averaged velocity <u> along the centre line is shown in Figure 3 and compared with previous experiment and CFD results [21-24]. The computed results are in good agreement with experimental results and better than the previous computational results, but the size of reverse

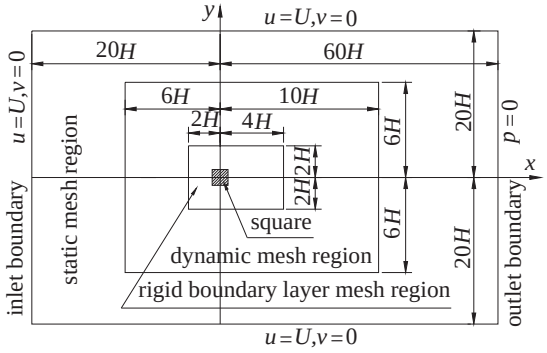

Figure 1 Sketch of computation domain

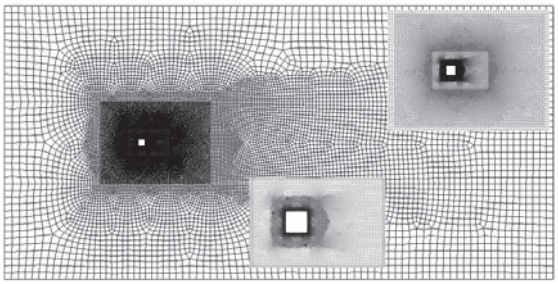

Figure 2 Initial computational meshes

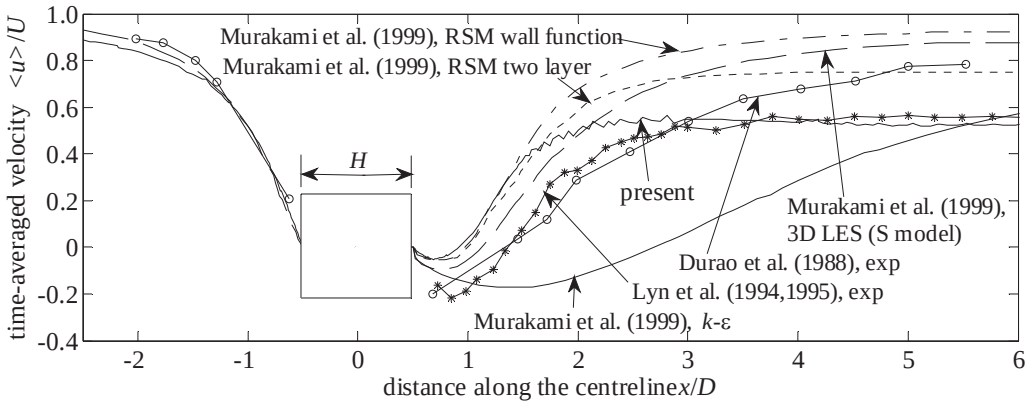

Figure 3 Comparison of time-averaged velocity <u> along the centerline

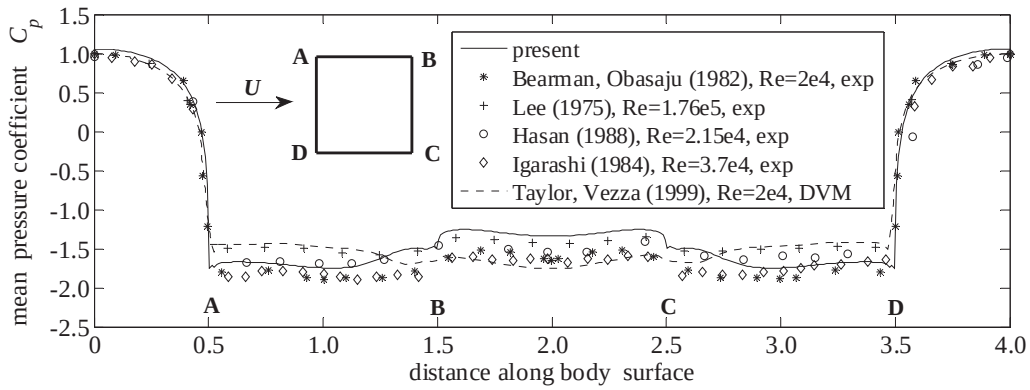

Figure 4 Mean pressure coefficient on body surface

flow region is smaller than experiment results. The latter may be induced by large turbulent viscosity in the RNG k-ε turbulence model. The mean surface pressure C_p around the square section is shown in Figure 4 and compared with previous experiment and CFD results [25-28, 10]. The corners of body are indicated in figure. The present results demonstrate a good agreement with experimental results. The Strouhal number of the fixed square section is St=0.129 by analyzing the present lift force time history. This is close to the experimental result St=0.12 [29] and the CFD results St=0.14 [9] and St=0.128 [10].

4.3 *Frequency response component of lift force on the oscillating square section*

As an example, the computed lift coefficient $C_L(t)$ is shown in Figure 5 at V_r=6, 7. The centre frequency of the complex Morlet wavelet is determined by using the wavelet entropy method [20]. The centre frequencies are set as f_c=4.0Hz and f_c=4.5Hz for V_r=6, 7, respectively. The corresponding scalograms obtained by CWT are shown in Figure 6. A unique ridge corresponding to the frequency response component of lift force can be found at V_r=7 since oscillation is in lock-in region. Two ridges can be observed at V_r=6 when the forced amplitude is small. One ridge is related to vortex-shedding frequency and the other is corresponding to frequency response component of lift force. As the forced amplitude gradually increases, oscillation will gradually go into lock-in region. Therefore, two ridges gradually merge into one at V_r=6 in Figure 6. This observation is in good agreement with the experiment result [7]. The ridge can be identified by snake penalization method [18].

The frequency response component of the lift coefficient can be expressed as

$$C_{Lf}(t)=D_{CLf}(t)\sin[2\pi ft+\beta_{CLf}(t)] \tag{12}$$

where the instantaneous amplitude $D_{CLf}(t)$ equals a certain value $D_{Li}(b)$ defined in Equation (11), such as $D_{L1}(b)$; phase angle $\beta_{CLf}(t)$ can be determined from $\varphi_{Li}(b)$ defined in Equation (11)， such

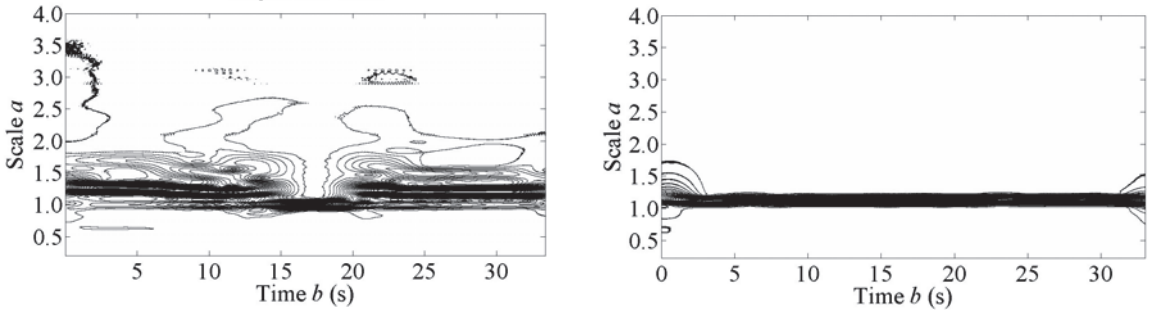
Figure 5 Computed lift coefficient



(a) Reduced velocity V_r=6 (b) Reduced velocity V_r=7

Figure 6 Scalogram of lift coefficient

as $\varphi_{L1}(b)$. Therefore, the instantaneous amplitude $D_{CLf}(t)$ and phase angle $\beta_{CLf}(t)$ of frequency response component can be determined from the corresponding wavelet ridge.

The instantaneous amplitude $D_{CLf}(t)$ and the corresponding phase angle $\beta_{CLf}(t)$ at different reduced velocities are shown in Figure 7 when the square section is subjected to a forced asymptotic transverse oscillation of varying amplitude defined in Equation (2). It is clear that the relation between instantaneous amplitude $D_{CLf}(t)$ and excitation amplitude $D_{Af}(t)$ is nonlinear. In general, the instantaneous amplitude $D_{CLf}(t)$ for reduced velocity V_r in lock-in region is larger than that for reduced velocity V_r outside lock-in region. An exceptional case is observed at V_r=6. When excitation amplitude is small, the instantaneous amplitude $D_{CLf}(t)$ at V_r=6 is relatively small. However, the instantaneous amplitude $D_{CLf}(t)$ rapidly increases when excitation amplitudereaches above 16mm. One can observe from Figure 6 that the oscillation in this case is gradually going into lock-in region. This reveals that the range of lock-in region increases with the

increasing excitation amplitude. This observation is in good agreement with the experimental result of Otsuki et al. [7]. The phase angle $\beta_{CLf}(t)$ at different reduced velocities is relatively steady as excitation amplitude increases. The phase angle $\beta_{CLf}(t)$ is negative or positive for wind speed U below or above the resonance speed. It is clear that positive phase angle $\beta_{CLf}(t)$ is required for vortex-induced oscillation which only occurs once the reduced velocity goes into the lock-in region. Some values of instantaneous amplitude $D_{CLf}(t)$ and the corresponding phase angle $\beta_{CLf}(t)$ with varying reduced velocity V_r at several excitation amplitudes are compared with previous experiment and CFD results at the corresponding excitation amplitudes, as shown in Figure 8 and 9. The most noticeable feature is the sudden increase from negative to positive phase angle through the lock-in region. This feature is perfectly reproduced by the present method. The reduced velocity corresponding to the resonance speed is adjacent to 8.0 from Figure 8 and 9. This observation is supported by the previous experiment results, such as that given by Otsuki et al. [7]. The simulated general tendency of instantaneous amplitude $D_{CLf}(t)$ and phase angle $\beta_{CLf}(t)$ is in good agreement with the previous experiment and CFD results. Nevertheless, two typical discrepancies can be found. One lies in the lock-in region where the instantaneous amplitudes D_{CLf} of the present and previous data are distributed in a large range. The other lies in below or above lock-in region where the phase angle β_{CLf} of the present and previous data are also dispersed. These discrepancies will be discussed in Section 4.4.

4.4 *Discussions*

Since the instantaneous flow field around the square cylinder is highly three-dimensional (3D), the 2D CFD simulation cannot fully reproduce this feature. The previous CFD study [24] has obviously demonstrated that the spectrum shape of lift force from 2D simulation shifts from the spectrum of lift force obtained from the experiment [29] to a relative high vortex-shedding frequency. This may induce the peak of amplitude D_{CLf} from the CFD simulation appearing at a relative low reduced velocity while that from the experiment data lies at a relative high reduce velocity, as shown in Figure 8.

The spanwise correlation of the fluctuating surface pressure on the square cylinder has been early studied by wind tunnel experiments [26, 29, 30]. The experimental lift force on the square cylinder is actually a space-averaged value. The present 2D simulated lift force does not take the influence of spanwise correlation into account. This may cause large discrepancy between the simulation and experiment results. The experimental lift forces may be mainly affected by the spanwise correlation of the fluctuating surface pressure on the side surface of the square cylinder.

In the following, only the frequency response component $L_f(t)$ of lift force on the square cylinder will be discussed. For two points A and B on the top or bottom side surface of the square cylinder along the axial direction, assume that the correlation coefficient $R_{AB}(z,t)$ is independent on the time t during the square cylinder oscillation.

$$R_{AB}(z,t) \approx R_{AB}(z) \tag{13}$$

Further assume that the phase angle $\beta_{CLf}(t)$ defined in Equation (12) is also independent on the axial position. The frequency response component $L_f(t)$ can be expressed as

$$L_f(t) = 0.5\rho U^2 H^2 C_{Lf}(t) \int_0^L R_{AB}(z)\mathrm{d}z \tag{14}$$

Define the axial correlation length scale of the square cylinder C_R as

$$C_R = \int_0^L R_{AB}(z)\mathrm{d}z \tag{15}$$

The frequency response component of the experimental lift coefficient $C_{Lf,E}(t)$ is defined as

$$C_{Lf,E}(t) = \frac{L_f(t)}{0.5\rho U^2 H^2 L} \tag{16}$$

Therefore, the experimental $C_{Lf,E}(t)$ and the present 2D simulation $C_{Lf}(t)$ have relationship:

$$L \cdot C_{Lf,E}(t) = C_R \cdot C_{Lf}(t) \tag{17}$$

The expression of $C_{Lf,E}(t)$ can be expressed by Eq. (12) and the corresponding instantaneous amplitude is defined as $D_{CLf,E}(t)$. Assume that experimental phase angle equals the simulation one, the relationship between the experimental $D_{CLf,E}(t)$ and simulating $D_{CLf}(t)$ can be given as

$$L \cdot D_{CLf,E}(t) = C_R \cdot D_{CLf}(t) \tag{18}$$

In this expression, the amplitude $D_{CLf}(t)$ from the 2D CFD simulation cannot be directly compared with the experimental amplitude $D_{CLf,E}(t)$ since the experimental square cylinder is a fully 3D body. At the same time, the correlation length scale C_R is dependent on the length L of the square cylinder. The amplitude $D_{Lf,E}(t)$ may vary with length of square cylinder for the same experimental condition.

Otsuki et al. [7] investigated the square cylinder of width H=150mm and length L=660mm in a wind tunnel. Referring to the spanwise correlation distribution of fluctuating pressure of the square cylinder [26, 29], the correlation length scale C_R is approximately 3.2H for L/H=4.4. Therefore, the ratio of the experiment $D_{CLf,E}(t)$ to the 2D simulated $D_{CLf}(t)$ is about 0.73 from Equation (18). Other factors are also needed to be mentioned. For example, the method of subtraction of the inertia force from the measured data consisting of the aerodynamic force plus the inertia force may introduce some numerical errors, as pointed out by Otsuki et al. [7]. The spanwise correlation of phase angle $\beta_{CLf}(t)$ may also introduce some numerical errors. These factors may further decrease the ratio of the experiment data to the 2D simulation result.

By considering the above correlation coefficient and numerical errors, the present numerical results are acceptable. If 3D CFD simulation and more advance turbulent models are used, better simulation result can be expected.

5 CONCLUSIONS

(1) The proposed CFD simulation integrated with the CWT analysis can be used to determine nonlinear features of the aerodynamic forces on the square section in forced large amplitude oscillation. The simulated results are in good agreement with the previous experimental data and CFD results.

(2) The amplitude of aerodynamic forces on the square section depends on the amplitude of the forced oscillation in addition to reduced velocity.

Flow above the free end of a surface-mounted square prism

N. Rostamy, J.F. McClean, D. Sumner, D.J. Bergstrom, J.D. Bugg

Department of Mechanical Engineering, University of Saskatchewan
57 Campus Drive, Saskatoon, Saskatchewan, Canada

ABSTRACT: The flow above the free end of a surface-mounted finite-height square prism was studied experimentally in a low-speed wind tunnel using particle image velocimetry (PIV). The prism was mounted normal to a ground plane and was partially immersed in a flat-plate turbulent boundary layer. Four finite square prisms of aspect ratios AR = 9, 7, 5 and 3 were tested at a Reynolds number of Re = 4.2×10^4. PIV velocity field measurements were made above the free ends in three vertical planes parallel to the mean flow direction at cross-stream locations of y/D = 0 (the flow centreline), 0.25, and 0.375 (where D is the side length of the square prism). The results show how the prism's aspect ratio influences the mean velocity field and the Reynolds stresses above the free end surface of the prism. A cross-stream vortex forms in the region of separated flow above the free end of the square prism, due to interaction between the separated flow from the leading edge of the prism and reverse flow over the free end. The centre of this vortex moves downstream and upwards as the aspect ratio is lowered. Another cross-stream vortex forms immediately behind the prism; the size and strength of this vortex increases as aspect ratio of the prism is lowered.

KEYWORDS: Bluff body, finite square prism, separated flow, vortex structures, particle image velocimetry

1. INTRODUCTION

The flow around surface-mounted circular cylinders and square prisms of finite height is more complex than the familiar case of a two-dimensional or "infinite" circular cylinder or prismatic body [1]. In engineering applications such as high-rise buildings, oil storage tanks, cooling towers, and chimneys, the flow fields of these prismatic structures are strongly three-dimensional due to the effect of the flow around the free end and the flow at the prism-wall junction.

A schematic of the flow past a surface-mounted finite-height square prism (of side length, D, and height, H), mounted normal to a ground plane and partially immersed in a flat-plate boundary layer (with thickness δ at the location of the prism), is shown in Figure 1. In this figure, x is the streamwise coordinate, y is the cross-stream coordinate, and z is the wall-normal coordinate. The flow field is influenced by the aspect ratio, AR (= H/D), the Reynolds number, Re (= DU_∞/ν, where U_∞ is the freestream velocity and ν is the kinematic viscosity), and the relative thickness of the boundary layer on the ground plane, δ/D or δ/H.

The flow field over and above the free end of the finite-height prism influences the flow pattern in the near-wake region, including the formation of a pair of mean streamwise trailing vortex structures in the upper wake and the downwash (downward-directed) flow associated with it. Few studies of finite circular cylinders and square prisms have examined, in detail, the flow separation on the free end and its potential for reattachment. Kawamura et al. [2] studied the flow pattern on the free ends of finite circular cylinders of AR = 8, 4 and 1 with δ/D = 1 at Re =

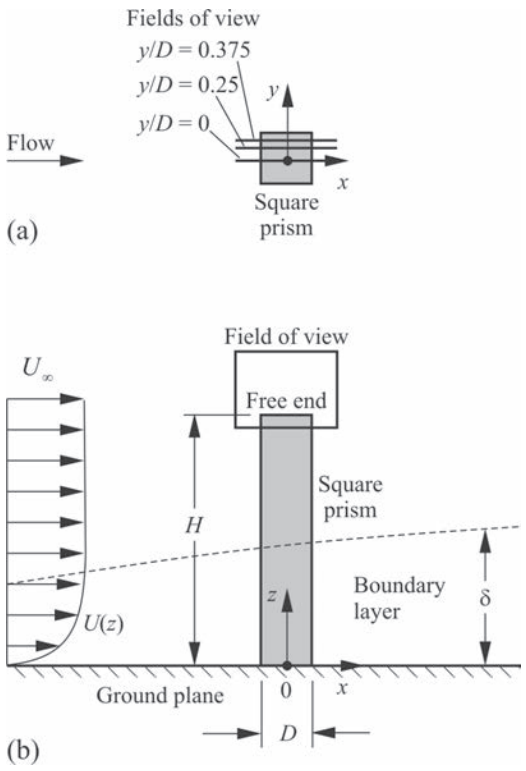

Figure 1. Schematic of the flow around a surface-mounted finite-height square prism partially immersed in a flat-plate boundary layer (with mean velocity profile, $U(z)$): (a) top view, showing the cross-stream positions of the fields of view for the particle image velocimetry (PIV) measurements; (b) side view, showing the field of view in the vicinity of the free end.

1.1×10^4 to 3.2×10^4. According to their flow visualization results, reattachment of the separated flow on the free end was sensitive to both AR and δ/H: reattachment of the flow on the upper surface occurred for the most slender and the least slender cylinders (for AR = 8 and δ/H = 0.125 and AR = 1 and δ/H = 1) but not for the intermediate cylinder (for AR = 4 and δ/H = 0.25). Leder [3] studied the flow past a finite circular cylinder of AR = 2 at Re = 2×10^5 and with δ/D = 0.008 using laser Doppler velocimetry (LDV). On the central vertical plane of the flow field, flow separated at the leading edge of the free end surface and reattached close to the trailing edge, at x/D = 0.34 (where x is measured from the centre of the cylinder). Weak recirculating flow was seen inside the time-mean separation bubble. Park and Lee [4] studied the flow around the free end of a finite circular cylinder of AR = 6 at Re = 7,500 using flow visualization, thermal anemometry, and particle image velocimetry (PIV). On the flow centreline, reattachment of the separated flow on the free-end surface was observed. Pattenden et al. [5] experimentally investigated the flow over a small-aspect-ratio surface-mounted finite circular cylinder of AR = 1 (well below a typical value for the critical aspect ratio), using PIV, surface flow visualization, and unsteady surface pressure measurements. Their results showed flow separation at the leading edge of the free end surface and, along the centreline, reattachment on the top of the circular cylinder at x/D = 0.17 (measured from the centre of the cylinder).

Recently, Krajnović [6] used large eddy simulation (LES) to study the flow around a finite circular cylinder with AR = 6, and reported that the flow on the top surface of the cylinder includes a large primary recirculation region and a secondary recirculation region. He showed

that the large recirculation region originates at the leading edge of the cylinder and reattaches at approximately 0.82*D* from the leading edge (i.e., at $x/D = 0.32$, as measured from the centre of the cylinder) in the streamwise direction and in the symmetry plane (y = 0). The results of his simulations disagree with the tip flow structure suggested by Roh and Park [7] but were in general agreement with the results of Pattenden et al. [5] and Kawamura et al. [2].

The above examples are all for the case of the finite circular cylinder. For the finite square prism, recent experimental studies have focused mostly on the wake dynamics [8–11], but without considering in depth the flow above the free end of the square prisms. In the present study, the flow field above the free-end surface of a surface-mounted, finite-height square prism was investigated in a low-speed wind tunnel using PIV. Of particular interest were the effects of prism aspect ratio on the flow field.

2. EXPERIMENTAL APPARATUS

The experiments were conducted in a low-speed closed-return wind tunnel with a test section of 1.96 m (length) × 0.91 m (height) × 1.13 m (width). The streamwise freestream turbulence intensity was less than 0.6% and the mean velocity non-uniformity outside the test section's wall boundary layers was less than 0.5%. An aluminum ground plane was installed on the floor of the wind tunnel test section and a fully developed turbulent boundary layer was produced on the ground plane at the location of the finite square prism.

Four different, smooth, aluminum square prism models, all of the same width, $D = 31.5$ mm, were tested. The free end of each prism was a flat surface with sharp perimeter edge. Each prism had a different height, giving prisms with AR = 9, 7, 5, and 3, similar to earlier experiments of [1,12]. The prisms were anodized flat black to minimize unwanted reflections from the laser light sheet used for the PIV measurements. Each prism was partially immersed in the turbulent boundary layer on the ground plane. The experiments were conducted at a freestream velocity of $U_\infty = 20$ m/s, giving a Reynolds number, based on prism width, of $\mathrm{Re} = 4.2\times10^4$.

The wind tunnel data were acquired using a computer with a 1.8-GHz Intel Pentium 4 processor, a National Instruments PCIe-6259 16-bit data acquisition board, and LabVIEW software. The freestream conditions were obtained with a Pitot-static probe, Datametrics Barocell absolute and differential pressure transducers, and an Analog Devices AD590 integrated circuit temperature transducer. To characterize the boundary layer on the ground plane, a boundary layer Pitot tube and an X-wire boundary layer probe were used to measure its mean velocity profile. At the location of the prism (with the prism removed), the boundary layer thickness was $\delta = 54$ mm providing a thickness-to-width ratio of $\delta/D = 1.7$ and a thickness-to-height ratio ranging from $\delta/H = 0.2$ (for AR = 9) to $\delta/H = 0.6$ (for AR = 3).

Velocity field measurements in the vicinity of the finite square prism were made with a PIV system. The laser light (532 nm) was supplied by a 200-mJ/pulse dual Nd:YAG Gemini PIV 15 laser from New Wave Research, which had a maximum pulse frequency of 15 Hz. A TSI light arm was used to deliver the laser beam from the laser to the light sheet optics. The light sheet optics included either −50-mm or −25-mm cylindrical lenses and 500-mm, 750-mm, or 1000-mm spherical lenses, depending on the location of the field of view. Images were acquired with a CCD camera (MegaPlus ES4020, double frames, 2048 × 2048 pixels) and captured by a 64-bit EDT PCI DV C-Link frame grabber on a computer workstation. The timing of the laser, camera, and frame grabber was controlled by a Berkeley Nucleonics 505-8C digital delay

generator synchronizer. The flow was seeded by atomized propylene glycol droplets produced by a theatrical fog machine.

PIV measurements were made above the free end surfaces of the prisms in vertical (*x*-*z*) planes located on the centreline of the model ($y/D = 0$) and at two offset locations ($y/D = 0.25$ and 0.375); the locations of these fields of view are shown in Figure 1. The light sheet optics were located above the wind tunnel test section and the laser light was directed through a small aperture in the test section roof and towards the ground plane. Each field of view was 61 mm × 61 mm (1.9*D* × 1.9*D*) yielding an image resolution of about 30 μm/pixel. For the tallest prism (of AR = 9), more than 25 fields of view were used to build a composite picture of the flow field upstream and downstream of the prism. For each field of view, an ensemble of 1,000 sample images was acquired from which the mean velocity vector field was determined. Image pairs were processed with a half-padded FFT cross-correlation algorithm, a relative maxima peak detection algorithm, and a Gaussian sub-pixel interpolation algorithm. A Hart correlation-based (CBC) validation method [13] with 50% overlap was used for reducing the sub-pixel errors and eliminating spurious vectors from the PIV results. The cellular neural network (CNN) method [14] together with dynamic threshold outlier identification was used as a post-interrogation algorithm to detect spurious vectors in PIV measurements. The fields of view were analyzed with interrogation areas of 64 × 64 pixels. A two-level analysis technique was used that halved the size during the second pass. In addition, a 50% interrogation area overlap was used in all cases. The resulting velocity vector fields contained approximately 63 × 63 velocity vectors with a vector spacing (spatial resolution) of approximately 0.03*D*. The uncertainty in the mean velocity measurements was estimated to be about 2%.

3. RESULTS AND DISCUSSION

Figure 2 shows the mean flow streamlines (obtained from the in-plane mean velocity components, $\overline{U}/U_\infty$, $\overline{W}/U_\infty$), on the wake centerline ($y/D = 0$) for each of the four prisms (of AR = 9, 7, 5, and 3). The mean fields are calculated from an ensemble of 1,000 instantaneous PIV velocity fields.

Upstream of the prism, for all four aspect ratios, part of the approach flow moves up and over the tip and separates from the leading edge of the free end. No flow reattachment occurs on the free end. The other part of the approach flow, closer to the ground plane, moves downwards as it nears the prism and recirculates upstream of the prism-wall junction. It is in this region where the familiar horseshoe vortex is located (although it cannot be discerned in Fig. 2). In the near-wake region, a strong downwash flow is observed immediately downstream of the free end in the near wake of the prism. The downwash originates downstream of the free-end recirculation zone, persists in the streamwise direction and descends into the central portion of the wake.

The mean streamlines show that part of the downwash flow is directed towards the ground plane and returns upstream to stagnate onto the rear surface of the prism; a large recirculation zone forms behind the prism. The rest of the downwash flow moves away from the prism into the far wake. A small vortex forms immediately downstream of the trailing edge of the free end. The size of the vortex is a function of the prism aspect ratio, such that the largest vortex occurs for the smallest aspect ratio (AR = 3, Fig. 2d). According to Figures 2a,b,c, for AR = 9, 7 and 5, respectively, some of the downwash flow is directed along the prism wall toward the ground plane, whereas for AR = 3 (Fig. 2d), flow moves upwards along the prism wall toward the free end, resulting in a larger vortex just below the free end.

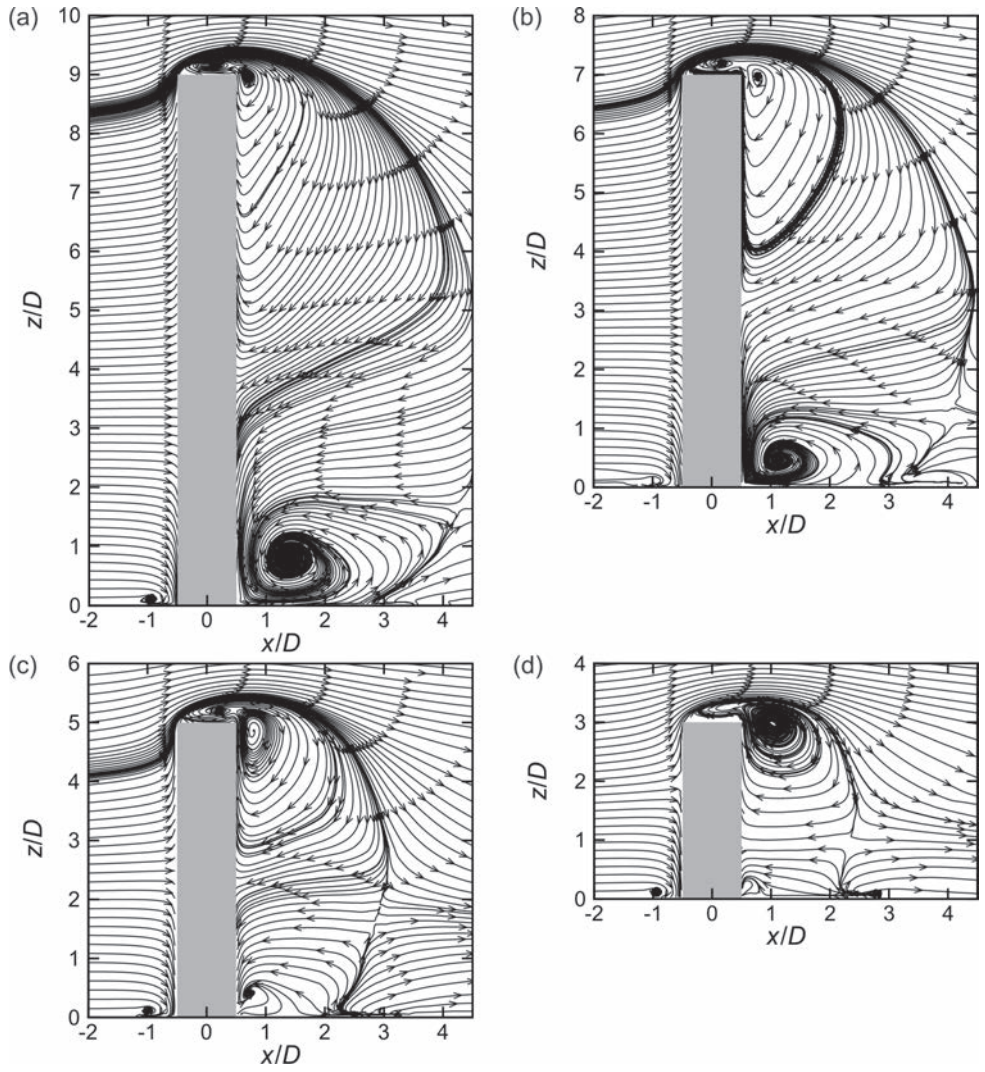

Figure 2. Mean streamlines in a vertical plane on the wake centerline (y/D = 0, the symmetry plane: (a) AR = 9; (b) AR = 7; (c) AR = 5; (d) AR = 3.

Another vortex, with CCW sense of rotation, can be found immediately behind the prism, near the prism-wall junction, for AR = 9 and 7 (Fig. 2a,b). This vortex is much weaker and nearly absent for the prisms of AR = 5 and 3 (Fig. 2c,d). The distinct near-wake structure for AR = 3, and to some extent for AR = 5, suggest the critical aspect ratio for these prisms is between AR = 5 and AR = 3.

Figure 3 shows an enlarged view of mean streamlines (on the flow centreline) and the CW vortex behind the square prism close to the trailing edge of the prism's free end surface. The size of the vortex is a function of aspect ratio, such that the largest vortex occurs for the smallest aspect ratio (AR = 3, Fig. 3d). This vortex is related to the flow direction along the rear surface of the prism (seen in Fig. 2). The centre of the vortex moves downstream as the prism aspect ratio decreases.

The mean streamlines above the free ends (on the flow centreline) of the square prisms are shown in Figure 4. Flow separating from the leading edge does not reattach onto the upper surface but extends into the near-wake region. Another small region of locally separated flow

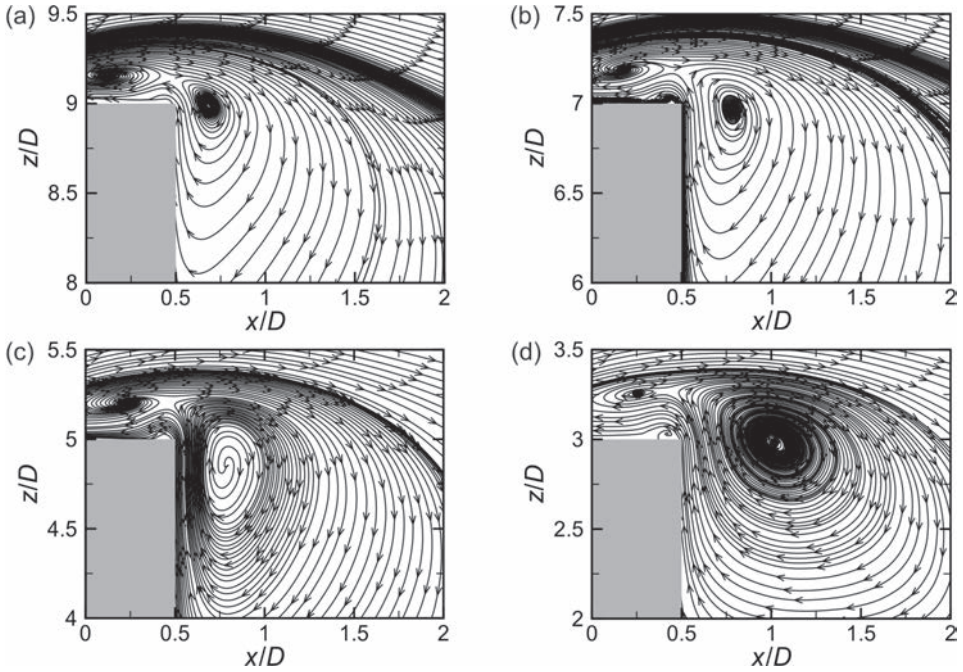

Figure 3. Mean streamlines immediately above and behind the prism, on the flow centreline (an enlargement of what is shown in Fig. 2): (a) AR = 9; (b) AR = 7; (c) AR = 5; (d) AR = 3.

may be seen on the upper surface just upstream of the trailing edge. A cross-stream vortex forms above the free end of the square prism, due to interaction between the separated flow from the leading edge of the prism and the reverse flow over the trailing edge. The role of the reverse flow coming up from the near wake of the prism and moving upstream over the free end surface is to form the vortices and saddle points in Figure 4. However, the behaviour of the reverse flow and its interaction with the separated flow changes with AR, and its overall behaviour is connected with the entire flow field around the prism. As seen in Figure 4, the centre of the cross-stream vortex moves downstream and upwards as the aspect ratio is lowered. Just behind this vortex, a saddle point is observed. As the aspect ratio is lowered, the locations of the vortex centre and saddle point are displaced farther away from the free end surface, moving from $z/D \approx 0.15$ above the surface for AR = 9 (Fig. 4a) to $z/D \approx 0.25$ for AR = 3 (Fig. 4d).

Contour plots of the streamwise turbulence intensity (u'/U_∞), above the free ends (on the flow centreline) of the finite square prisms are shown in Figure 5. This figure illustrates regions of elevated streamwise turbulence intensity above the free end surfaces that extend prominently downstream of the prisms. According to Figure 5, for all aspect ratios, the streamwise turbulence intensity level increases from its minimum value close to the free end surface to its highest level occurring along the shear-layer boundary between the outer flow and the mean recirculation zone. The maximum level of turbulence intensity for the prism of AR = 9 (Fig. 5a) is $u'/U_\infty \approx 0.43$, while for AR = 7, 5, and 3 (Fig. 5b,c,d) its value is $u'/U_\infty \approx 0.4$. For finite circular cylinders, however, the highest levels of u'/U_∞ are almost twice those for square prisms [15]. According to Figure 5, the region of highest level of u'/U_∞ is approximately located 0.2D to 0.3D above the free end surfaces of the square prisms and in the streamwise position range of x/D = −0.3 to −0.2.

Figure 6 shows the contours of the in-plane Reynolds shear stress field ($-\overline{u'w'}/U_\infty^2$) above the free end surfaces of the finite square prisms. The flow above the free end is characterized by

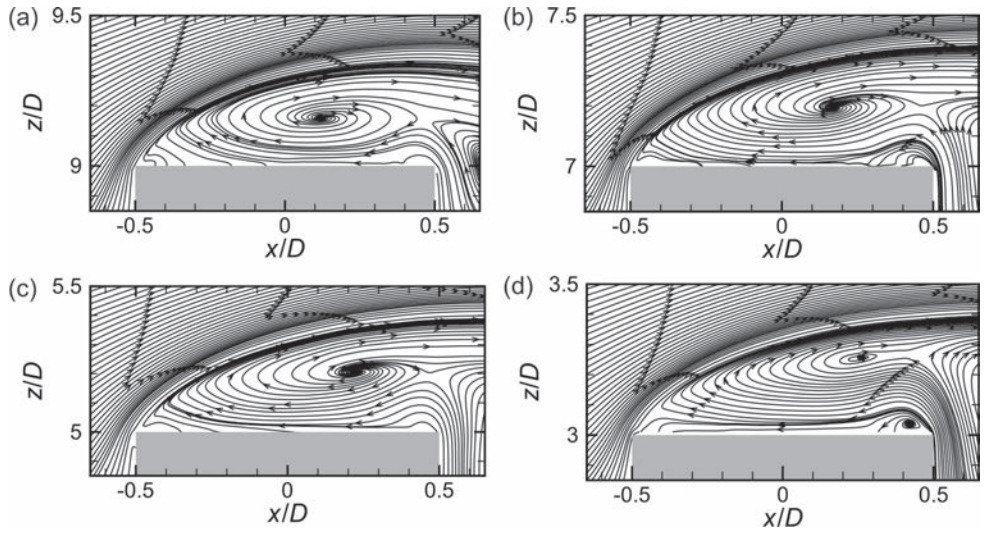

Figure 4. Mean streamlines above the free end on the flow centreline (an enlargement of what is shown in Figs. 2 and 3): (a) AR = 9; (b) AR = 7; (c) AR = 5; (d) AR = 3.

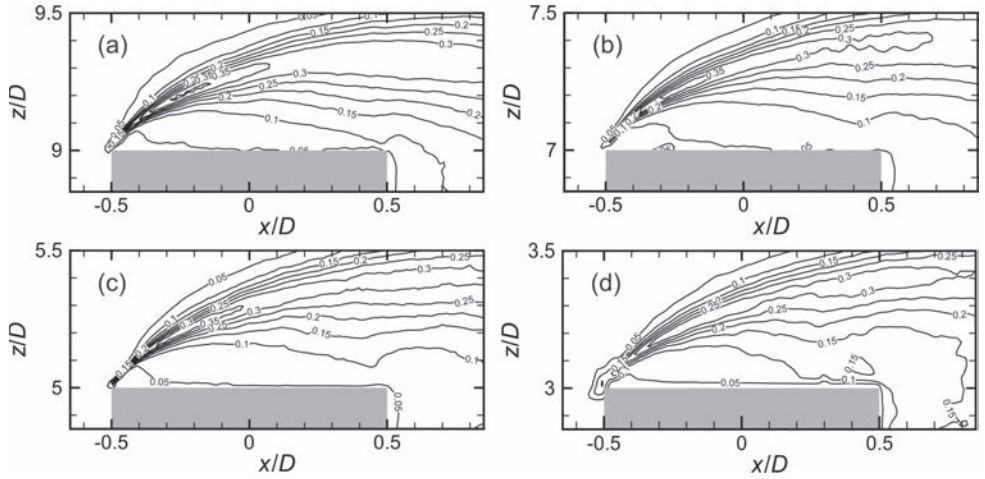

Figure 5. Streamwise turbulence intensity contours in a vertical plane on the wake centerline (y/D = 0, the symmetry plane): (a) AR = 9; (b) AR = 7; (c) AR = 5; (d) AR = 3.

two regions of elevated Reynolds shear stress: a region of negative shear stress above the free end that extends into the upper part of the near-wake region, and a region of positive shear stress originating from the leading edge and following the separated shear layer bounding the mean recirculation zone. The Reynolds shear stress behaviour does not change significantly as the aspect ratio of prism changes. However, as the prism aspect ratio increases, the region of negative Reynolds shear stress becomes wider so that for the prism of AR = 9 (Fig. 6a), the contour of negative Reynolds shear stress reaches the trailing edge of the free end surface.

Figure 7 shows the mean streamlines in three vertical (x-z) planes above the free ends of the square prisms; the three planes correspond to the three cross-stream positions of y/D = 0, 0.25, and 0.375 (illustrated in Fig. 1). According to Figure 7, the mean flow pattern above the free end of a square prism of a given aspect ratio changes considerably moving away from the

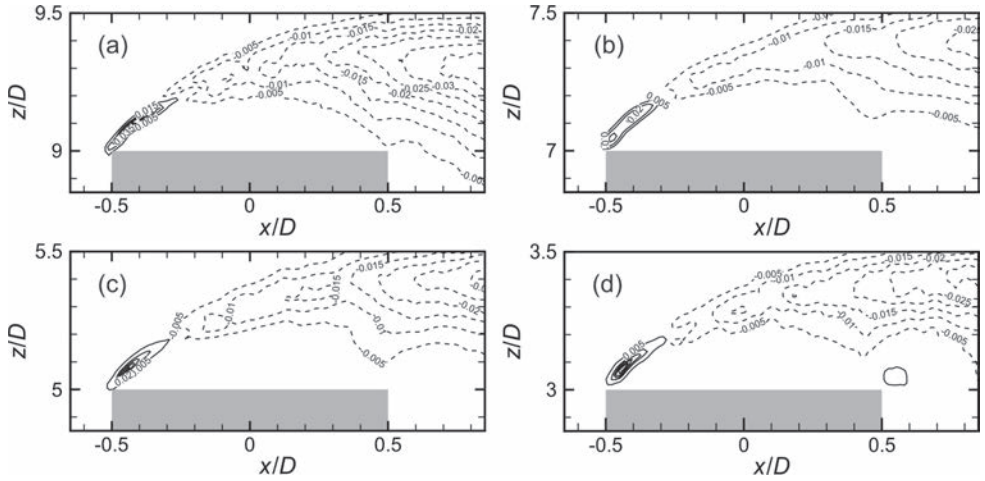

Figure 6. Reynolds shear stress contours in a vertical plane on the wake centerline (y/D = 0, the symmetry plane): (a) AR = 9; (b) AR = 7; (c) AR = 5; (d) AR = 3. Solid contour lines represent positive Reynolds shear stress, dashed contour lines represent negative Reynolds shear stress.

flow centreline. For the square prisms of AR = 9, 7, and 5, the cross-stream vortex seen at y/D = 0 (Fig. 7a,d,g), is absent away from the symmetry plane, however, the cross-stream vortex is still present at all the y/D positions considered for the prism of AR = 3 (Fig. 7j,k,l)). In addition, the reverse flow and its local separation from the trailing edge is more dominant for the prism of AR = 3 at different y/D locations (Fig. 7j,k,l), while for the more slender prisms (AR = 9, 7, and 5), the effect of the shear layer separated from the leading edge is more dominant than the reverse flow as the distance from the symmetry plane increases (Fig. 7a-i).

4. CONCLUSIONS

In the present study, the flow field above the free end surface of a surface-mounted finite square prism was investigated in a low-speed wind tunnel at Re = 4.2×10^4 using PIV. The prism was mounted normal to a ground plane and was partially immersed in a flat-plate turbulent boundary layer with δ/D = 1.7 at the location of the prism. Four prism aspect ratios were considered, AR = 9, 7, 5, and 3. PIV velocity measurements were made in vertical planes at the cross-stream locations of y/D = 0, 0.25, and 0.375 above the free end of the prism.

Flow separation occurs from the leading edge of the free end and the separated flow extends into the near-wake region. Unlike the circular cylinder case, there is no reattachment of the separated flow on the free end surface. A prominent CW vortex is found within the mean recirculation zone above the free end. A second CW vortex is found downstream in the upper part of the near wake. Elevated levels of turbulence intensity and Reynolds shear stress occur above the free end. The reverse flow and its local separation from the trailing edge of the free end surface was more dominant for the prism of AR = 3 at different cross-stream locations (y/D), while for prisms of AR = 9, 7, and 5, the effect of the shear layer separated from the leading edge was more dominant than the reverse flow as the cross-stream distance (y/D) increases. The results suggest a distinct flow pattern and behaviour for the finite square prism of AR = 3, and place the critical aspect ratio between AR = 3 and AR = 5 for these experimental conditions.

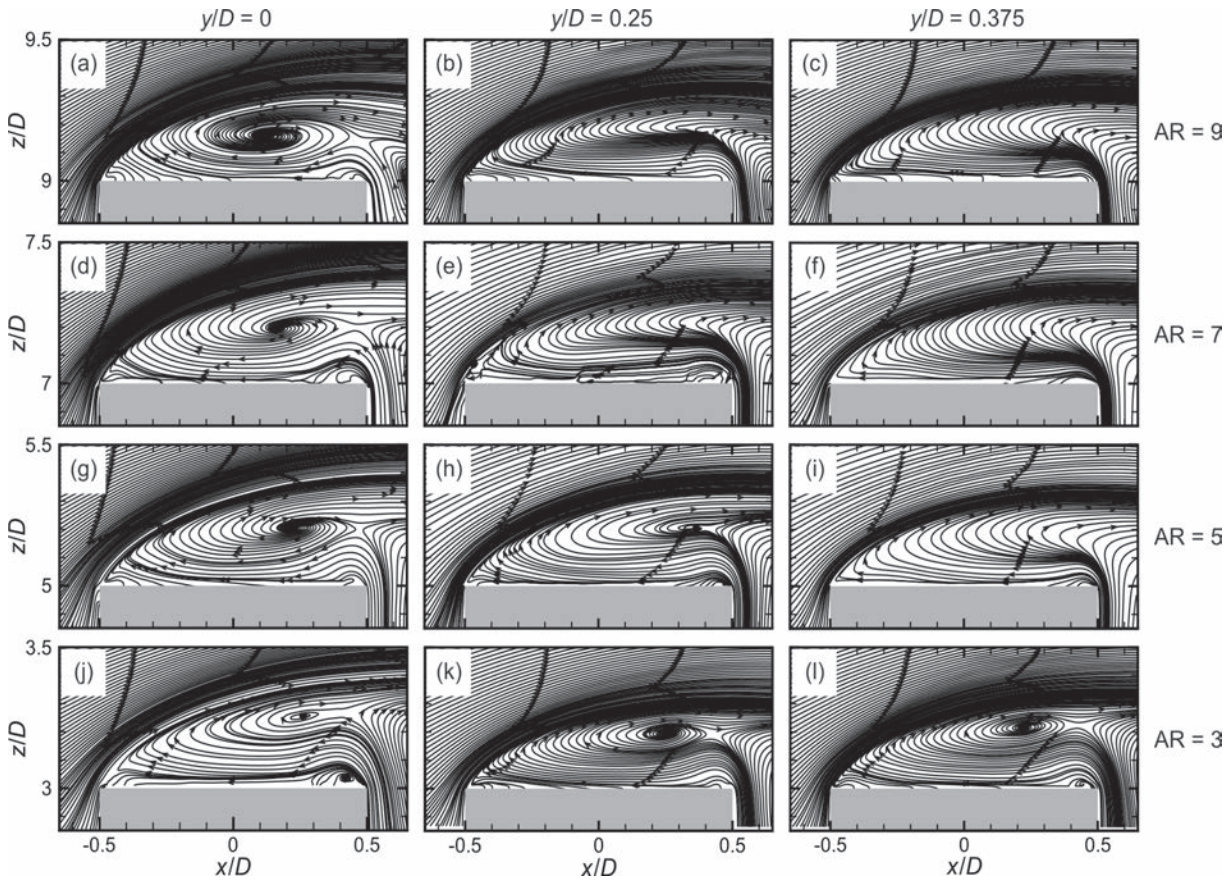

Figure 7. Mean streamlines for the flow over the free end of the finite square prism for aspect ratios of AR = 9 (first row, (a,b,c)), AR = 7 (second row, (d,e,f)), AR = 5 (third row, (g,h,i)), and AR = 3 (fourth row, (j,k,l)), for measurements made in vertical planes at y/D = 0 (left column, (a,d,g,j)), y/D = 0.25 (middle column, (b,e,h,k)), and y/D = 0.375 (right column, (c,f,i,l)).

Abstract. *The aim of the present study is to investigate the turbulent flow around a square cylinder. This is one of the most common studied bluff bodies. The unsteady flow is studied by using computational fluid dynamics (CFD) tools and different turbulence models. Simulation results are compared to laser doppler velocimetry (LDV) measurement data of the flow field published in the literature. The results are also compared with other numerical studies which can be used as verification. In addition, computed force coefficients are compared with experimental measurements.*

Keywords: LES, DNS, bluff body, numerical simulation, square.

1 INTRODUCTION

The flow past a square cylinder has been studied by many investigators for a long period of time. Large eddy simulation (LES) is a good approach for calculation of such unsteady turbulent flows which are three-dimensional and have strong separation and vortex shedding features. The flow past a square cylinder is often used as a benchmark case for testing various sub-grid scale models of LES, as in Sohankar et al. [1] and Rodi et al. [2]. The numerical results in the literature are comprehensive and it is often compared to the experimental works by Lyn et al. [3] and Durao et al. [4]. In more recent years Brun et al. [5] investigated the coherent structures in the flow around the square cylinder both numerically and experimentally. Fröhlich and Terzi [6] coupled LES and Reynolds-Averaged Navier-Stokes(RANS) to simulate the same flow. Filippini et al.[7] and Grigoriadis et al.[8] have investigated the flow around the square cylinder with LES model, Wissink [9], Djedini and Antonia[10] performed DNS.

The codes, FLUENT, MGLET and OpenFOAM have been used in present work for numerical simulations. These codes use the finite volume method to solve the Navier-Stokes equations. FLUENT (FL) is a commercial CFD software developed by ANSYS whereas OpenFOAM (OF) is an open-source code. MGLET is an in-house CFD code by Manhart [15] used for DNS.

2 FLOW CONFIGURATION AND COMPUTER EXPERIMENTS

2.1 Flow Model and Numerical Solution Procedure

In the present work, two different sub-grid scale models are used for LES simulations, i.e., the Smagorinsky's eddy-viscosity model (SM) and the kinetic energy transport model (KET). Simulation results from these two different models are compared with experimental results. For LES, two different Reynolds numbers have been studied, i.e Re=14000 and 21400. For DNS only the Re=14000 case is considered, The Reynolds number is based on the free-stream velocity (U_0) and the crosssection length of the square cross-section.

The governing equations solved in LES modeling are a set of filtered Navier-Stokes (N-S) equations. The continuity and filtered N-S equations can be written as

$$\frac{\delta \overline{u}_i}{\delta x_i} = 0 \tag{1}$$

and

$$\frac{\delta}{\delta t}\left(\overline{u_i}\right) + \frac{\delta}{\delta x_j}\left(\overline{u_i u_j}\right) = -\frac{\delta \overline{P}}{\delta x_i} - \frac{\delta \tau_{ij}}{\delta x_j} \frac{\delta}{\delta x_j}\left(\nu \frac{\delta \overline{u_i}}{\delta x_j}\right) \tag{2}$$

where the overbar points out the filtering operation. τ_{ij} is the subgrid-scale turbulent stress defined by

$$\tau_{ij} \equiv (\overline{u_i u_j} - \overline{u_i}\ \overline{u_j}) \tag{3}$$

and will to be modeled using the Smagorinsky model (SM). In the orginal eddy-viscosity model proposed by Smagorinsky [11], the subgrid-scale stresses are modeled using

$$\tau_{ij} - \frac{1}{3}\delta_{ij}\tau_{kk} = -2C_s\overline{\Delta^2}\left|\overline{S}\right|\overline{S_{ij}} \tag{4}$$

where C_s is the model coefficient (C_s =0.1~0.2), S_{ij} is the resolved rate-of-strain tensor, $\left|\overline{S}\right| = \sqrt{2\overline{S_{ij}}\,\overline{S_{ij}}}$ is its modulus and $\overline{\Delta} \equiv V^{1/3}$ where V is the volume of the cell. In the dynamic procedure, the model coefficient C_s is computed during the LES simulation (DSM) on-the-fly. Details of the procedure can be found in Germano et al. [12].

In the kinetic energy transport (KET) model, the unresolved stresses are modeled by solving a transport equation for the kinetic energy. More details can be found in Kim and Menon [13].

LESs are performed by the FL and OF software. FL employs a cell-centered finite-volume method that permits use of polyhedral cells. Higher order methods are used for discretization of the N-S equations. In order to ensure accuracy, efficiency and stability, bounded central-differencing is adopted to solve filtered momentum equations. This is a non-dissipative, second-order-accurate scheme combined with a nonlinear flux-limiter to suppress numerical oscillations. For pressure-velocity coupling, the PISO algorithm is used. The temporal discretization in the segregated solvers employs a fully implicit, three-level, second-order accurate scheme. The discretized equation system is solved using the point-wise Gauss-Seidel iterative algorithm with and acceleration of an algebraic multi-grid (AMG) method. More details can be found in Kim [14].

DNS calculations have been performed by the direct numerical simulation solver MGLET [15]. MGLET is a finite-volume code in which the Navier-Stokes equations are discretized on a staggered Cartesian mesh with non-equidistant grid-spacing. The discretization of advection and diffusion terms is second-order accurate. For time integration an explicit third-order Runge-Kutta scheme is used. The Poisson equation for the pressure is solved by an implicit procedure [16].

In the OpenFOAM (OF) finite volume open source code, the cell-centre values of the variables are interpolated at face locations using second-order central difference scheme for the diffusive terms. The convection terms are discretized by the so-called limited linear scheme, a second order accurate bounded total variational diminishing (TVD) scheme resulting from the application of the limiter (see Sweby[17]) to the central differencing. The advancement in time is obtained by the implicit two-step second order backward differentiation formula. The pressure-velocity coupling is applied via the pressure-implicit PISO algorithm, using predictor-corrector approach. The discretized equation system is solved by Preconditioned Conjugate Gradient (PCG) methods, see Jakobs [18].

2.2 Computational Domain, Grid and Boundary Conditions

Fig. (1) shows the the computational domain and its boundaries. The incoming flow velocity U_0 corresponds to Reynolds number 14000 and 21400 ($Re=U_0D/\nu$) where D is the crossection length of the square cylinder. The turbulence intensity of the incoming flow is 2% for Re=21400 and 6% for Re=14000 matching the turbulence level in the experimental circula-

tion tunnel. The outlet surface has zero pressure condition (atmospheric) as seen in Fig. (1). Simulations are performed with periodic conditions at the side walls. The cylinder surface is considered as no-slip wall. The upper and lower surfaces are defined as symmetry conditions.

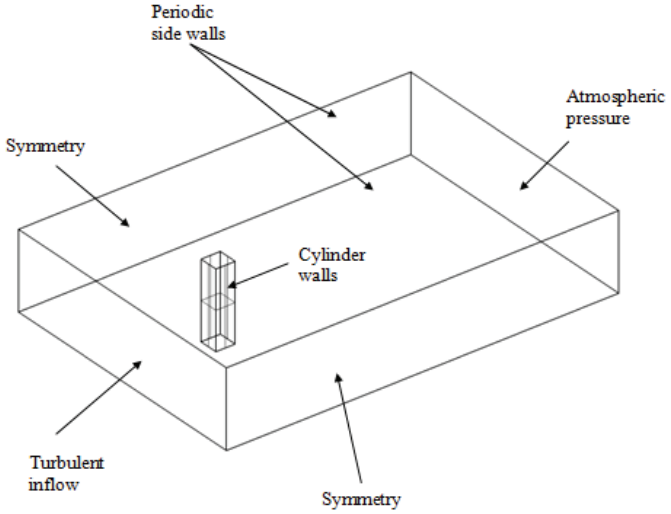

Figure 1. 3D Computational domain with boundary surfaces and its boundary conditions.

The size of the entire 3D computational domain can be seen in Fig. (2). The inlet and outlet are a distance 4.5D and 15D away from the rectangular section's front and back surfaces, respectively. The length of the cylinder in spanwise direction is 4D. The distance from the cylinder bottom and upper surface to the boundary surfaces of computational domain is 6.5D. The size of the computational domain is comparable with works reported in the literature [1], [2], [5], [7], [8].

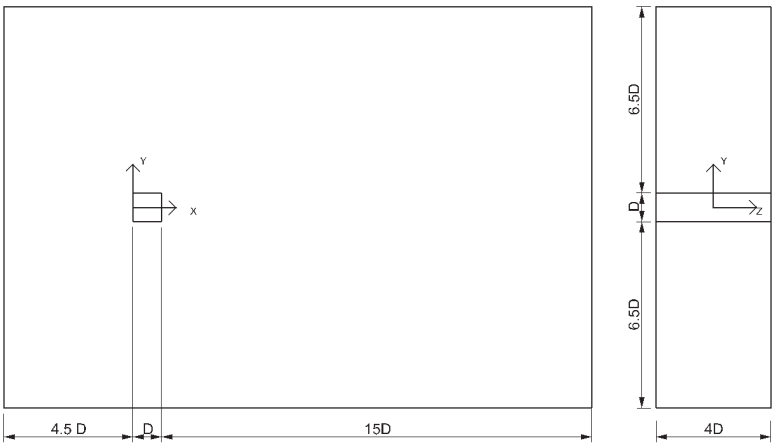

Figure 2. Size of the 3D computational domain.

In the LES calculations, a hexagonal type grid with unstructured quadrilateral type elements in streamwise and vertical direction (xy plane) is used as seen in Fig. (3a) and Fig. (3c). The grid is structured in spanwise direction (z direction). Close to the square cylinder wall, structured grid layers are employed in order to have sufficient small mesh size to resolve the

boundary layer (Fig. 3b.) The number of structured cells in these layers is 15 for the cylinder surface. The grid spacing normal to the wall for the first layer is 0.002D at the cylinder and expands out from the surface with the ratio equal to 1.2. Total number of elements in the 3D domain is varying from 1 to 4 million dependent on the expansion ratio from cylinder surface and resolution in the wake. Outside the hexahedral layer the quadrilateral elements in xy plane expand with the ratio 1.1 and reach the maximum size of 0.2D near the outer boundaries. This expansion is controlled in the wake region close to the rear of the cylinder (see Fig. 3a). The grid size is kept between 0.025D, 0.02D and 0.015D in this area for the meshes which has 1 million, 2 million and 4 million total elements respectively as seen in Table 1..The number of elements for discretizing the rectangular section with clustering towards the corners and element size in spanwise direction are showed in Table 1. The resulting y^+ values are in the order of 1 at the cylinder surface.

	Total number of elements	Number of elements in spanwise direction	Element size in wake region	Number of elements on the cylinder surface (crossection)
MESH1	1 million	30	0.025D	110x110
MESH2	2 milion	32	0.02D	120x120
MESH3	4 million	39	0.15D	140x140

Table 1: Computational grid resolution for LES calculations.

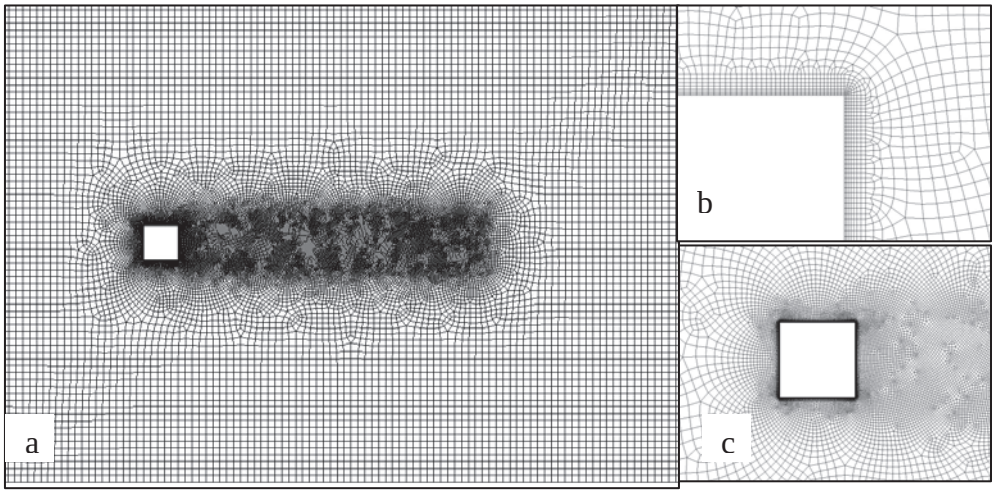

Figure 3. Cross-section of the 3D computational mesh, whole domain (a), around the trailing upper corner (b), around the square cylinder (c).

For DNS simulations, a structured mesh (850x450x400 elements) is used with the same domain size. In order to verify the current simulation is an sufficiently resolved direct numerical simulation, the Kolmogorov length scale η is estimated as $\varepsilon = (\nu^3 / \varepsilon)^{1/4}$, where the energy dissipation rate $\varepsilon = \nu\overline{(\partial u_i / \partial x_k)^2}$ is calculated from the simulation flow field. The local grid size Δ relative to Kolmogorov length scale is presented in Table 2 at different streamwise positions in the mid-section. The data in Table 2 shows that the adopted grid spacing is sufficiently fine to resolve almost all essential scales in the wake ($\Delta \sim< 7\eta$,). This value is slightly higher but comparable with results from literature, Khoury et.al. [19].

	X/D=1.5	X/D =2.5	X/D =4	X/D =9
Y/D=0.5	6.22	6.69	7.71	8.56
Y/D=0.375	6.04	6.84	8.11	8.97
Y/D=0.25	5.78	7.03	8.31	9.39
Y/D=0.125	5.71	7.20	8.36	9.11
Y/D=0	5.08	7.37	8.17	9.45

Table 2: Grid resolution $\Delta = \max(\Delta x, \Delta y, \Delta z)/\eta$ at various streamwise locations (Re=14000).

The time is non-dimensionalized by the uniform inlet velocity (U_0) and crossection length D as $T=tU_0/D$ and the simulations are carried out for T=140 in order to reach statistical convergence. The total simulation time corresponds to approximately 20 vortex shedding cycles. The Strouhal number, $St= fD/ U_0$ where f is the frequency, is gathered from the lift coefficient as a result of a FFT analysis. Mean drag and deviation of lift coefficients are calculated from the instantaneous forces.

3 RESULTS

In the LES calculations, at Reynolds number Re=21400, the effect of the temporal and spatial discretization on the simulation results is investigated by applying three different mesh sizes with different time steps. Beside this, the effect of the inlet turbulence level on the flow field has also been investigated.

Table 3: Mean drag and RMS of lift coefficients and Strouhal numbers (Re=21400).

The calculated lift and drag force coefficients in addition to the Strouhal numbers (based on lift coefficients) are compared with experimental data. In Table 3., the calculated mean drag coefficients, standard deviation of lift coefficients and Strouhal numbers are tabulated for 1, 2 and 4 million elements and different time steps (0.0001, 0.00025 and 0.0004 sec.). Use of SM, DSM and KET sub-grid scale models are also shown. In CASE-7, the incoming flow is considered smooth in order to investigate the effect of inlet turbulence (CASE-2). The re-

sults from FLUENT and OpenFOAM calculations are also compared. (CASE-2 vs. CASE-10 and CASE-4 vs. CASE-8)

For LES calculations at Reynolds number RE=14000, the computational mesh has one million elements (MESH1) and the time step is 0.00025 sec. The time and spanwise averaged streamwise velocity obtained by OpenFOAM using Smagorinsky sub-grid scale model is shown in Fig. 4 together with the DNS and experimental results. Here, U_0 is the free stream velocity and D is the length of the square cylinder crossection.

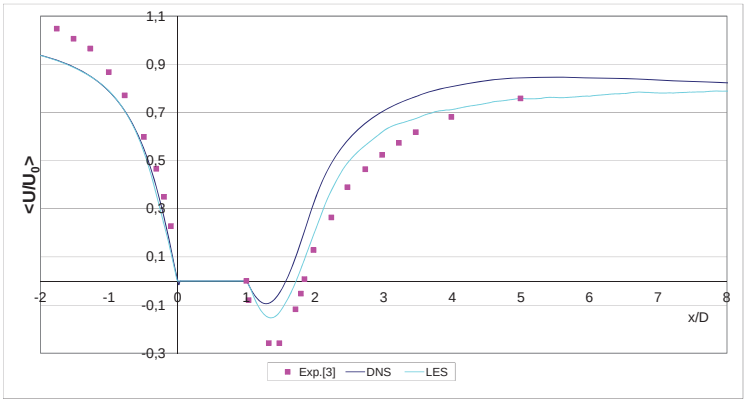

Figure 4. Time and spanwise averaged streamwise velocities at centerline in front and behind the square cylinder (Re=14000, MESH1).

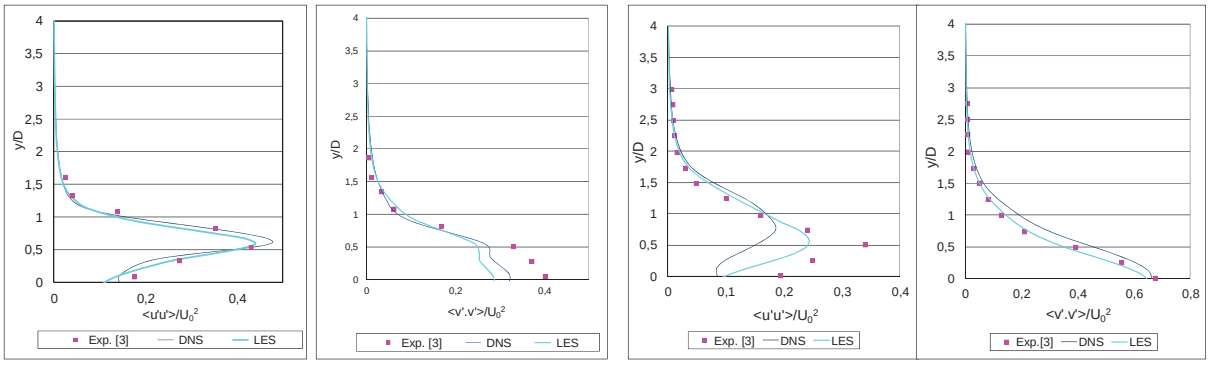
As seen in Fig. (4), in LES, the minimum of the mean velocity in the near wake is estimated better than by DNS. This region is close to the center of the main vortex and kinetic energy has itsmaximum value. The fair prediction of the mean velocity may be due to underestimation of the velocity fluctuations because of slightly higher Δ values and the effect of unresolved small turbulent eddies in the wake region. However, as seen in Fig. (5), the time and spanwise averaged Reynolds normal stresses $< u'u' >$ agree well with experimental results for both DNS and LES. But the vertical component of Reynolds stresses $< v'v' >$ has been under-predicted in the near wake, 1.5D from origin of the coordinate system which is shown in Fig. (2). At the section 2.5D from origin, the $< v'v' >$ values have been predicted well for both DNS and LES but here $< u'u' >$ values are different from experimental results. Consequently, in the wake, Reynolds stresses have not been predicted well at the same time for both components. This results in the difference between calculations and experiments for the turbulent kinetic energy in the wake.



x/D=1.5 x/D=2.5

Figure 5. Time and spanwise averaged Reynolds normal turbulent stresses in the wake, Re=14000.

In Fig. (6), the measured (Durao et.al.[4]) and calculated turbulent kinetic energy contours by LES and DNS are plotted. The distribution of the turbulent kinetic energy, k, is calculated on the basis of local isotropy, i.e. $k = 3/4\left(\overline{u'^2} + \overline{v'^2}\right)$. The contours reveal distributions which are qualitatively similar to each other in the simulations and the experiment. The shear layer surrounding the recirculation bubble has intense velocity fluctuations and turbulent kinetic energy increase as the downstream distance increase, with maximum values around the center of the main circulation bubble.

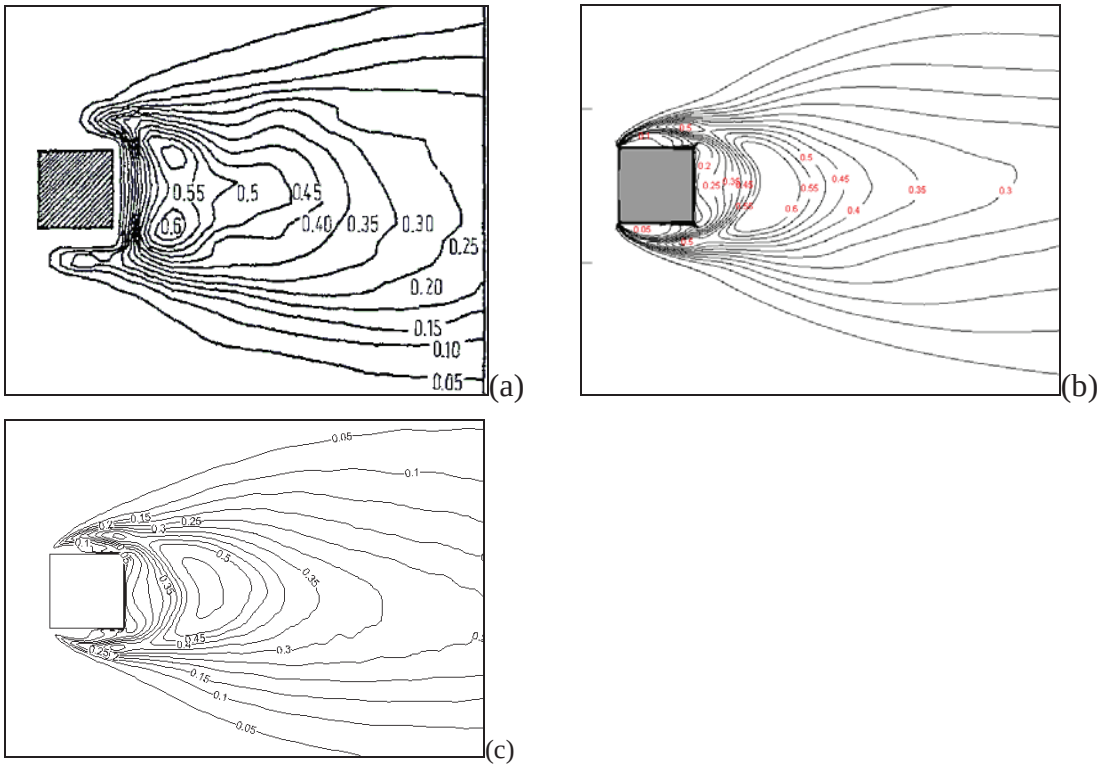


Figure 6 Spanwise averaged and normalized kinetic energy contours, (a) experiment [4] , (b) DNS and (c) LES at Re=14000.

In Fig. (7b), are shown experimental visualization results by Durao et.al[4] for Reynolds number Re=14000. Calculations of the instantaneous streamwise velocity contours have been performed by MGLET with DNS, and are shown in Fig (6 a). The streamwise velocity is normalized with free stream velocity (U_0) and spanwise averaged. Flow visualization has been made by injection of a solution of fluorescein-sodium at the upstream face of the cylinder. The calculated shear layer and vortex formation are very close to the experimental visualization as seen in Fig. (6)

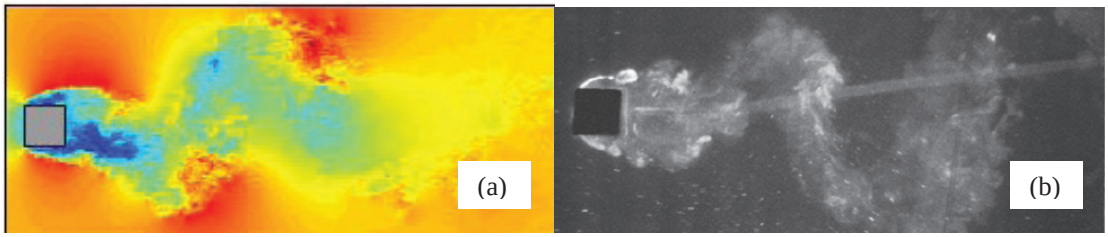

Figure 7. Instantaneous normalized streamwise velocity (U/U_0) contours by (a) DNS and (b) flow visualization experiments [4] for Re=14000.

4 CONCLUSIONS

- For Reynolds number Re=21400, the results from LES simulations with both codes and sub-grid scale models give good agreement with experimental data. One million elements and 0.0004 sec. time step size seem enough to predict acting forces and frequency of the lift with reasonable accuracy for the OF code. However the FL code gives poor results for the Strouhal number, and the mean drag coefficient is slightly over-predicted for coarse meshes (see CASE9 and CASE-10 in Table 3). The OF code seems less sensitive to grid resolution.
- Simulations show that the lift coefficient is sensitive to inlet turbulence level.
- For Reynolds number Re=14000, the variation of the streamwise component of the velocity is well predicted while the vertical component is underpredicted near the centerline in the wake ($y/D<0.5$) for both LES and DNS compared to experimental results. The calculated mean streamwise velocity is also underpredicted compared to experiments in the near wake and probably inside the separation bubble ($x/D<2$).
- DSM and KET which are more costly models, do not bring significant advantages for predicting drag and lift coefficients. The SM model can be used to simulate such flows.

ABSTRACT: Statistical analyses of tornado-induced damages in Japan have been conducted and compared with Fujita Tornado Damage Scale for determining the parameters of tornado model. Based on determined parameters, tornados were scaled down and reproduced by tornado generator facilities for comparison with observed statistics. Then, by utilizing multiple-fan wind tunnel, non-stationary flow of tornado was simulated and wind pressure measurement of prism models under such flow was conducted to evaluate the distributions of wind pressure coefficients due to overshoot phenomenon observed in tornado-like wind velocities.

KEYWORDS: Tornado, Tornado model, Multiple-fan wind tunnel,
Tornado simulator, Non-stationary wind, Wind pressure characteristics

1 INTRODUCTION

Non-stationary winds induced by tornados have been investigated such as by Maeda et al ([5]) for overshoot phenomena of wind forces caused by gusty winds; by Ikeuchi et al ([2]) for the effect of wind direction changes. However, these investigations cannot be confirmed generally in the traditional turbulent boundary layer wind tunnels and many assumptions must be determined preliminarily. In this research, non-stationary wind direction change induced by tornados is focused. It is intended to clarify the effect on the prism models caused by such dramatic wind direction change by multiple-fan wind tunnel.

1.1 *General Instructions*

It was reported three casualties and one fully damaged building caused by gusty winds in Tokuno-jima, Kagoshima Prefecture on 11/18, 2012 ([8]). Generally speaking, the occurrence probability that tornado attacks one specific location is low and tornado-dependent wind resistant design for buildings is not provided in the current Japanese regulations. However, for nuclear power plants or long life structures, wind resistant design considering tornados that possess low occurrence probabilities must be considered. To include the observed tornado-induced damages in Japan, the practical tornado resistant design for important structures is essential and necessary.

In order to fully understand the tornado feature in Japan, including the wind speed profile and the wind direction change, the investigation is conducted as follows: (1) statistical studies on the recent tornado records for the specific virtual tornado model in Japan; (2) understanding the characteristics of tornado through reproducing tornado-like winds by tornado generator facilities; and (3) investigating the non-stationary effect of winds on prism models in a short period by utilizing multiple-fan wind tunnel in University of Tokyo ([7]).

2 PARAMETERS – *THEORETICAL TORNADO MODEL*

2.1 *Statistical Information of Tornado-induced Damage in Japan and Assumptions for Modeling*

Although plenty of reports or surveys have been carried out for investigation on tornado-induced damages in Japan, investigation items, such as damage path width or length, are judged subjectively based on the status of building damage appearances, which may sometimes results in significant biases for statistical studies. In order to avoid such data bias, this research utilized weather database since 1961 provided by Japan Meteorological Agency. The database includes all the tornado and downburst events. However, several assumptions are necessary for further investigations. The modeling of tornado in this research is assumed that counterclockwise Rankine tornado remains circular and moves constantly. And only horizontal wind speed component is investigated in this research.

2.2 *Time History and Occurrence Probability of Simulated Tornado Model*

Based on Fujita Tornado Damage Scale, Table 1 lists the recent records and the simulated models used in this research (VF). Applying the parameters of a simulated VF3 tornado in Table 1 as a Rankine tornado, Figure 1 shows the simulated time history and wind direction change. It is indicated that significant effects on structures can be considered resulted from the extremely high wind speed in the right side of the tornado and from the dramatic changes of wind speed and direction in a short period for the center of the tornado passing.

Table 1 Recent records and assumed tornado models

model	F scale	Wind speed (m/s)	movement (m/s)	radius (m)
Toyohashi	3	81	16.2	28.3

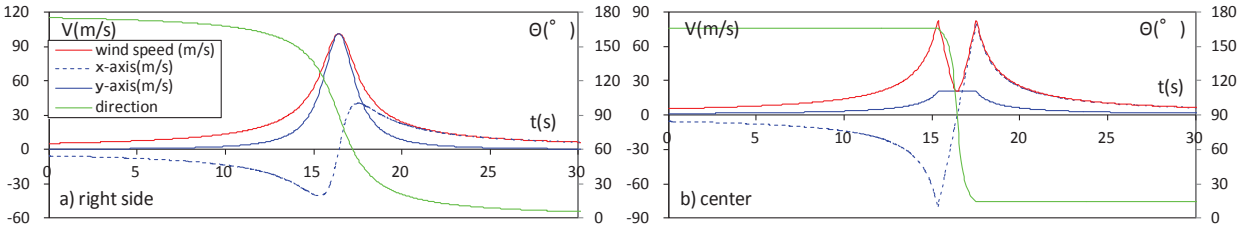

Figure 1 Wind speed and direction profile of assumed tornado model

Figure 2 shows the simulated parameters of tornado models in Table 1 and the ones suggested by American guideline, American National Standard for Estimating Tornado and Extreme Wind Characteristics at Nuclear Power Sites (ANSI/ANS-2.3-1983).
Comparing suggested tornado models by American standard and the simulated tornado models utilized in this research, it is known that the moving speed of the simulated one is 10% higher than American standard and the magnitude is only 25%. Based on this comparison, the simulated

tornado model specified in Japan is assumed F3 scale and the corresponding parameters are utilized for further experiments.

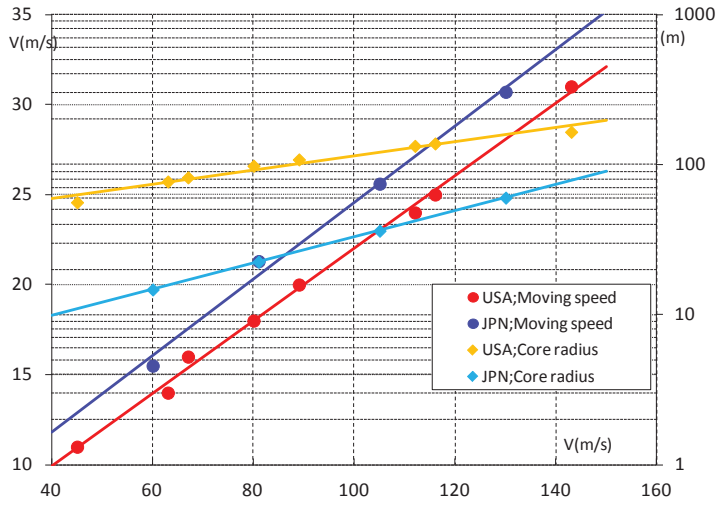

Figure 2 Comparison of assumed tornado models in Japan and suggested models by American standards

3 TORNADO REPRODUCTIONS BY TORNADO GENERATOR FACILITIES

To understand the characteristics of wind speed and wind direction changes of a tornado, a VF3 simulated tornado model mentioned in the previous section is simulated by the tornado generator facilities.

3.1 *Tornado Generator Facilities*

For the tornado generator facilities, the fan is hidden inside the main facility which can be driven by active control system to move constantly and straightly shown in Figure 3. 18 guide vans are set in the fan to generate rotary downward flows and the setting angle of vans tangent to the fan can be arbitrarily adjusted. The maximum moving speed of the main facility is 0.4m/sec. In this research, tornados with the setting angle of vans, 30°, and the rotation frequency of the fan, 8Hz, are generated for investigation of non-stationary wind flows. Sampling rate is 20Hz for 40 seconds for each sample.

Wind speed is measured from the center to the outer radius of a still simulated tornado. Figure 4 shows the wind speed profile along Z-Z axis of a still simulated tornado. The core radius is 100mm (R) and the tangent maximum wind speed is 4.29m/sec (V_m). However, the center of the simulated tornado is 10mm away from the centerline of the moving line of the experimental table.

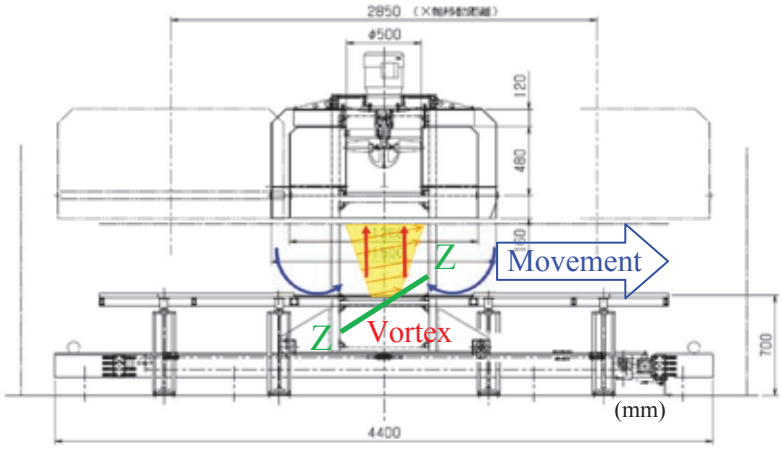

Figure 3 Tornado simulator with vortex generator

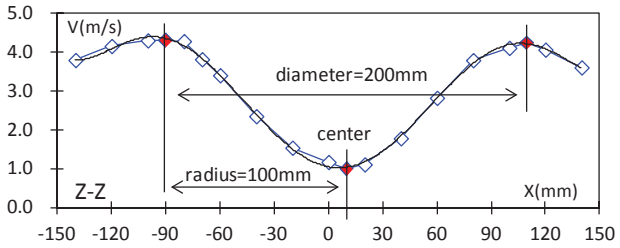

Figure 4 Wind speed distribution along Z-Z axis

3.2 *Characteristics of Wind Speed and Direction Changes of Tornado Winds*

Figure 5 shows the time histories of wind speeds and directions at the center of tornado and the right side of the moving path of the tornado when the moving speed is 0.1m/sec and 0.3m/sec (V_t). Wind speed measurements are conducted by I type hot-wire anemometers and Figure 5 shows the ensample average of 10 samples. From Figure 5, instead of Rankine tornado model, Shakeel's theoretical model ([4]) seems fit better to the experimental results (hereafter SA model). The formula to represent SA model are as follows.

Boundary layer thickness:

$$\delta(r') = \delta_0\left[1 - e^{-0.5r^2}\right] \tag{1-1}$$

Radial function:

$$r = {r'}/{r_{max}} \qquad \eta = {z}/{\delta} \tag{1-2}$$

T=tangential velocity component

$$T(\eta, r) = f(r) = 1.4\frac{V_{max}}{r}\left[1.0 - e^{-1.256r^2}\right] \tag{1-3}$$

W=vertical velocity component

$$W(\eta, r) = g(r) = 93.0r^3e^{-5r}V_{max} \qquad \eta > 1 \tag{1-4}$$

T=tangential velocity component

$$T(\eta, r) = f(r)[1 - e^{-\pi\eta}\cos(2b\pi\eta)] \quad (1\text{-}5)$$

R=radial velocity component

$$R(\eta, r) = f(r)[0.672e^{-\pi\eta}\sin\{(b+1)\pi\eta\}] \quad (1\text{-}6)$$

W=vertical velocity component

$$W(\eta, r) = g(r)[1 - e^{-\pi\eta}\cos(2b\pi\eta)] \qquad \eta \le 1 \quad (1\text{-}7)$$

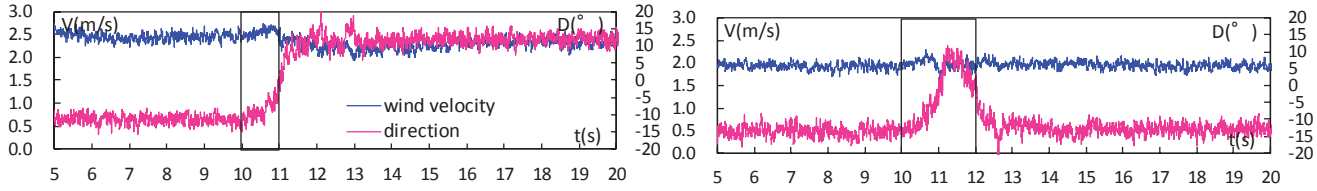
4 EXPERIMENT BY MULTIPLE-FAN WIND TUNNEL

4.1 *Simulation of Non-stationary Wind Flow based on Tornado Characteristics*

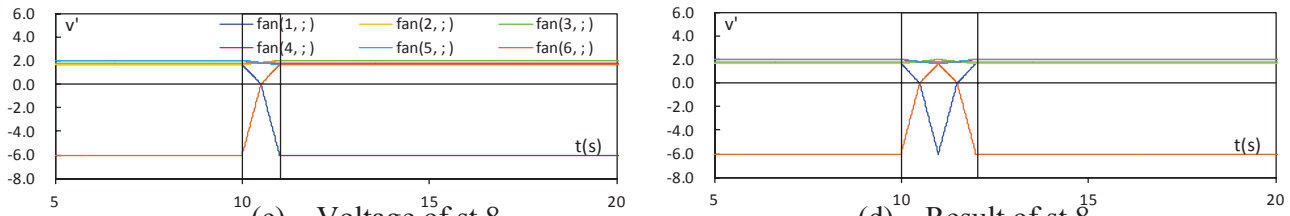
In order to investigate the non-stationary characteristics of a tornado, a multiple-fan wind tunnel is utilized to simulate part of the wind speed and direction profiles which are shown in Figure 5. A multiple-fan wind tunnel with 6×3 small fans is introduced in this research. As shown in Figure 6, fans are arranged in three vertical columns and each column contains six fans. Each fan can be actively controlled by computer independently. The rotation range of each fan is 0~3000rpm. By changing the input voltages of fans, non-stationary winds due to wind speed or direction changes can be simulated. To generate non-stationary wind flow caused by wind direction change, rotations of upper fans and lower fans can be controlled in the clockwise and counterclockwise direction. By balancing the rotation of these fans, stable wind direction change can be achieved. For the further measurement of wind speeds, the location with x=600mm, y=300mm, and z=300mm, is assumed as the measuring point. The mechanism of measurement is indicated as Figure 7.

Table 2 List of 9 types of non-stationary wind flows

stream type	⊿U(m/s)	⊿D(°)	⊿t(s)	remarks
st.1	–	–	–	stationary (0.9m/s)
st.2	–	–	–	stationary (2.2m/s)
st.3	1.2	–	1	velocity only
st.4	–	23.4	1	direction only
st.5	–	24.7	1	direction only (reverse)
st.6	1.5	22.0	1	vel & dir
st.7	1.2	18.8	1	vel & dir (reverse)
st.8	–	21.0	2	direction only
st.9	–	21.8	2	direction only (reverse)



(a) Voltage of st.4 (b) Result of st.8



(c) Voltage of st.8 (d) Result of st.8

Figure 8 Examples of non-stationary wind flows, st4 and st8

To control each fan to generate non-stationary winds, it is necessary to vary the voltage in a short period. For the performance of fans in this research, the shortest period is 1 second. Further, to change the stationary status to non-stationary status (wind direction change here) which includes significant inverse rotation of fans, the wind speeds of fans are limited. In this research, the wind speed change is 50% of the maximum wind speed and 20° of the wind direction change.

Table 2 lists the simulated wind flow by multiple-fan wind tunnel. Wind flows st1 and st2 represent two stationary flows with two velocities; Wind flow st3 represents non-stationary flow with wind speed change of 1.2m/sec; Wind flows st4 and st5 represent two non-stationary flows with wind direction changes of 23.4° and 24.7° (reversely); Wind flows st6 and st7 represent non-stationary flows with both wind speed and direction changes; and Wind flows st8 and st9 represent the same condition as st4 and st5 but the period enlarges from 1 second to 2 seconds.
It is assumed that the downward wind direction change is indicated "-" and the upward direction is indicated "+". For non-stationary wind flows st3~st9, input voltages of fans arranged in the left column and right column are 60% of that in the middle column. Figure 8 shows the relationship of input voltage and wind speed and direction changes of st4 and st8 respectively. All the simulated wind flows remain uniform in the first 10 seconds and then start to change. An X type hot-wire anemometer is used for measurement in 1000Hz for 30 seconds. Ensample averaging is conducted by two records and moving averaging of every 200 samples is also executed.

4.2 *Distributions of Wind Speed and Direction*

In order to grasp the distributions of wind speed and direction of non-stationary wind flows inside the wind tunnel, a hot-wire anemometer is set at 25 grid measuring points shown as Figure 9. Interval of two neighboring measuring points is 25mm. Figure 10 shows the contour distributions of wind speed and direction of non-stationary st4. Each sub figure in Figure 10 represents the averaging result in certain period. It is indicated that the change of wind speed between two measuring points is less than 0.1m/sec and the wind direction change is quite stable.

4.3 *Wind Pressure Measurements on Square Prism Model*

As the results of circular prism model can eliminate the effect of velocity change ([7]), a square prism model is used to investigate the distributions of wind pressure coefficients due to non-stationary wind flow. The rotation of the square prism model is 5° and from 0°~45°. Wind pressures are recorded in 1000Hz for 30 seconds. Since the reference static wind pressure is different at different location in non-stationary wind flow, the reference static wind pressure measured on the wall of working sections of the wind tunnel is assumed for the calculation of wind pressure coefficients ([7]). The following equation is used for the definition of wind pressure coefficient.

$$C_p(t) = \frac{p'(t) - p_s(t)}{\frac{1}{2}\rho U_R(t)^2} \tag{2}$$

where $p'(t)$: measuring point; $p_s(t)$: reference static pressure; $U_R(t)$: basic wind speed.

It is known that the instantaneous maximum negative pressure around -1.2 is observed when the rotation angle is 15° ([3]). Figure 11 shows the dramatic large negative pressures when the wind direction changes in a very short period. Further, considering the wind direction change of 20° and the rotation angle of the model, the case of a 110° wind direction change can also be derived as shown in the diagram of Figure 12 and the time histories in Figure 13.

Figure 11 Distribution of wind pressure coefficient of st5 flow with 5° rotation angle

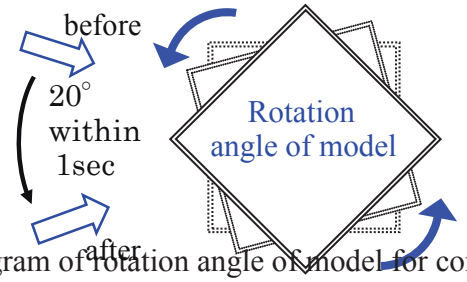

Figure 12 Diagram of rotation angle of model for continuous wind pressure coefficient measurements of 110°

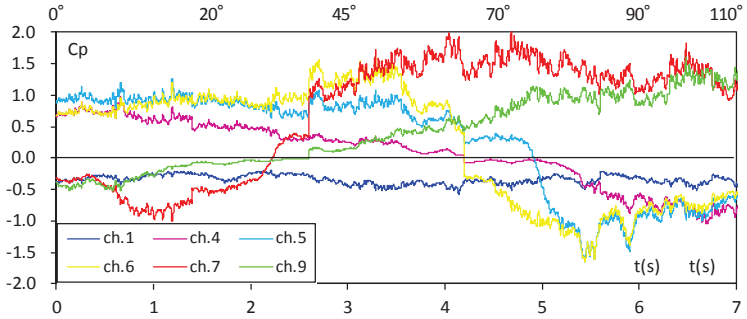

Figure 13 Derivation of wind pressure coefficients for each rotation angle for each pressure tubes

4.4 *Calculation of Wind Force Coefficients*

Wind force coefficients are derived by integrating wind pressures; however, due to the rotation of models, wind force coefficients are investigated in the x-direction and y-direction of the original model coordinates.

Figure 14 shows the wind force coefficient time histories in st4 flow for rotation angle of model equals 15° and 45°. It can be indicated clearly that instantaneous large wind forces shown in x-, y-, and torsion direction before and after the wind direction change. In this research, the shortest period is 1 second. Obvious overshoot phenomena cases are rare to investigate. Figure 15 shows respectively the obvious cases of wind speed change and wind direction change for st5 flow with 15° rotation angle and st4 flow with 10° rotation angle.

5 CONCLUSIONS

Parameters of tornado model were first determined, based on statistical studies of recent tornado records in Japan. Then, tornado wind flow was simulated by tornado generator facilities and compared with theoretical tornado models. Nine types of non-stationary wind flows were simulated by multiple-fan wind tunnel for part of the tornado flow simulated in the generator facilities. Wind pressure measurements were then conducted under these types of non-stationary wind flows. From experimental results, it was indicated that large wind pressure coefficient around -1.2 were obtained when the rotation angle of model is 15° under wind direction change of 20° for a square prism model. And the overshoot phenomenon was also clearly observed. It is also indicated that a wind direction change of 110° can also be conducted by proper adjustment of rotation angle of the model and wind direction change. It may be anticipated that in the field scale, the effect on structures due to non-stationary wind flows is much more significant and essential.

Wall-mounted finite cylinder wake structure modification due to boundary layer-wake interaction: Half-loop and full-loop coherent structure topologies

Z. Hosseini [a], J. A. Bourgeois [a], R. J. Martinuzzi [a]

[a]*University of Calgary, 2500 University Dr., Calgary, AB, Canada*

ABSTRACT: Earlier studies suggest that two types of shedding structures can be recognized in the wake of surface mounted cylinders. For height to width ratios lower than a critical limit, in the time averaged wake, a counter rotating vortex pair is present at the free-end. For taller cylinders another counter rotating pair is also noticed at the cylinder base. While some differences in the shedding process are discussed; due to insufficiently resolved data in spatial domain a detailed comparison of the three-dimensional turbulent field is not well documented. In addition to height to width ratio, boundary layer thickness can also change the wake structure; its effects, however, are not examined thoroughly. This work shows that the boundary layer has a key role on the shedding process. It is shown that even for a rather tall cylinder (significantly taller than the critical limit suggested in earlier work) both types of wakes can be observed depending on the boundary layer thickness. The three-dimensional phase averaged flow is reconstructed from planar PIV measurements and comparisons of the mean and dynamic wake structures are presented.

KEYWORDS: Bluff-body wake, turbulent boundary layer, coherent structure, counter rotating vortices, phase averaged flow.

1 INTRODUCTION

The prediction and control of wake transport processes requires an understanding of the turbulent coherent vortex structures due to the fundamental role they play in mixing and dispersion processes. The coherent structures in finite wall-mounted bluff body wakes give rise upon averaging to trailing streamwise vortex pairs [1-4]. In the vicinity of the obstacle tip, 'free-end' vortices induce downwash of flow toward the ground, while near the wall junction, 'junction' vortices induce upwash from below. As reported in [2-4], the junction vortex pair is not always present. The presence or absence of junction vortices can be of importance concerning safety for flow over stacks since the free-end vortex pair transports pollutants toward the ground when uninhibited by counter-rotating junction vortices. Similarly, the free-end downwash may be a concern in debris transport in strong winds over buildings which may endanger pedestrian traffic. Likewise, in combustor design using bluff-body flame stabilizer or fuel injection devices, the wall surface should be sheltered from hot gases in the core of the flow and a design ensuring junction vortices can meet this requirement.

While large differences in the mean and turbulent fields of the two wake types are observed (as discussed in [4] and presented in more details in the following), there is a lack of consensus on the parameters influencing the generation of these vortices. Sumner et al. [2] and Wang & Zhou [3], suggest that a sufficiently high aspect ratio h/d (where h is the height and d the width of the cylinder), will result in the presence of junction vortices. They, respectively, showed for circular- and square-cross-section cylinders that $h/d=3$ or less show dipole distributions of streamwise vorticity (only a free-end vortex pair) while $h/d=5$ or above show a quadrupole dis-

tribution of streamwise vorticity (free-end and junction vortex pairs). On the other hand, Wang et. al. [4] suggest that the boundary layer thickness (δ) plays an important role on presence of the upwash at the junction of the symmetry plane. They show for a cylinder with aspect ratio $h/d=5$ the upwash is present for a sufficiently thick boundary layer but it vanishes for a thin boundary layer. They suggest the effect of the boundary layer is less important for taller cylinders.

The present study aims to elucidate key role of the boundary layer by examining the flow around a rather tall building (with an aspect ratio clearly larger than the limit suggested in [2,3]) immersed in two very thin boundary layers with respect to the height. Using synchronized particle image velocimetry (PIV) and surface pressure measurements, the three-dimensional time averaged and phase averaged coherent structures in the wake of the cylinder are reconstructed and analyzed along with their respective velocity, vorticity, and Reynolds stress fields.

2 EXPERIMENTAL SETUP

The measurements were conducted in a suction type open-test-section wind tunnel shown in figure 1. A square cylinder with aspect ratio $h/d=8$ ($h=101.6mm$, $d=12.7mm$) was mounted on a sharp-leading-edge flat plate in the working section as shown in figure 2. The wake measurements were conducted for two turbulent boundary layers: the natural boundary layer developed over the flat plate and a tripped boundary layer with a $6.35mm$ rod positioned $1cm$ from the leading edge. The boundary layer thickness measured at the location of the obstacle ($x=200mm$ from the leading edge of the flat plate) with the cylinder removed was $\delta/h=0.09$ and 0.32 respectively. Boundary layer profiles and root-mean-square velocity fluctuations measured with hot-wire anemometers (TSI model 1210-20) are shown in figure 3. The free stream velocity was $U_\infty=15m/s$, corresponding to a Reynolds number $Re=U_\infty d/\nu=12,000$, with turbulent intensity of 0.8%. The measured Strouhal number was $St=fd/U_\infty=0.10 \pm 0.003$ with f the vortex shedding frequency. The Strouhal number was invariant with the change in boundary layer thickness.

A grid of several horizontal (x-y) and vertical (x-z) planes were measured using a LaVision FlowMaster high-frame-rate particle image velocimetry (PIV) system. These planar measurements are used to reconstruct the phase averaged three-dimensional flow. A pulse separation of $50\mu s$ was used and frame rates of 500 to $1000\ Hz$ captured 4 to 8 data points per shedding cycle. The estimated uncertainty on individual vector measurements is $\Delta u/U_\infty=\pm 0.025$. Conditional sampling (phase averaging) of the PIV measurements was performed using the fluctuating surface pressure difference on opposing sides of the obstacle at $z=h/2$ as the instantaneous phase of the shedding cycle. The sampling rate for the pressure is $10.24\ kHz$ and is sychronized with the PIV measurements using a TTL trigger. The shedding period is discretized into twenty equal phase steps, φ_n, ($\Delta\varphi = \pi/10$) between $\varphi=0$ and $\varphi=2\pi$. This number of bins was chosen as a compromise between statistical convergence and precision. A double decomposition ensemble average is undertaken for each phase step [5].

3 RESULTS

The boundary layer interactions with the vortex formation process results in topological differences both in the mean and dynamic fields. Figures 4 presents the mean sectional streamlines in the symmetry plane. For both the cases there is a downwash close to the free-end and an upwash in the base region at the junction. The separated streamlines from the free-end and the junction form a lee saddle point in the symmetry plane. The bifurcation lines extending from this saddle point separate the downwash region from the free-end and the upwash region near the mounting plate. For the thicker boundary layer (tripped case) the upwash at the junction is stronger thus the saddle point is located at a higher position. For the thinner boundary layer (untripped case), the upwash downstream of the saddle point is very weak. Similar observations were made in [4].

The mean streamlines at *z/h=0.25*, *0.50* and *0.75* are shown in figure 5. In general the recirculation regions are shorter in the tripped case. The largest difference is observed at the lower plane where for the untripped case the streamlines are diverging from the symmetry plane, in contrast to the tripped case where the streamlines converge onto the symmetry plane. The recirculation length is reduced largely for the tripped case while it stays almost the same as the middle plane in the untripped case.

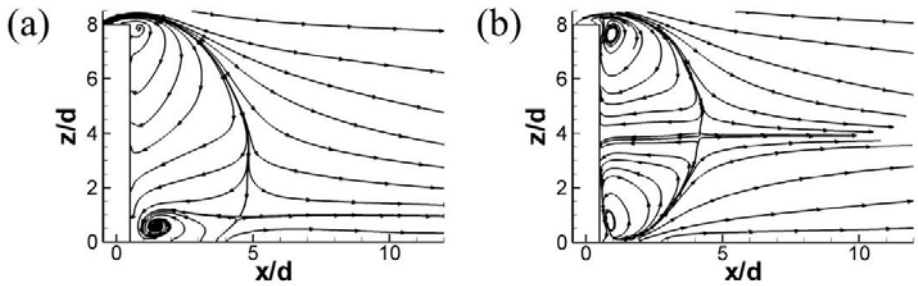

Figure 4. Mean flow streamlines in the symmetry plane for (a) untripped and (b) tripped cases. While the flow is similar close to the free-end, large differences are observed at lower heights.

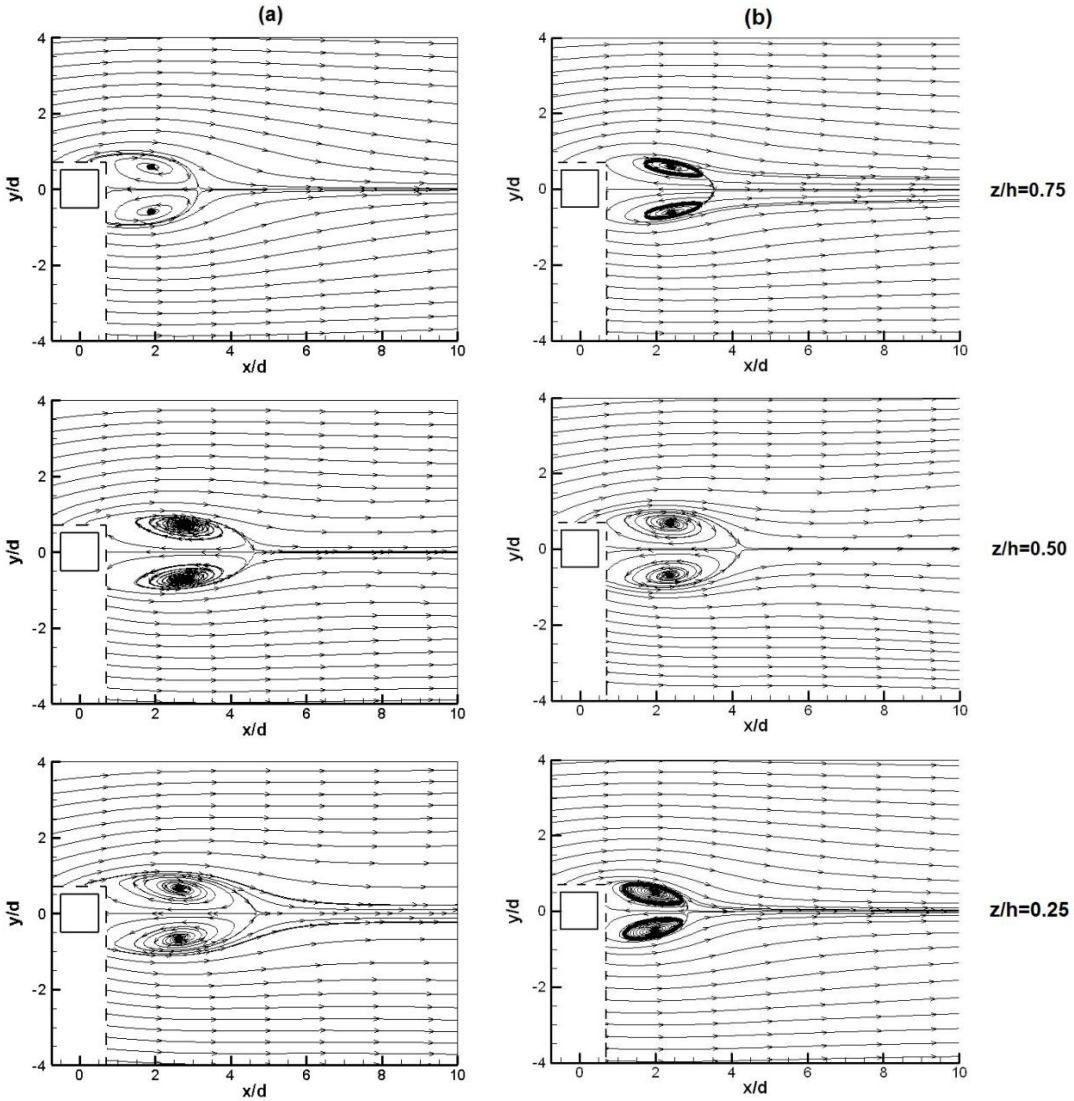

Figure 5. Mean flow streamlines in the symmetry plane for (a) untripped and (b) tripped cases. The largest differences are observed between the lower planes.

The mean vortex structures identified from λ_2-criterion [6] are shown in figures 6. For the untripped case a counter rotating vortex pair is present close to the free-end (dipole type). For the tripped case, on the other hand, another counter rotating vortex pair is also observed at the junction (quadrupole type). The free-end vortices look very similar both in strength and shape. In the tripped case, however, they are pushed up by the strong upwash induced by the junction vortices.

The rotation direction of these vortex pairs is such that the free-end pair induces a downwash and the junction pair induces an upwash in the wake. Thus a stronger upwash at the junction in the symmetry plane is due to the formation of the stronger junction vortices in the thicker boundary layer case.

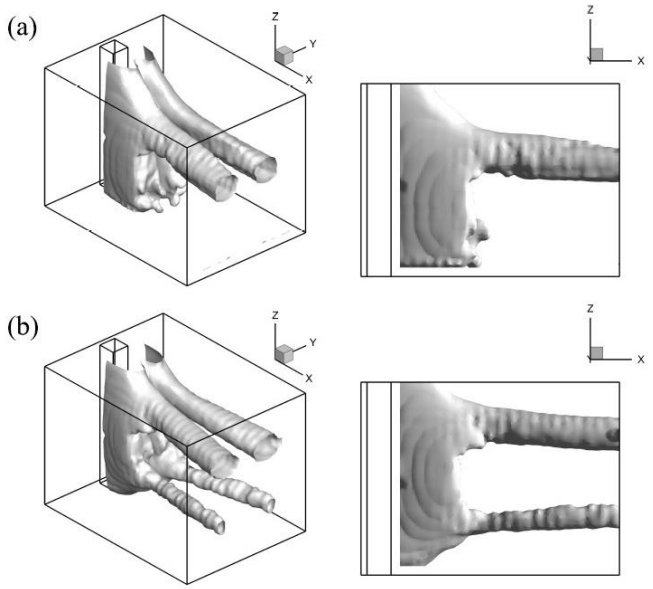

Figure 6. Mean vortex structure identified from $\lambda 2$-criterion for (a) untripped and (b) tripped cases which are respectively referred to as dipole and quadrupole wakes.

The differences indicated in the mean fields are due to different shed structures formed in each types of wake. To this end, a phase average decomposition is conducted to elucidate the typical wake and shed vortices structure. To justify the use of this decomposition the velocity fluctuations were measured at several spanwise and streamwise locations with a hot-wire anemometer. The power spectra along the span at $x/d=4$ and $y/d=2$, obtained from three realizations each *20* second long, is shown in figure 7. For all positions the power spectra exhibits a sharp and prominent peak at $St=0.102 \pm 0.003$ which is associated with the periodic vortex shedding. The peak is broadened at $z/h=0.25$ and *0.75* in the tripped case and $z/h=0.75$ in the untripped case; which is an evidence for a disruption of the regular von Karman structures that are shed parallel to the cylinder axis. It should be noted that the Strouhal numbers for both cases are very close. This is consistent with [7] where they examine the Strouhal number changes as a function of boundary layer thickness and show that at small boundary layer thickness to height ratios the Strouhal number remains constant.

Even though the Strouhal numbers for both the cases are the same, the power distributions are clearly different. The sharper peaks in the untripped case suggest that the shed structures have a clearer periodic behavior, i.e., the behavior is more similar to the periodic von Karman structures. Another difference is in the energy distribution. In the untripped case a significant portion of the energy is distributed among the low frequency fluctuations. The higher frequency fluctua-

tions, however, are less strong compared to the tripped case. This can also be seen in figure 8 where the symmetric and anti-symmetric parts of the pressure fluctuations are shown. The symmetric part is the sum of the pressure signals measured at the opposite faces of the obstacle and the anti-symmetric part is the difference. For a truly periodic shedding the pressures at either side are two periodic signals with 180^o phase shift. In a quasi-periodic shedding the sum represents the low frequency fluctuating part of the signal and the difference represents the high frequency fluctuations. Figure 8 shows that, the energy of the low fluctuations is slightly larger in the untripped case. The fluctuations in the anti-symmetric part, however, are stronger in the tripped case. It should be noted that with phase averaging only the periodic part of the high frequency fluctuations are categorized as coherent and the rest are assumed to be incoherent. As will be shown later, the coherent fluctuations obtained from phase averaging have the same level of energy and the difference is observed in the incoherent parts. These differences in the power distribution suggest that the shed structures behave differently.

Figure 9 shows the phase averaged vortical structures identified from λ_2-criterion. For both the cases the structures are shed alternatively from either side of the obstacle. In the dipole case the structure is connected to the ground almost vertically while is bent streamwise close to the free-end forming a half loop shape. In the tripped case, the shed structures are turned around both at the free-end and the junction forming a full loop shape. As shown in the figure the vertical part is called principal core and the streamwise part is called connector strand. The principal cores shed similar to the von Karman structures and thus they behave similarly. The connector strands, on the other hand, have a different form and thus their imprint is distinct. The broader peaks and higher level of non-periodic fluctuations in the tripped case, for example, are due to the presence of this non-von Karman type structures. By time averaging, connector strands give rise to streamwise vortex pairs. Thus time averaging of the half loop and full loop structures results in respectively the dipole and quadrupole wakes shown in figure 6.

To illustrate the significance of the shed structures in the turbulent field, contours of time-averaged squared lateral velocity fluctuations, $\overline{v'^2}$, as well as the recirculation region boundaries are plotted in figure 10 in three horizontal planes. The effect of the connector strands in the planes close to the strands, i.e., at *z/h=0.75* in the untripped case and *z/h=0.25* and *0.75* in the tripped case, can be seen as reducing the recirculation length and introducing three-dimensionality into the wake distribution. The recirculation length for a two-dimensional shedding is approximately the same as the vortex formation length, i.e., the distance downstream of the bluff body where the fluctuations reach the maximum value [8]. In these planes, however, the maximum fluctuation occurs farther downstream of the saddle point at the end of the recirculation region.

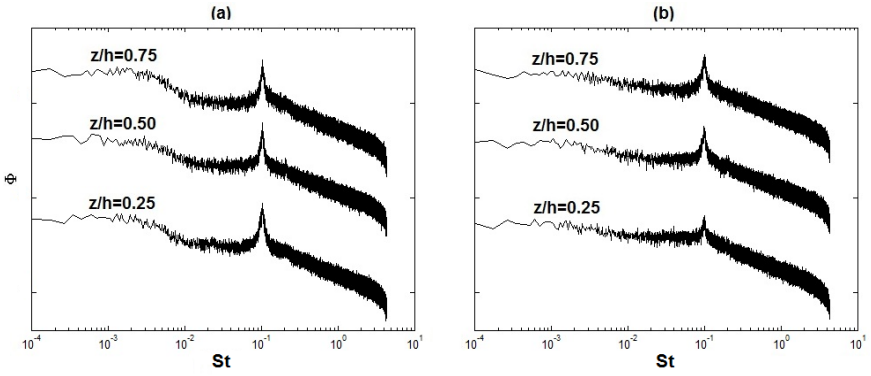

Figure 7. Power spectral density functions for (a) untripped and (b) tripped cases at *x/d=4* and *y/d=2*. Spectra at *z/h=0.50* and *0.75* are offset for clarity.

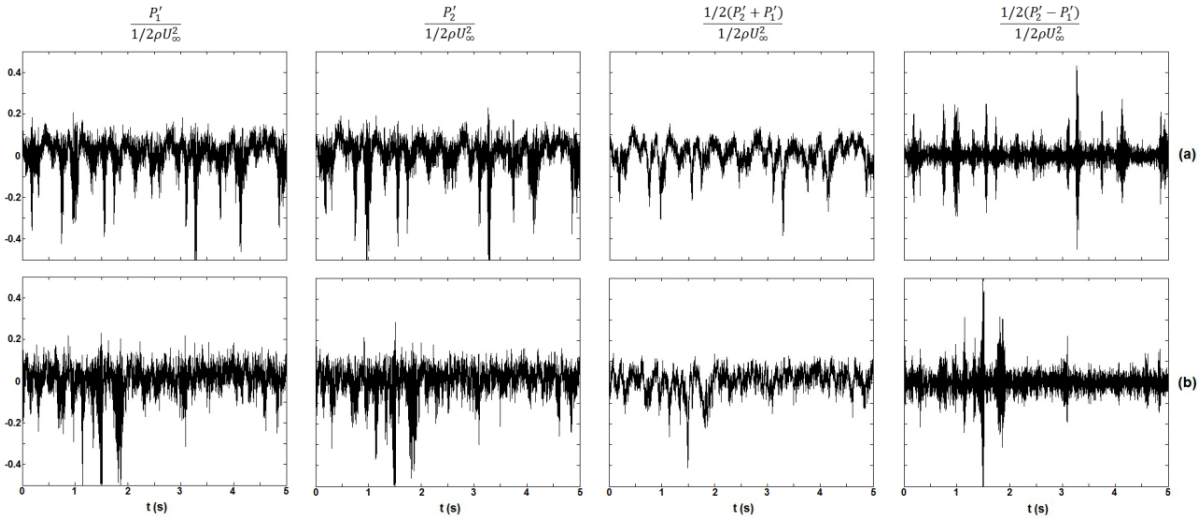

Figure 8. The pressure signals and the symmetric and anti-symmetric parts at z/h=0.25 for (a) untripped (b) tripped cases.

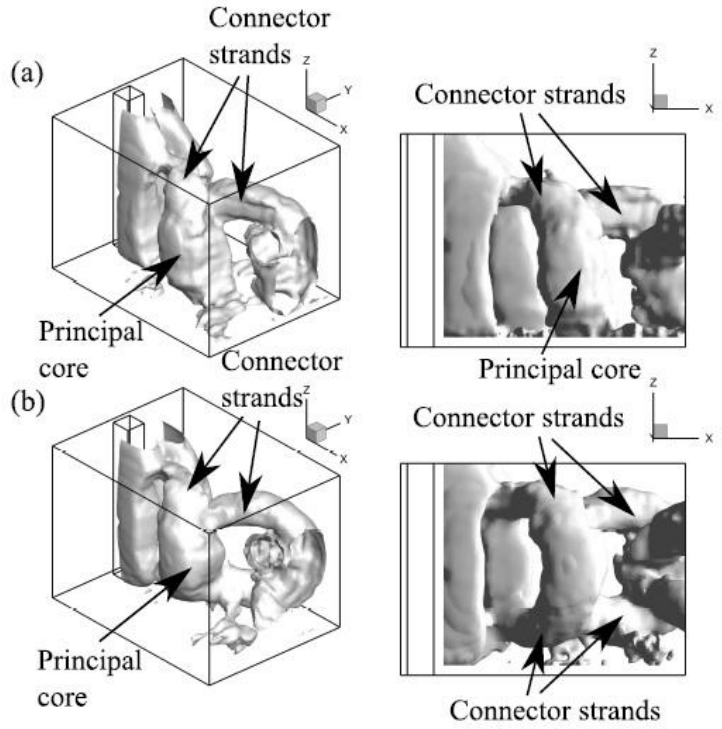

Figure 9. Half loop and full loop vortical structures, identified from $\lambda 2$-criterion, shed alternately from either side of the cylinder in (a) dipole (b) quadrupole wakes.

Another effect of the strands is decreasing the shear layer width and as discussed before enhancing the level of fluctuating energy. The maximum level of lateral fluctuations in the lower and upper planes in the tripped case is enhanced by more than 25% compared to the middle plane. Note that for the untripped case the connector strands are located at a lower position and thus this effect is not seen at *z/h=0.75*.

Figure 11 shows contours of $\overline{w'^2}$ at the symmetry plane. In the untripped case there is one maximum at the top while for the tripped case there are two maxima (with the same order of

magnitude) at the top and the bottom, close to the connector strands. Thus it can be concluded that the connector strands enhance the level of vertical fluctuations greatly. It should also be noted that for the present case, the full loop structures are almost symmetric and therefore the top and bottom strands act similarly.

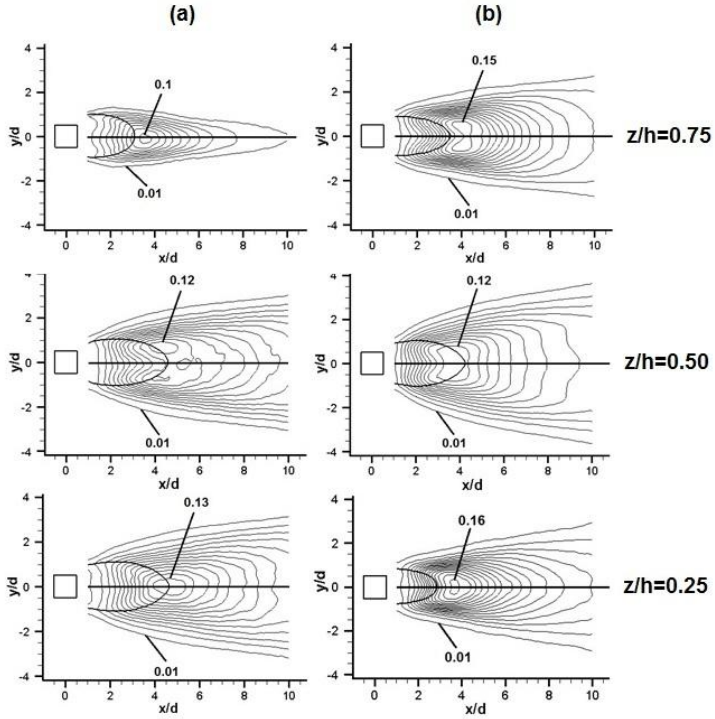

Figure 10. Contours of lateral fluctuations at *z/h=0.25*, *0.50* and *0.75* for (a) utripped and (b) tripped cases. The maximum fluctuation is located farther downstream of the end point of the recirculation region in the planes close to the connector strands.

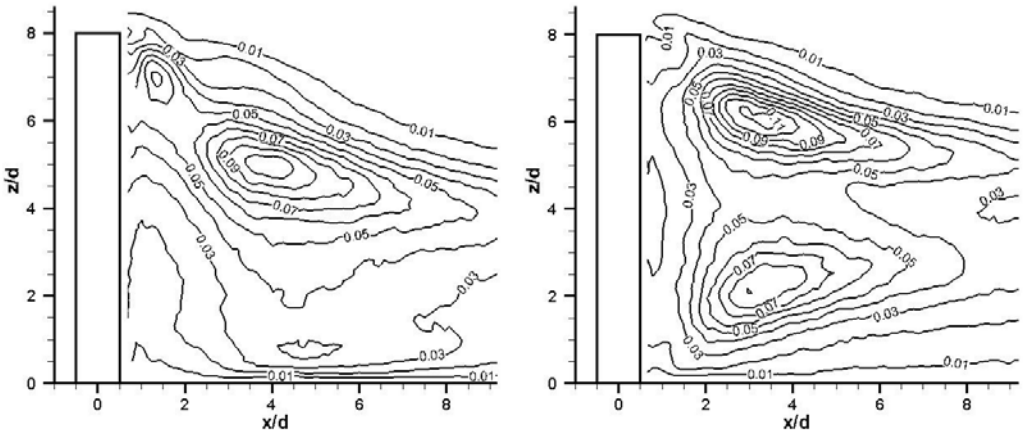

Figure 11. Contours of constant w'^2 for untripped (left) and tripped (right) boundary layers. The connector strands enhance the level of fluctuating energy.

From figures 10 and 11, it is concluded that in the planes close to the connector strands the total fluctuation level is increased. In figure 12 contours of total lateral fluctuations (repeated for the sake of comparison) as well as the coherent and incoherent parts are plotted for planes at

z/h=0.25 for both the wakes. This figure reveals that the increase in the lateral fluctuating level in the tripped case is due to the enhancement in the incoherent fluctuations, i.e., the parts that are not periodic as the regular von Karman structures. It could be argued that this increase could be due to the boundary layer effects since the tripped boundary layer is extended to this plane ($\delta/h=0.32$). Figure 13, however, shows that the same trend is observed in the plane close to the top strands, i.e. *z/h=0.75*, where compared to the middle plane the maximum level of incoherent fluctuations is larger. Thus the passage of the connector strands can be seen as an increase in the non-periodic fluctuating energy.

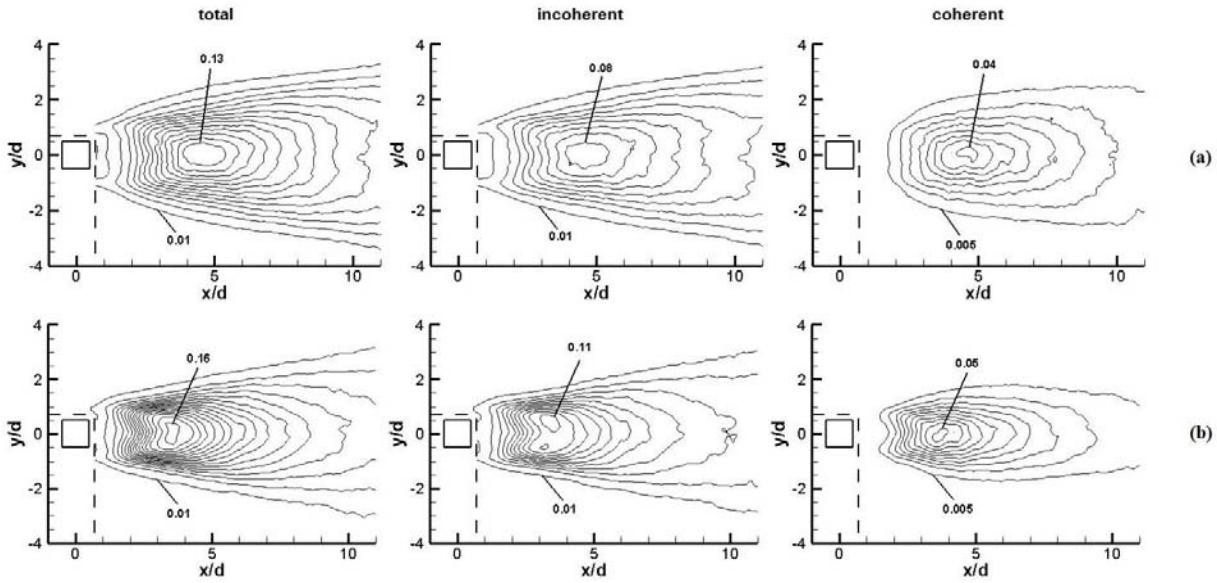

Figure 12. Decomposition of v'^2 into coherent and incoherent components for (a) untripped (b) tripped cases at *z/h=0.25*. The increase in the total fluctuating energy in the tripped case is mostly due to the increase in the non-periodic fluctuations which are categorized as incoherent in phase averaging.

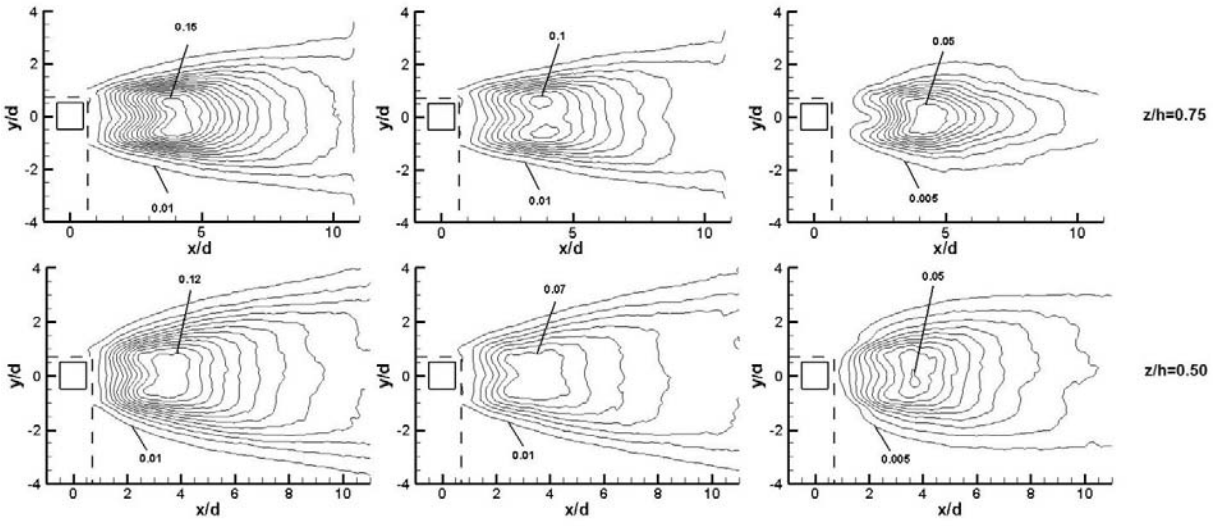

Figure 13. Decomposition of v'^2 into coherent and incoherent components for the tripped case.

4 CONCLUSION

The flow behind a tall square cylinder ($h/d=8$) mounted on a flat plate immersed in two thin boundary layers ($\delta/h=0.09$ and 0.32) is visualized using a 2-D PIV system. The three-dimensional phase averaged coherent structures are reconstructed from the velocity field at several horizontal and vertical planes measured simultaneously with the surface pressure as the reference signal. While the previous studies suggest that for cylinders immersed in thin boundary layers with aspect ratio taller than 3 the quadrupole wake is expected, the present work shows that depending on the boundary layer thickness both the wake types can form. This demonstrates the key role of the boundary layer even for boundary layers as thin as the ones considered here.

The shed structures form a half loop shape in the dipole wake and full loop shape in the quadrupole wake. The time averaging of these shed structures give rise to the different mean vortex distribution. The structures shed anti-symmetrically from either side of the obstacle and no evidence of symmetric shedding is observed.

The practical significance is in the large deviation of the wake distribution between the two cases. The rotation of the strands in the streamwise direction alters the mean and turbulent field greatly. The recirculation length is shortened and no longer coincides with the formation length as it does in two-dimensional shedding. The level of lateral fluctuating energy is increased by more than 25%; this increase is in the incoherent fluctuations. The distribution of the vertical velocity fluctuation is also altered highly. In the dipole wake only one maximum is observed close to the free-end while in the quadrupole wake another maximum with the same order of magnitude is observed close to the junction. Due to the large vertical velocities induced by the strands the wake width is reduced in the planes close to the strands.

All these effects are observed in the planes in proximity to the connector strands, i.e., $z/h=0.75$ in the dipole wake and $z/h=0.25$ and 0.50 in the quadrupole wake. Thus the largest difference between the two wakes is present at the lower plane, which is influenced by the strands in the quadrupole wake but remains undisturbed in the dipole wake. This is particularly important in predicting the wake load of tall buildings on pedestrians.

ABSTRACT: The influence of corner shaping on the aerodynamic behavior of square cylinders is studied through wind tunnel tests. Beside the sharp-edge corner condition considered as a benchmark, two different rounded-corner radii (r/b = 1/15 and 2/15) are studied. Global forces and surface pressure are simultaneously measured in the Reynolds number range between $2.5 \cdot 10^4$ and $1.8 \cdot 10^5$. The measurements are extended to angles of incidence between 0 and 45°, but the analysis and the discussion presented herein is focused on the low angle of incidence range. It is found that the critical angle of incidence where the flow reattaches on the lateral face exposed to the flow decreases as r/b increases and that an intermittent flow condition exists. In the case of turbulent incoming flow, two different aerodynamic regimes governed by the Reynolds number have been recognized.

KEYWORDS: Square cylinder, rounded corners, intermittence, Reynolds number effect

1 INTRODUCTION

A careful modeling of the corners shape of building and structural elements exposed to the wind has become a major objective for a wind-response-oriented optimal design. The introduction of rounded or chamfered corners has often the positive effect of reducing the drag force and the fluctuation of the transversal force due to vortex shedding [e.g. 1, 2], but can produce a relatively complicated aerodynamic behavior whose physical or numerical modeling may be challenging. In contrast to sharp-edge bodies, the absence of fixed separation points can introduce significant dependencies on the Reynolds number and on the characteristics of the incoming flow that must be taken into account during the design stage [e.g. 2 – 4].

The simplest and probably the most commonly investigate sharp-edge body is the square cylinder, thus it is the natural candidate to investigate the effect of corner shaping on the aerodynamic behavior of bluff bodies. With the twofold purpose of investigating the basic behavior of rounded corners and providing technical information useful for wind engineers, a series of wind-tunnel tests on square cylinders with rounded corners has been carried out. Rigid models of cylinders with two corner radii (r/b = 1/15 and 2/15), beside the sharp-corner case, have been realized and tested measuring the global forces and the pressure field along a cross-section. The considered Reynolds number range is between $2.5 \cdot 10^4$ and $1.8 \cdot 10^5$. Two levels of turbulence intensity (0.2% and 6%) in the incoming flow have been considered.

Section 2 provides a brief review of the current knowledge on the aerodynamic behavior of sharp-edge square cylinders, with particular reference to the qualitative description of the flow field for different angles of incidence. These concepts are then used as a guide for the interpretation of the experimental results presented in Section 3 and discussed in Section 4. Due to the space limitation, the discussion is focused on two specific phenomena that have been observed:

1) the intermittence of the vortex-shedding regime at the critical angle of incidence in smooth flow; 2) the inversion of the lift coefficient slope at zero angle of incidence in turbulent flow.

2 AERODYNAMIC BEHAVIOUR OF SHARP-CORNER SQUARE CYLINDERS

Sharp-edge square cylinders have been studied by several researchers who focused their attention on numerous aerodynamic parameters including pressure distribution, drag and lift forces, vortex shedding properties, as well as near wake velocity field [e.g. 5 – 11]. The flow pattern around a square cylinder is strongly dependent on the angle of incidence, α, and at least two characteristic flow regimes are clearly identified and separated by a critical angle of incidence, α_{cr} located about 12-15° [8]. For $\alpha < \alpha_{cr}$ the boundary layer on the lateral faces is completely separated, while for $\alpha > \alpha_{cr}$ the flow reattaches on the lateral face exposed to the wind forming a separation bubble [e.g. 10, 11]. A further sub-classification of the two mentioned regimes is possible [8], but is not relevant for the purpose of the present study. The subcritical regime ($\alpha < \alpha_{cr}$) is characterized by negative slope of the lift coefficient, which changes sharply to positive as α becomes grater than α_{cr}. Besides, the transition from the subcritical to the supercritical regime produces a rapid increment of the Strouhal number that corresponds to the reduction of the wake width due to the flow reattachment [6]. In the critical regime both the drag coefficient and the fluctuating lift coefficient have a minimum value. This scenario is not strongly modified by the Reynolds number and the characteristics of the incoming flow, even if some significant influence does exist. The thickening of the shear layers due to a small-scale free-stream turbulence promotes the formation of the separation bubble which tends to appear for smaller angle of incidence and to shrink towards the leading edge [6]. This mechanism is probably influenced by the Reynolds number as suggested in [4] for a the case of a 2:1 rectangular cylinder, however no effect has been revealed on square cylinders [9].

3 EXPERIMENTAL RESULTS

The experimental tests are carried out in the closed-circuit wind tunnel at the University of Genova with cross section 1700 × 1350 mm. The models are realized through the assemblage of aluminum plates, have a span length l = 500 mm and are mounted in cross-flow configuration on a force balance realized by six resistive load cells. End plates are installed at the extremities of the models to maintain a two-dimensional flow condition and separate the model from the boundary layer on the wind-tunnel walls. The mid-span cross section of the models is instrumented by a ring of N pressure taps (N ranges from 20 to 44 for the different tested models) connected through short tubes to 32-channel PSI pressure scanners mounted inside the model. Figure 1 shows the cross section of the tested cylinders and the reference system used for the presentation of the results. Beside the sharp-edge square cross section used as a benchmark test, two rounded-corner configurations with r/b = 1/15 and 2/15 (r and b being, respectively, the corner radius and the square size, Fig. 1) have been considered.

The force balance measurements are analyzed calculating the steady aerodynamic drag and lift coefficients (C_D and C_L) the Strouhal number (St) and the fluctuating lift coefficient (C_L^{rms}) defined as:

$$C_D = \frac{\mathrm{E}[D]}{0.5\rho blU^2} \qquad C_L = \frac{\mathrm{E}[L]}{0.5\rho blU^2} \qquad St = \frac{n_s b}{U} \qquad C_L^{rms} = \frac{\mathrm{E}\left[\left(L - \mathrm{E}[L]\right)^2\right]^{0.5}}{0.5\rho blU^2} \tag{1}$$

where D and L are, respectively, the measured drag and lift forces (Fig. 1), ρ the air density, U the undisturbed mean wind velocity; E[•] is the statistic average operator that is implemented as a time average adopting the hypothesis of ergodic behavior; n_s is the vortex shedding peak frequency estimated by fitting the Power Spectral Density (PSD) function of L through a Gaussian function in the neighborhood of its peak. Analogously, steady and fluctuating pressure coefficients are defined as

$$C_p = \frac{\mathrm{E}[p - p_0]}{0.5\rho U^2} \qquad C_p^{rms} = \frac{\mathrm{E}\left[\left(p - \mathrm{E}[p]\right)^2\right]^{0.5}}{0.5\rho U^2} \tag{2}$$

where p is the pressure measured on the body surface and p_0 is the static wind-tunnel pressure.

The influence of the Reynolds number (Re) is explored both varying the wind-tunnel velocity U in the range 5 – 25 m/s, as well as the body size b in the range 60 – 150 mm. No blockage correction has been adopted since the focus of the paper is the qualitative description of the behavior, which is not affected by slight modifications of the estimated numerical values.

Two conditions for the incoming flow have been considered: 1) smooth flow condition characterized by a turbulence intensity about 0.2%; 2) turbulent flow condition, produced through a grid realized by square bars, characterized by the intensity of the longitudinal turbulence I_u about 5% and integral length scale L_u about 20 mm. These parameters are substantially stable through the whole considered wind velocity range (Fig. 2).

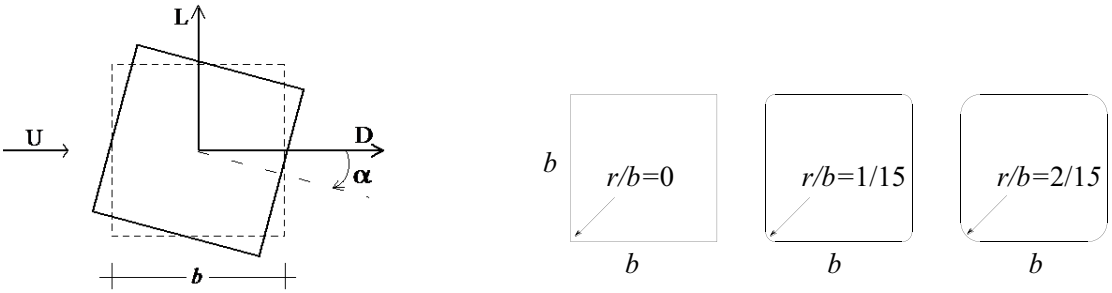

Figure 1. Experimental setup

Figure 3 shows the variation of C_D (a), C_L (b), St (c) and C_L^{rms} (d) with respect to the angle of incidence for the three considered models in smooth flow. No significant influence of the Re has been observed in the range between $2.69 \cdot 10^4$ and $1.65 \cdot 10^5$. It can be observed that the three models have a similar qualitative behavior characterized by the inversion of the lift slope for a critical angle of incidence, α_{cr}, that decreases as r/b increases. For $\alpha = \alpha_{cr}$ the steady drag and the fluctuating lift coefficients have a minimum value, while the Strouhal number increases sharply. For the sharp-corner model α_{cr} was found about 12° and is in substantial accord to previous experimentations (see [11] for a review of previous results). In the case of rounded-corner models it was found $\alpha_{cr} = 7°$ and 5° for r/b = 1/15 and 2/15, respectively. Tamura & Miyagi [2], working in similar flow conditions, found $\alpha_{cr} = 4°$ for r/b = 2.5/15.

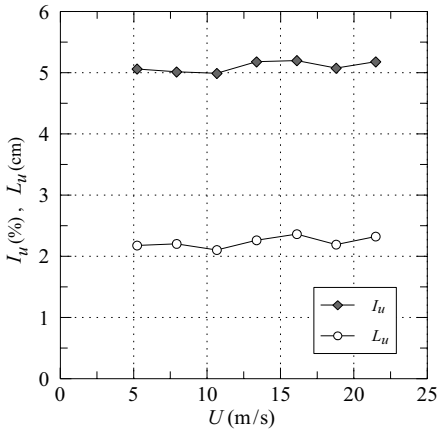

Figure 2. Intensity and integral length scale of the longitudinal turbulence in turbulent flow condition.

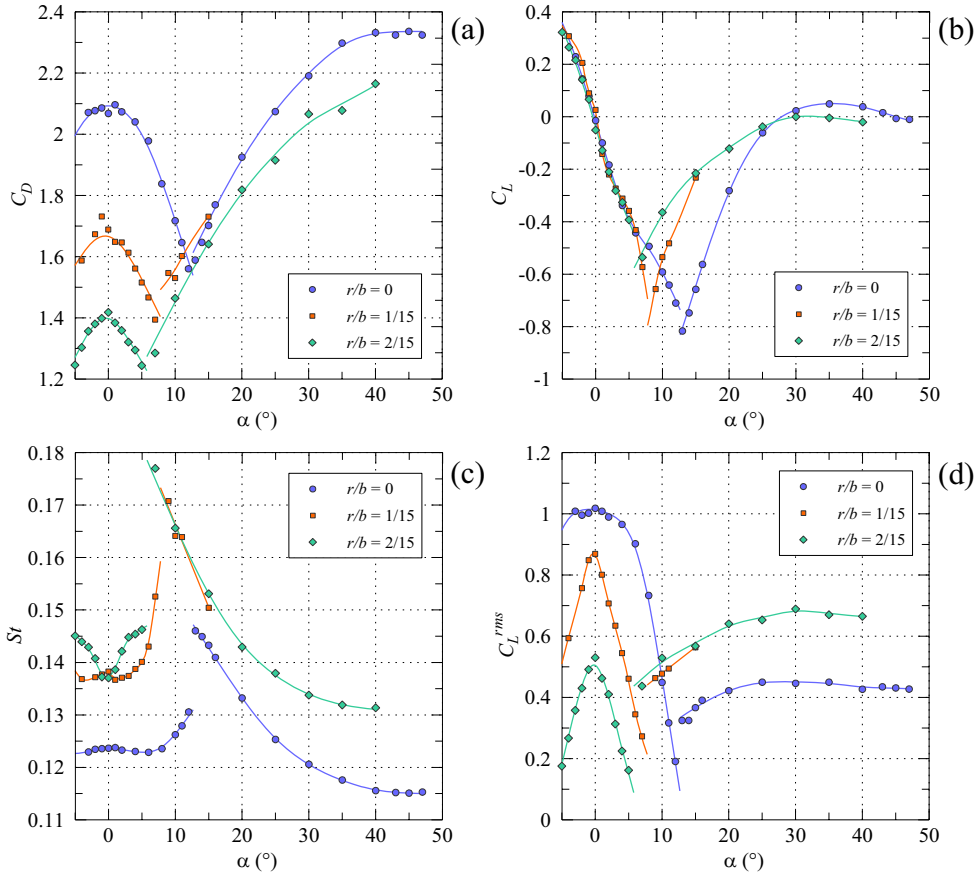

Figure 3. Steady drag (a) and lift (b) coefficients, Strouhal number (c) and fluctuating lift coefficient (d) in smooth flow condition.

Figure 4 shows the variation of C_D (a), C_L (b), St (c) and C_L^{rms} (d) with respect to the angle of incidence, for r/b = 2/15, in turbulent flow for Re between $2.49 \cdot 10^4$ and $1.81 \cdot 10^5$. For the tests corresponding to $Re = 2.49 \cdot 10^4$, $5.14 \cdot 10^4$, $7.81 \cdot 10^4$, a model with b = 75 mm was used, while a larger model with b = 150 mm was adopted for the other tests. A very strong dependency on Re

is observed for small angle of incidence. In particular two distinct behaviors can be observed, which are separated by a critical Reynolds number $Re_{cr} \simeq 5 \cdot 10^4$. These two regimes are referred to as subcritical ($Re < Re_{cr}$) and supercritical ($Re > Re_{cr}$).

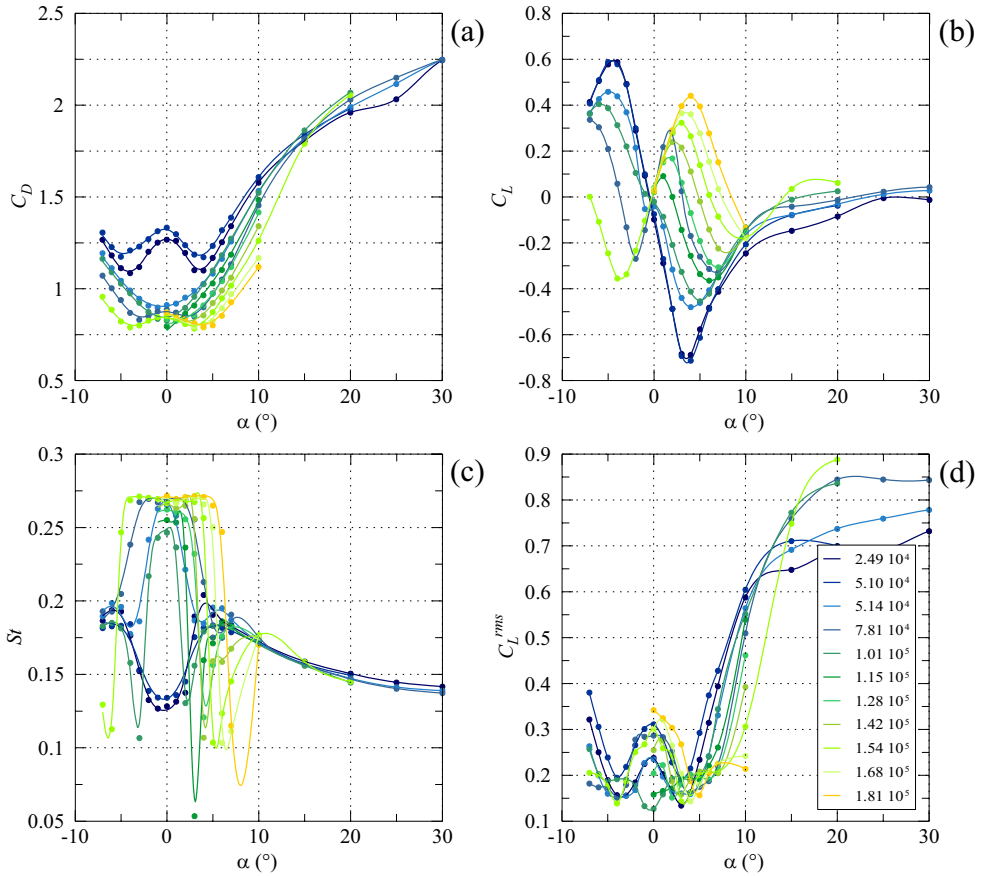

Figure 4. Steady drag (a) and lift (b) coefficients, Strouhal number (c) and fluctuating lift coefficient (d) in turbulent flow condition for $r/b = 2/15$ and different Reynolds numbers.

The results obtained for $Re = 2.49 \cdot 10^4$ and $5.10 \cdot 10^4$ are practically coincident even if are obtained using two different models (b = 75 mm and 150 mm, respectively) and are substantially similar to the results observed in smooth-flow condition. The steady drag coefficient for $\alpha = 0$ is about 1.3, (slightly lower than in smooth flow). The minimum value of the steady lift coefficient is about -0.7 and is obtained for $\alpha = 3$ - 4° (slightly before than α_{cr} in smooth flow); the Strouhal number is about 0.13 for $\alpha = 0$ and rapidly increases up to 0.18 for $\alpha = 4°$ (again not far from the values observed in smooth flow).

As Re increases, the steady lift slope for $\alpha = 0$ switches from negative to positive; further increments of Re have the result of extending the range of α for which a positive slope is observed. This trend seems quite regular with respect to Re, even if some small discrepancies between the behavior of the two models (different b) have been observed and may be related to the effect of the turbulence scale parameter L_u/b. The maximum value of the steady lift coefficient increases as Re increases and is obtained for larger and larger angles of incidence; for $Re = 1.82 \cdot 10^5$ the maximum C_L is about 0.45 and appears for $\alpha = 4°$. In the region where the steady lift slope is positive the Strouhal number is about 0.27 (approximately twice the value obtained in smooth flow) and is practically insensitive to Re. As the slope of C_L becomes negative, St drops to a very

low value about 0.10 and then recovers the trend observed in smooth flow for $\alpha > 10°$. The minimum value of the steady drag coefficient is reached for the angle of incidence corresponding to the maximum vales for C_L and St.

The supercritical regime has been observed only for $r/b = 2/15$, while for $r/b = 1/15$ only the subcritical regime has been observed for Re up to $2.32 \cdot 10^5$.

4 DISCUSSION

During the experimentation described in Section 3 two main issues clearly emerged and require a discussion. The former regards the sharp discontinuity of the aerodynamic behavior observed for $\alpha = \alpha_{cr}$ in smooth-flow condition. The latter issue is related to the two distinct flow behaviors observed for different Re in turbulent flow for $r/b = 2/15$.

4.1 *Discontinuity of the aerodynamic behavior at the critical angle of incidence in smooth flow*

For the case of sharp-corner square cylinders, the existence of two flow regimes separated by the critical angle of incidence has been clearly documented through accurate flow visualization techniques [8, 10]. The qualitative similarity of the behavior observed for the three tested models suggests that a modification of the corner geometry (within the considered limits) does not produce qualitative variations of the flow pattern, but rather modifies the limit of existence of the flow regimes known for the sharp corner case. In particular the increment of r/b produces a reduction of α_{cr}.

The transition between these two regimes is due to the reattachment of the mean flow on the lateral face exposed to the wind, generating a separation bubble; however to the authors' knowledge the unsteady nature of this transition has never been carefully investigated. Figure 5 shows a time-frequency analysis of the lift force measured in smooth flow on the sharp-edge model (a) and rounded-corner models with $r/b = 1/15$ (b) and 2/15 (c) for $\alpha = \alpha_{cr}$. The colormaps represent the amplitude of the wavelet transform of L, plotted with respect to the time t and the frequency n non-dimensionalized through b and U; the mother wavelet used for the analysis is an analytic Morlet type; the lift coefficient is reported below the maps for reference. The length of the considered time windows is 800 non-dimensional time units, which roughly correspond to 120 cycles of vortex shedding. From the wavelet maps it can be observed that the vortex-shedding peak frequency changes with time fluctuating between the values reported in Figure 3 for angles just before and after α_{cr}. This result suggests that the wavelet maps can be employed to study, from a qualitative point of view the stability of the two concurrent flow regimes (subcritical and supercritical) that appear in the neighborhood of α_{cr}, as well as the transition from one regime to the other. The comparison of the three wavelet maps reveals that the flow around the sharp-corner cylinder tends to have smooth and frequent transitions between the two flow regimes giving rise to a behavior that may be identified as irregular vortex shedding (Fig. 5a). On the contrary, in the case of rounded-corner cylinder with $r/b = 2/15$, a proper intermittent behavior has been found as documented in Figure 5c, where the transition between supercritical to subcritical, as well as from subcritical to supercritical regime is clearly visible. The transitions are very sharp and the time in which the system remains stable in a regime is relatively long (in Figure 5c the length of the subcritical phase corresponds to about 50 cycles of vortex shedding).

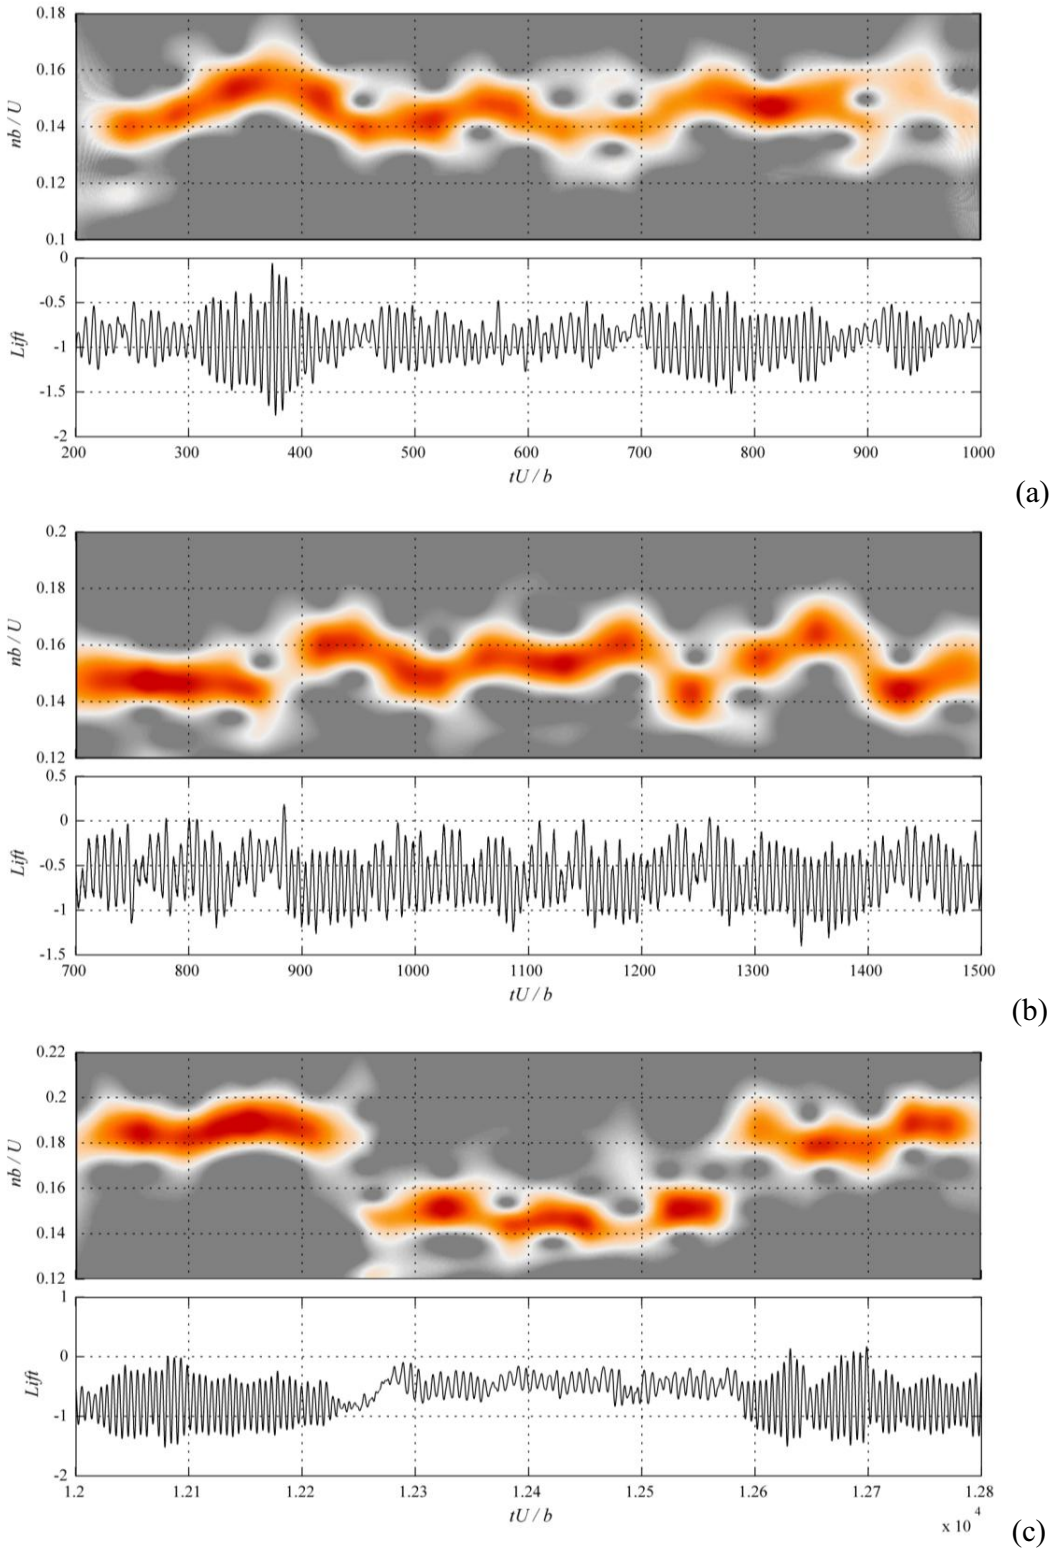

Figure 5. Wavelet map and time history of the lift coefficient for sharp corners (a), r/b = 1/15, r/b = 2/15 (c).

4.2 *Inversion of the lift slope at small angle of incidence in turbulent flow*

The analysis of the results obtained in turbulent flow for the rounded cylinder with $r/b = 2/15$ suggests the existence of two flow regimes for small angle of incidence, whose transition is governed by the Reynolds number.

On the basis of aerodynamic coefficients and Strouhal number, it may be deduced that in the subcritical *Re* regime the aerodynamic behavior is similar to the one observed in smooth-flow condition, even if the sharp transition with intermittence for $\alpha = \alpha_{cr}$ described in Section 4.1 does not take place. This analogy (which implies the conclusion that the free-stream turbulence has a limited effect in the subcritical *Re* regime) can be verified by comparing the mean and fluctuating pressure coefficients obtained in smooth and turbulent flow for $\alpha = 0$ and different *Re* (Fig. 6). In particular it can be observed that C_p obtained in turbulent flow and subcritical regime (Fig. 6c, *Re* $= 2.49 \cdot 10^4$ and $5.10 \cdot 10^4$) is very similar to C_p obtained in smooth flow (Fig. 6a), which is substantially independent of *Re*; the same analogy also applies to the fluctuating pressure coefficients (Fig. 6b and d).

For small angles of incidence the passage to the supercritical *Re* regime deeply changes the aerodynamic behavior: the steady drag coefficient drops to values about 0.7 (Fig. 4a), the steady lift slope switches to positive (Fig. 4b) and the Strouhal number doubles (Fig. 4c). The steady pressure coefficient (Fig. 6c) is strongly dependent on *Re*, whose increment has two major effects: 1) the suction near the leading edges increases; 2) the point on the lateral faces where the base pressure is recovered moves upstream. As far as the fluctuating pressure coefficient is concerned (Fig. 6d) an increment of *Re* produces: 1) a reduction of the pressure fluctuation by the midpoint of the lateral faces; 2) an increment of the pressure fluctuation near the trailing edges; 3) an increment of the pressure fluctuation on the leeward face. The above observations suggest that in the supercritical *Re* regime the flow reattaches on the lateral faces even for $\alpha = 0$ forming two the separation bubbles that shrink towards the leading edges as *Re* increases.

Figure 7 shows the steady pressure coefficient for smooth flow (Fig. 7a) and turbulent flow (Fig. 7c), as well as the respective fluctuating coefficients (Fig. 7b and d) for $\alpha = 4°$. It can be observed that while in smooth flow condition the pressure field is only slightly modified by passing from $\alpha = 0$ to $\alpha = 4°$, in case of turbulent flow the modifications are relevant and can be summarizes as: 1) near the lower (in Fig. 7) leading edge the pressure field is independent of *Re* and the separation bubble tends to shirk as α increases likewise it happens for the sharp-corner cylinder for $\alpha > \alpha_{cr}$; 2) near the upper leading edge the steady pressure field is strongly dependent on *Re* and the point where the base pressure is recovered shifts downstream. A further increment of α prevents the flow reattachment on the leeward lateral face and produces a flow pattern similar to the one observed in smooth flow for $\alpha > \alpha_{cr}$. The angle of incidence for which this transition arises corresponds to the maximum of the steady lift coefficient and is strongly dependent on *Re*.

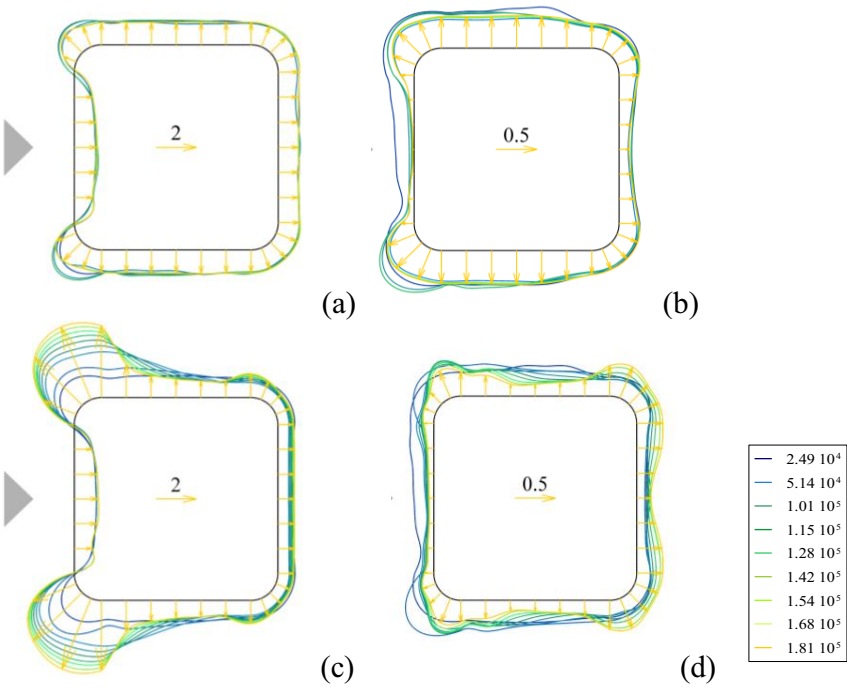

Figure 6. Pressure coefficients for $\alpha = 0$. Smooth flow C_p (a) and C_p^{rms} (b); turbulent flow C_p (c) and C_p^{rms} (d).

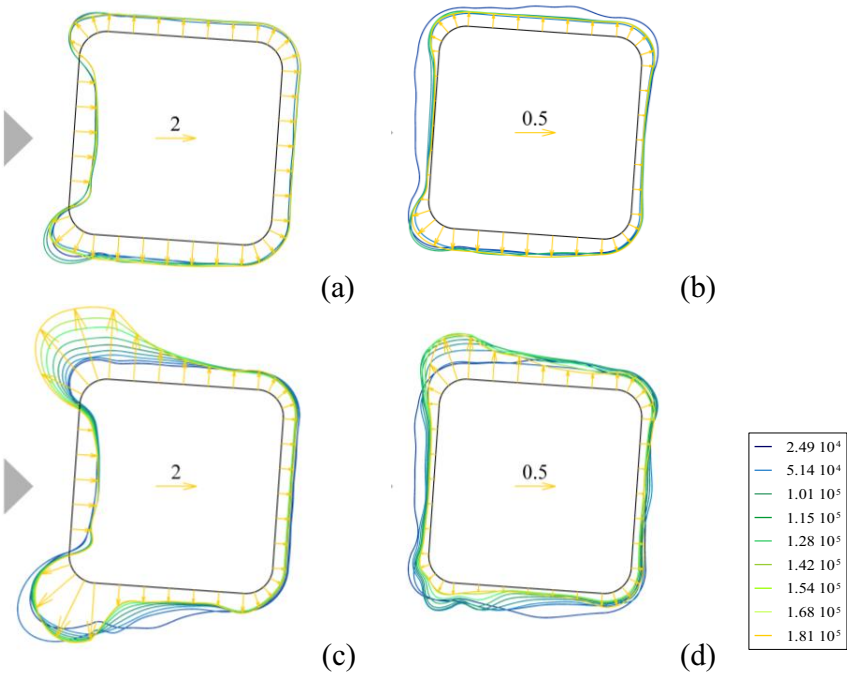

Figure 7. Pressure coefficients for $\alpha = 4°$. Smooth flow C_p (a) and C_p^{rms} (b); turbulent flow C_p (c) and C_p^{rms} (d).

5 CONCLUSIONS

The effects of corner shaping on the aerodynamic behavior of square cylinders have been investigated through the analysis and discussion of wind-tunnel experiments. It has been found that rounded corners promote the reattachment of the flow on the lateral faces producing 1) a reduction of the critical angle of incidence α_{cr}, 2) an intermittent behavior for $\alpha = \alpha_{cr}$, 3) the inversion of the lift slope for small angles of incidence. This latter effect has been observed only for r/b = 2/15, however it cannot be excluded that it may appear also for smaller r/b ratios at sufficiently high Reynolds numbers.

The technical implications of the mentioned effects are important due to the large variation of the aerodynamic coefficients, as well as in relation to galloping instability. From the results obtained in smooth flow it can be concluded that the classical galloping model (based upon a quasi-steady assumption) cannot be adopted due to the observed intermittent behavior. On the other hand, the results obtained in turbulent flow reveal that the lift coefficient or rounded corner cylinders can be negative or positive for different *Re* and that, in supercritical *Re* regime, the necessary condition for galloping (negative lift slope) does not appear at $\alpha = 0$, but in a range between 5° and 10°.

POD analysis of the finite-length square cylinder wake

Wang Hanfeng

School of Civil Engineering, Central South University, Changsha, China

ABSTRACT: The near wake of a wall-mounted finite-length square cylinder with H/d = 7 is measured with PIV in three spanwise planes, i.e. near cylinder free end, at mid span and near the flat wall. The Reynolds number based on freestream velocity and cylinder width is 9300. Proper orthogonal decomposition (POD) technique is utilized to analyze the experimental data. Under the effects of free-end downwash flow, the near wake is highly three dimensional and drastically different from that of a 2D cylinder. The turbulent kinetic energy distributes over more POD modes relative to 2D cylinder wake. Low-dimensional model is not applicable to reconstruct this 3D flow. Both symmetrical and anti-symmetrical vortices structures occur in the finite-length cylinder wake, which can be identified based on the coefficients of the first two POD modes.

1 INTRODUCTION

The flow around a two-dimensional (2D) cylinder has long been the subject of extensive study. However, in engineering applications, the cylinder like structures are often finite in length (or height), with one end free and other end mounted on the ground, such as aerodynamic forces on high-rise buildings, plume behaviors behind chimneys, etc. Due to the effects of cylinder free end and boundary layer, the flow around a finite-length cylinder differs drastically from that behind a 2D cylinder[1, 2]. The near wake of a wall-mounted finite-length cylinder is characterized by the presence of two pairs of longitudinal tip and base vortices, in addition to the possible spanwise Karman vortex shedding. The interactions between these three types of vortices complicate the flow and make it highly three dimensional. The tip vortices are associated with the downwash flow behind cylinder free end[3, 4]. The base vortices depend on the conditions of the boundary layer where the cylinder mounted. When the boundary layer thickness is negligibly small, the base vortices will not present[4, 5].

The near wake of a finite-length cylinder depends strongly on H/d, where H and d are cylinder characteristic height and width, respectively. When H/d falls below a critical value, vortex shedding changes from antisymmetrical to symmetric[5-7]. The critical value is 2~6, depending on factors such as the boundary layer thickness and incoming turbulence intensity[6, 8]. Wang & Zhou[2] measured the near wake of finite-length square cylinder with H/d = 3, 5 and 7. They found both symmetrical and anti-symmetrical vortex shedding can be observed throughout cylinder span for all tested H/d. At mid-span of the cylinder with H/d = 7, which is larger than the critical value proposed, there are still more than 10% of instantaneous vortices are symmetrically arranged.

The proper orthogonal decomposition (POD) is a quantitative and an unbiased method that has been increasingly applied in conjunction with instantaneous whole-filed measurement techniques such as PIV for identifying the coherent structures. The POD technique provides an optimal set of basis function (POD mode) from an ensemble of data to reconstruct the coherent structures as mixtures of POD modes. This method has been successfully used in various types of flows, such as jets, mixing layers, channel flows and cylinder wakes. Detailed information about POD in fluid dynamics may be found in Sirovich[9].

The present paper aims to reveal the difference between the near wake structure of wall-mounted square cylinder with $H/d = 7$ and 2D one using PIV and POD techniques. From the PIV data, the time-averaged velocities, and other turbulent statistical quantities were obtained. Comparisons are also made in the context of POD mode and mode energy distribution to highlight the three dimensional effects for the wall-mounted finite-length cylinder wake.

2 EXPERIMENTAL DETAILS & POD METHOD

2.1 *Experimental setup*

All experiments were conducted in a closed-loop low-speed wind tunnel with a 2.4m long test section of 0.6m×0.6m. The flow velocity in the test section was uniform to 0.1% and the longitudinal turbulence intensity was less than 0.4%. A flat plate of 0.5m in width and 1.2m in length was installed in the test section with its upper surface 0.15m from the bottom wall. The leading edge of the flat plate was rounded to avoid flow separation. A square cylinder with a width d = 20mm was placed at the centerline, 0.3m downstream from the leading edge of the plate, as shown in figure 1. The H/d was 7. All measurements were conducted at a free-stream velocity $U_\infty = 7\text{ms}^{-1}$, corresponding to a Reynolds number $\text{Re}_d \equiv U_\infty d/\nu = 9300$, where ν is the kinematic viscosity of fluid. A LDA was used to document the boundary layer at the cylinder axis. The boundary layer disturbance thickness (δ) was estimated to be 27mm so that $\delta/d \approx 1.35$. Considering the thickness of the boundary layer, it may result in pronounced upwash flow and associated base vortices[10]. A nominal 2D square cylinder (with $H/d \approx 28$) wake was also measured at the same Re_d for comparison.

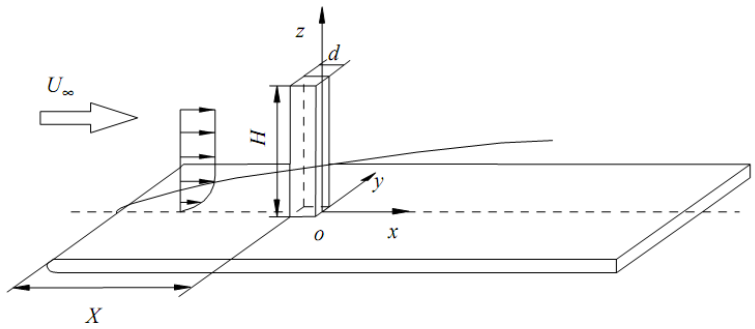

Figure 1. Experimental setup and the definition of coordinate system.

2.2 *PIV measurements*

A Dantec standard PIV2100 system was used to measure both the instantaneous and time-averaged flow fields. Flow illumination was provided by two NewWave standard pulse laser sources of a 532 nm wavelength, each with a maximum energy output of 120 mJ pulse^{-1}. Particle images were taken using one CCD camera (HiSense type 13, gain×4, double frames, 1280×1024 pixels). Synchronization between image taking and flow illumination was provided by the Dantec FlowMap Processor (PIV2001 type). PIV measurements were performed in three (x, y) planes at $z^* = 1$, 3.5 and 6, i.e. 1d above the flat plate, cylinder mid-span and 1d lower than the free end. The superscript asterisk in present paper indicates normalization by U_∞ and/or d. The image magnification was 148 μm/pixel. In processing PIV images, an interrogation area of 32×32 pixels was used with a 50% overlap in both directions, producing 78×62 in-plane velocity vectors. For each case, a total of 1500 PIV images were captured to calculate time-averaged velocities and Reynolds stresses and perform POD analysis.

2.3 *POD method*

The snapshot POD method, proposed by Sirovich[9], was employed to analysis the PIV data. By this method, each instantaneous PIV data is considered a snapshot of the flow field. The present snapshot POD follows the procedure outlined by Meyer *et al.*[11]. The first step is to calculate the mean velocity field, which can be considered the zero mode of POD. The rest of analysis works on the fluctuation parts of the velocity components (u_i^n, v_i^n), where u and v denote the fluctuation velocity in streamwise and lateral directions. Index n runs through the N snapshots, and i runs through the M positions of velocity vectors in a given snapshot.

All fluctuating velocity components from N snapshots are arranged in a matrix U as:

$$U = \left[u^1, u^2 \ldots u^N\right] = \begin{bmatrix} u_1^1 & u_1^2 & \ldots & u_1^N \\ \vdots & \vdots & \vdots & \vdots \\ u_M^1 & u_M^2 & \ldots & u_M^N \\ v_1^1 & v_1^2 & \ldots & v_1^N \\ \vdots & \vdots & \vdots & \vdots \\ v_M^1 & v_M^1 & \ldots & v_M^1 \end{bmatrix} \tag{1}$$

The autocovariance matrix C is created as $C=U^TU$. A set of N eigenvalues λ^i and corresponding set of eigenvectors A^i which satisfy $CA^i = \lambda^i A^i$ are evaluated. The eigenvalues are ordered by decreasing value as $\lambda^1 > \lambda^2 > \ldots > \lambda^N > 0$. The normalized POD modes φ^i are constructed from the projection of the eigenvectors A^i as:

$$\varphi^i = \frac{\sum_1^N A_n^i u^n}{\left\| \sum_1^N A_n^i u^n \right\|}, \qquad i = 1, 2, \ldots N \tag{2}$$

Each snapshot can be expanded in a series of the POD modes with expansion coefficients a_i for each φ^i. The coefficients a_i also called POD coefficients, are determined by projecting the fluctuating part of the velocity field onto the POD modes $a^n = \Psi^T u^n$, where $\Psi = [\varphi^1, \varphi^2 \ldots \varphi^N]$. Then, the expansion of the fluctuation part of a snapshot n is obtained from:

$$u^n = \sum_{i=1}^{N} a_i^n \varphi^i \tag{3}$$

Readers may refer to Sirovich[9] and Meyer *et al.*[11] for more details of the POD method.

3 RESULTS & DISCUSSIONS

Figure 2 presents the contours of $\overline{U^*}$, $\overline{u^*_{rms}}$, $\overline{v^*_{rms}}$ and $\overline{u^*v^*}$ at $z^* = 6$ and 3.5 for a finite-length cylinder with $H/d = 7$, together with those for a 2D square cylinder at the same Re_d for comparison. The overbar denotes time-average and the subscript *rms* indicates the root-mean-square value of fluctuation velocity. The results at $z^* = 1$ are qualitatively similar to those at $z^* = 3.5$ thus not present here. The streamwise extent of the reverse flow zone at mid-span, indicated by the bold line in figure 2(i), is far larger than that of 2D cylinder (figure 2a). A shorter reversed flow zone implies stronger entrainment of high-speed free-stream fluid into the wake, i.e. stronger vortex shedding. The maximum values of $\overline{u^*_{rms}}$, $\overline{v^*_{rms}}$ and $\overline{u^*v^*}$ at the mid-span (figure 2 j, k & l) are about

one-half of those for a 2D cylinder at the same Re_d (figure b, c & d), which also suggests that the vortex shedding is less organized in a finite-length cylinder wake. Near the free end (z^*=6), all the contours appear to converge towards the centerline with increasing x^* due to downwash flow from the free end, which differ not only quantitatively but qualitatively from those at mid-span. Under the effect of free-end downwash flow, the reverse flow zone at $z^* = 6$ shrinks significantly relative to that at mid-span, while still far larger that of 2D cylinder.

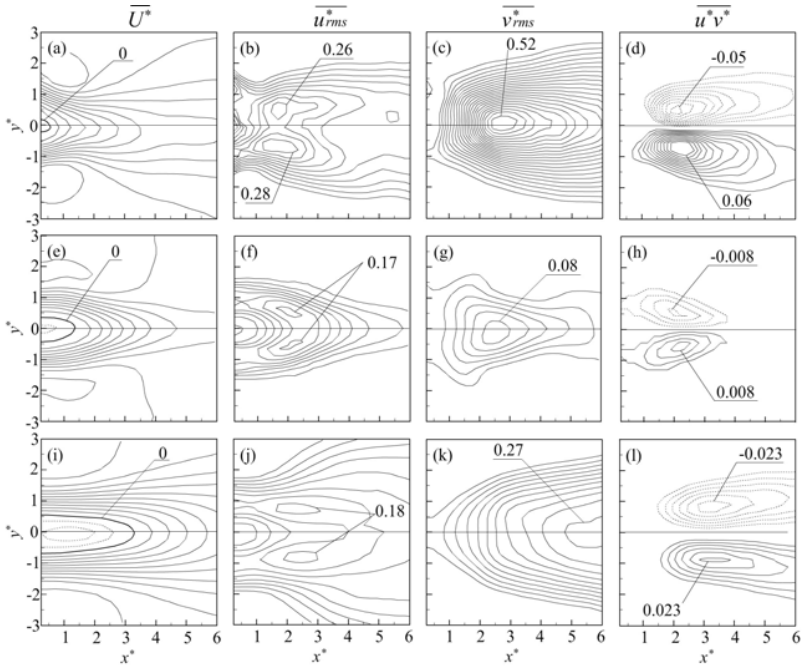

Figure 2. The contours of $\overline{U^*}$, $\overline{u^*_{rms}}$, $\overline{v^*_{rms}}$ and $\overline{u^*v^*}$. (a-d) 2D square cylinder; (e-h) $z^* = 6$, for $H/d = 7$; (i-l) $z^* = 3.5$, for $H/d = 7$. (a, e & i) Contour interval = 0.1; (b, f & j) 0.02, 0.02, 0.02; (c, g & k) 0.02, 0.01, 0.02; (d, h & l) 0.005, 0.002, 0.004.

To reveal the three-dimensionality of vortex structures for finite-length cylinder, POD analysis was applied in spanwise planes of different z^*. Since the sample size or number of snapshots necessary to obtain converged POD analysis was about 1000[12], the 1500 PIV records at each spanwise position for present experiments are sufficient. POD analysis was also applied for a 2D square cylinder wake at the same Re_d for comparison.

Figure 3 shows the first 3 modes of u^*, v^* and ω_z^* for a 2D square cylinder wake. The contour structures of Mode1 and 2 are highly correlated. Particularly, Mode 2 can be regards as a streamwise shift of Mode 1, with the phase difference of about 1/4 shedding circle. These observations are similar to those in a 2D square cylinder wake[13]. For Mode1 and 2, the contours of ω_z^* with positive and negative values present alternating pattern. This pattern inherently resembles the alternating Karman vortex structure. The pattern of Mode 3 is drastically different from those of the first two modes, as shown in figure 3. The contours of $\phi_{w_z}^*$ are somewhat symmetrical about the wake centerline. However, the strength of Mode3 is far weaker than Mode 1 and 2, with the maximum of $\phi_{w_z}^*$ less than 5% of those for the first two modes, which may suggest that its contribution to the total fluctuation energy is limited.

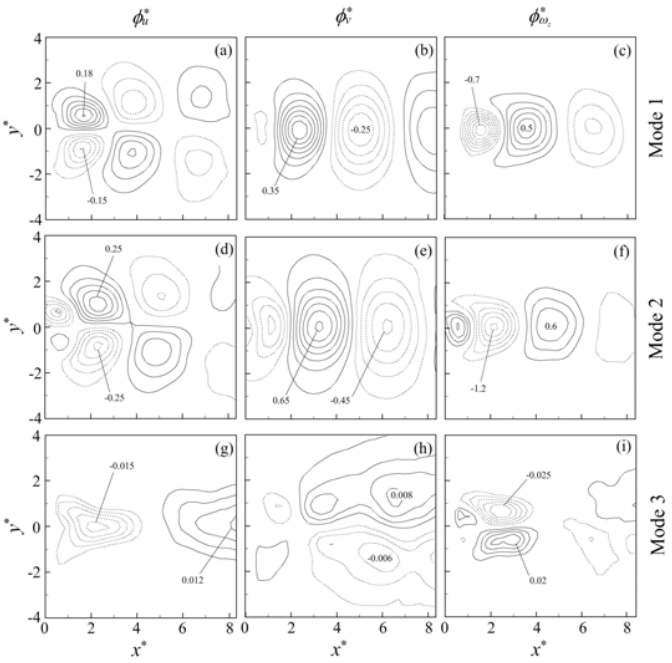

Figure 3. Contours of the first three POD modes in a 2D square cylinder wake: φ_u^*, φ_v^* and $\varphi_{w_z}^*$.(a) Contour interval = 0.03, (b) 0.05, (c) 0.1, (d) 0.05, (e) 0.1, (f) 0.2, (g) 0.003, (h) 0.002 and (i) 0.005.

Figures 4 & 5 present the first three modes in the finite-length cylinder wake at z^* = 6 and 3.5. The results at z^* = 1 are qualitatively similar to those at z^* = 3.5, thus not present here. At z^* = 6, i.e. 1d lower than the free end, Wang & Zhou[2] found over 55% spanwise vortices are symmetrical or approximately symmetrical. They ascribed this observation to the free-end downwash flow, which tends to change vortex shedding from anti-symmetrical to symmetrical. For a wall-mounted finite-length circular cylinder (H/d = 7, Re_d = 1060), Okamoto & Sunabashiri[5] suggested the anti-symmetrical vortex shedding vanishes at 0.5d lower than the free end. For the present finite-length square cylinder wake, Wang & Zhou[2] suggested that about 13% of vortices at 1d lower than the free end are anti-symmetrical. Drastically different from that of 2D cylinder wake, the contours of $\phi_{w_z}^*$ of Mode 1 is symmetrical about the centerline, as shown in figure 4(c). Although $\phi_{w_z}^*$ of Mode 2 is also approximately symmetrical about the centerline, its structure does not correlate with Mode1. The contours of $\phi_{w_z}^*$ for the first two modes converge towards the centerline, accord with the behavior of time-averaged quantities as shown in figure 2(e-h). For Mode3, the structure becomes more complicated and less organized.

At z^* = 3.5, i.e. the cylinder mid-span, the positive and negative $\phi_{w_z}^*$ contours for the first two modes occur alternately along centerline (figure 5c & f), generally similar to those of 2D cylinder wake. However, a close look at the topology may find that the contours are stretched in transverse direction and the local extreme values occur symmetrically on both sides of the centerline (figure 5c & f), which are far different from those of 2D cylinder wake (figure 3 c & f). The transverse stretched $\phi_{w_z}^*$ contours of the first two energetic modes are ascribed to the free-end downwash flow, which tends to entrain fluid from near the free end and separate the shear layers from both sides of the cylinder. The structure of Mode3 for finite-length cylinder (figure 5g-i) is drastically different from that of 2D cylinder. It is interesting that, a close resemblance

can be observed between Mode 1 at $z^* = 6$ (figure 4a-c) and Mode 3 at $z^* = 3.5$ (figure 5g-i) except the opposite sign.

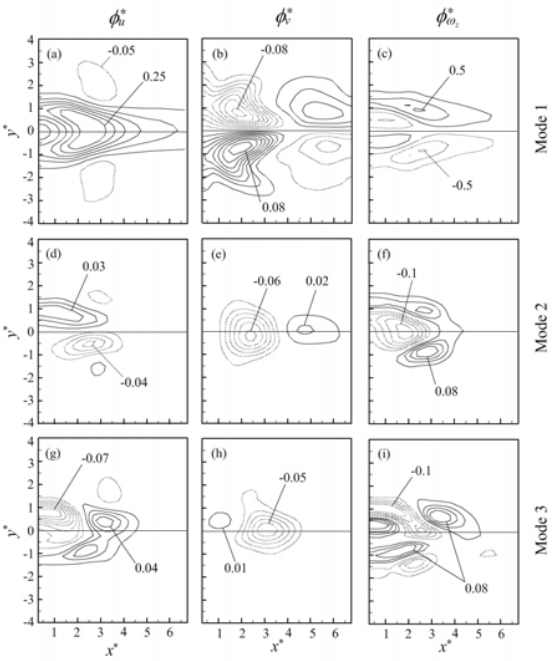

Figure 4. Contours of the first three POD modes of φ_u^*, φ_v^* and $\varphi_{w_z}^*$ at $z^* = 6$ for $H/d = 7$ (a) Contour interval = 0.05, (b) 0.01, (c) 0.2, (d) 0.01, (e) 0.01, (f) 0.02, (g) 0.01, (h) 0.01 and (i) 0.02.

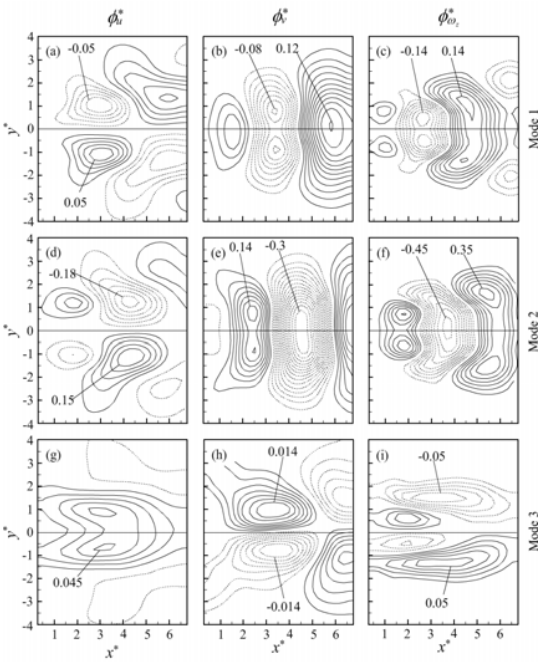

Figure 5. Contours of the first three POD modes of φ_u^*, φ_v^* and $\varphi_{w_z}^*$ at $z^* = 3.5$ for $H/d = 7$ (a) Contour interval = 0.01, (b) 0.02, (c) 0.02, (d) 0.03, (e) 0.02, (f) 0.05, (g) 0.01, (h) 0.002 and (i) 0.01.

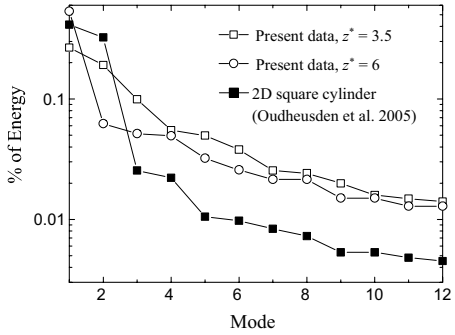

Figure 6. Fractional contribution to the turbulent kinetic energy by different mode.

The fractional contributions to the turbulent kinetic energy (TKE) from different modes are illustrated in figure 6. For the 2D square cylinder at $Re_d \approx 10000$[13], the fractional contribution reduces quickly with increasing mode number. Over 73% (41.3% + 32.4%) TKE is from the first two modes, suggesting the near wake is dominated by the alternating Karman vortex shedding. The TKE from the symmetrical Mode 3 diminishes remarkably to about 2.5%. For the present finite-length cylinder, at $z^* = 3.5$, the first two modes account for 45.9% (the first and second modes contributes 26.7% and 19.2%, respectively) of total TKE, significantly smaller than that for 2D cylinder wake. Contrary to the reduced contribution of the first two modes, the TKE contributions from higher modes are larger than the corresponding values for 2D cylinder. Particularly, the TKE from the symmetrical Mode 3 is 10% at $z^* = 3.5$, which suggests that symmetrical vortex shedding is still remarkable. This observation accord with the finding proposed by Wang & Zhou[2] that about 10% vortex shedding is symmetrically arranged at cylinder mid-span. The TKE contributions from Mode 1 and 2 are close to each other for 2D cylinder wake, which is also observed at the mid-span for $H/d = 7$. This observation may because the first two modes are highly correlated. However, the TKE contribution at $z^* = 6$ is completely different. First, the TKE from the symmetrical Mode 1 is over 54%, which is far larger than that at mid-span. Second, the TKE from Mode 2 is about only 1/10 of that from Mode 1, suggesting the near wake at $z^* = 6$ is dominated by Mode 1 which represent the effects of free-end downwash flow, as shown in figure 4(a-c). Figure 6 also suggests that, the TKE distributes over more modes for the finite-length cylinder wake than for 2D cylinder wake. For example, for 2D cylinder wake, the first two modes account for over 70% of total TKE, while at mid-span of $H/d = 7$, it needs 6 modes to contribute 70% of total TKE.

In view of the small TKE contribution from Mode 3 and other higher modes in 2D cylinder wake, the instantaneous velocity field can be reconstructed with a low-order flow model incorporating only the time-averaged and the first two POD modes[13] via:

$$u_{LOM} = \overline{U} + a_1\phi^1 + a_2\phi^2 \tag{4}$$

$$a_1 = \sqrt{2\lambda_1}\sin\theta, \quad a_2 = \sqrt{2\lambda_2}\cos\theta \tag{5}$$

where u_{LOM} is the instantaneous velocity field and θ is the vortex-shedding phase angle (Durao et al. 1988). The coefficient a_1 and a_2 are not independent, but forms an ellipse in the (a_1, a_2) plane. The cross plot of a_1 and a_2, normalized by their own eigenvalues, is shown in figure 7. For the 2D square cylinder wake, as shown in figure 7(a), the cross plot of normalized (a_1, a_2) approximately forms a circle, confirms the relation shown in Eqs. (4 & 5). As shown in figure 7(a), the observed scatter of the data point around the theoretical circle can be an indication of cycle-to-cycle variations of the vortex shedding process, induced by small scale fluctuations or turbu-

lence[13]. This scatter reduces with decreasing Re_d. Ma & Karniadakis[14] found the cross plot of (a_1, a_2) forms nearly an ideal circle and not scattering presents at Re_d = 185.

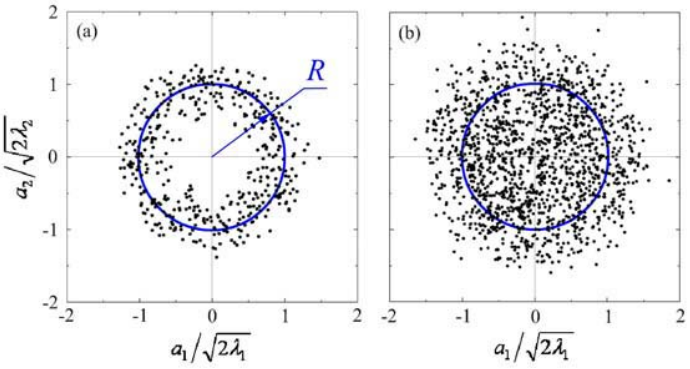

Figure 7. Snapshot mode coefficient correlation (a) 2D cylinder wake, (b) at mid-span for H/d = 7.

For the present finite-length cylinder, at z^* = 3.5 (figure 7b), the points distribute more dispersedly in (a_1, a_2) plan relative to that of 2D cylinder wake. Considering the Re_d is the same for figure 7(a & b), the dispersion in figure 7(b) may be ascribed to the different vortex shedding mechanism in a finite-length cylinder wake. As shown in figure 6, at z^* = 3.5, since the first two modes accounts for less than half of total TKE, the low-order model may be not applicable. It is worth mentioning that, each point in figure 7 indicates a snapshot. For the points near the origin point (as shown in figure 7b), the TKE contributions from the first two modes are quite limited, because of the small absolute values of a_1 and a_2. For theses snapshots, the main TKE are from Mode 3 and other higher modes, which are less organized. One the other hand, for the points away from the origin point, most TKE are from the first two modes.

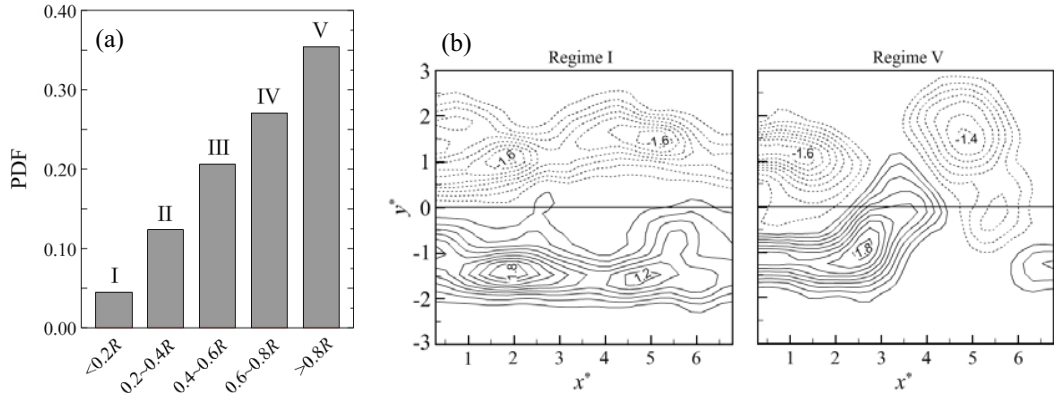

Figure 8. PDF of different flow regimes and typical instantaneous vorticity contours for Regime I and V. (a) PDF distribution; (b) normalized vorticity contours for Regime I and Regime V, contour interval = 0.2

Since the vortices in mode 1 and mode 2 are stagger arranged, different from those in mode 3 and other higher modes, it may be possible to use the distance between the snapshot point and origin point to classify the instantaneous flow status. Five regimes are classified based on this distance, i.e. <0.2R, 0.2~0.4R, 0.4~0.6R, 0.6~0.8R and >0.8R. The probability density function for these five regimes determined from 1500 instantaneous snapshots is shown in figure 8(a). Figure 8(b) presents two typical instantaneous vorticity contours for Regime I and V, respectively. For Regime I, the most TKE are from mode 3 and other higher modes; while for Regime V, most TKE are from the first two modes. Since the flow structure of the first two modes is different from that of the other higher modes, as shown in figure 5, the corresponding flow structures for Regimes I and V are also different (figure 8b). For Regime I, the shear layers from both

sides of the cylinder do not roll into successive vortices and the near wake is symmetrical about the wake centerline. For Regime V, the near wake is dominated by stagger arranged vortices, similar to those observed in 2D cylinder wake.

4 CONCLUSIONS

The near wake of a wall-mounted finite-length cylinder has been measured with PIV and analyzed using POD technique. The cylinder aspect ratio H/d = 7. PIV measurements were conducted in spanwise planes at z^* = 1, 3.5 and 6. The following conclusions may be drawn from the analysis of the data:

(1) The flow depends strongly on the spanwise position, the contours of $\overline{U^*}$, $\overline{u^*_{rms}}$, $\overline{v^*_{rms}}$ and $\overline{u^*v^*}$ converge towards wake centerline near the free end (z^* = 6), which is significantly different from those at mid span. Under the effects of free-end downwash flow, the streamwise extend of reverse flow zone at most spanwise positions of present tested finite-length cylinder is larger than that for 2D cylinder, and the magnitudes of $\overline{u^*_{rms}}$, $\overline{v^*_{rms}}$ and $\overline{u^*v^*}$ are significantly suppressed, especially near the free end.

(2) At the mid span of H/d = 7, although the vortical structures of the first two POD modes are staggered arranged along wake centerline and highly correlated with each other, somewhat similar to those in 2D cylinder wake, the vorticity contours are stretched in lateral direction with the local extreme values occur symmetrically on both sides of centerline. Near the free end, i.e., z^* = 6, the structure of first POD mode is completely different from that of higher modes.

(3) For finite-length cylinder wake, the TKE distributes over mode POD modes relatively to that of 2D cylinder wake. Instantaneous vortex shedding patterns can be classified based on the coefficients of the first two POD modes. Both symmetrical and anti-symmetrical vortex shedding occurs in the near wake at z^* = 3.5.

ABSTRACT: With high frequency force balance (HFFB) technique, 14 square tall buildings models with recessed corners were tested in two different simulated wind fields to obtain aerodynamic forces. The effects of turbulence intensities and corner recession ratios on mean and RMS coefficients of the aerodynamic base moment and torque in typical wind directions were analyzed. The test results indicate that two types of corner recession have dramatic effects on the aerodynamic coefficients of base moment and torque, and the model with a corner recession ratio of 7.5% is the best one to cut down the aerodynamic forces coefficients. Empirical formulae are fitted for aerodynamic force coefficients of square tall buildings with different corner recession ratios, which provide technical support for the revisions and supplements of load codes.

KEYWORDS: aerodynamic force coefficients, corner recession, empirical formula, HFFB technique, tall building, wind tunnel test.

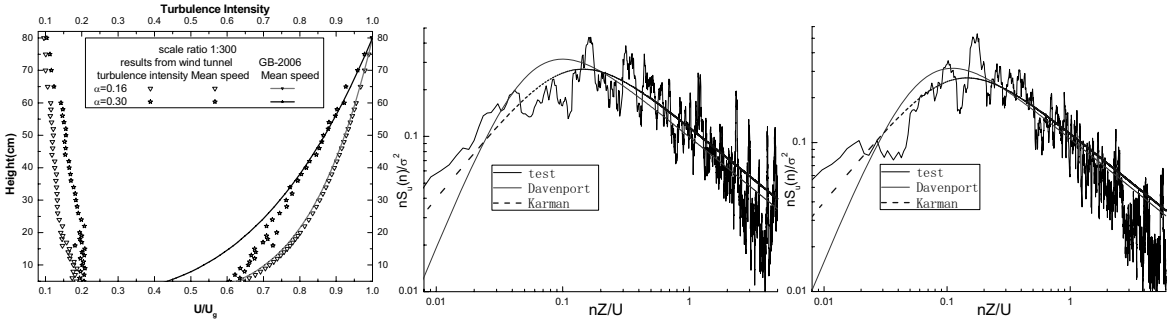
1 INTRODUCTION

With enormous utilization of light-weight and high-strength materials, super-tall buildings are becoming ever-increasingly high, flexible, and low in damping. These flexible structures are totally sensitive to dynamic wind load, which plays a significant role in the structure design and should be put more emphasis. Across-wind response of super-tall buildings gradually exceeds along-wind response as their heights increase, which is the crux of structural wind-resistant design [1]. Besides, comfort problem is becoming more and more serious especially under strong winds. Recently, primary wind-induced vibration control measures of super-tall building consist of structure measures, mechanical treatments and aerodynamic wind-resistant measures [2], which play an essential role in initial project design of the super tall building to vitally reduce wind load and wind-induced response [3]. Corner recession modification serves as one type of typical aerodynamic measures for high-rise buildings. Melbourne and Cheung [4], Miyashita etc [5], Gu and Quan [6] have discussed the effects of corner recession modification on aerodynamic characteristics for high-rise buildings through high frequency balance test and aeroelastic model test, and point out that corner recession modification basically reduces the peak value of power spectra densities for across-wind base moment, and that the model with corner recession ratio of 10% greatly reduces the peak value of spectrum for aerodynamic force. Besides, Kawai [7] has discussed the effects of corner recession modification on aerodynamic instability of square and rectangular models, and states that corner recession ratio of 5% would effectively prevent aerodynamic aeroelastic divergence, especially for the square model; however, as for high side-length ratio of rectangular section corner modification measure is not effective in preventing divergence. Irwin [8], Suresh etc [9] have discussed characteristics of wind load of Taipei 101

building, and these research results indicated that it is the double corner recession modification that reduces RMS of across-wind aerodynamic force by 40%, along-wind mean wind load by 20% and total base moment by 25%. Moreover, Tse etc [10] investigate the impact of aerodynamic modifications on the building economics of tall structures and indicate that corner recession models act more effectively than corner cutting model in decreasing base moment. Those researches primarily aim at wind-induced effect of models with specific corner recession ratio, especially the aerodynamic power spectra of across-wind response and wind-induced response, and the author gave some qualitative conclusions, however, there existed no comprehensive empirical formula portraying the effect of aerodynamic modification measures on square building which can be directly applied as standard.

In this paper, 14 square tall buildings models were tested to determine the effects of two types of corner recession modification on characteristics of aerodynamic force. In order to provide technical support for the revisions and supplements of load codes, empirical formulae for effect of corner recession modification on base aerodynamic coefficients are provided by using the nonlinear least-squares method. However, due to space constraints, only the preliminary results are given in this paper to illustrate the influences of corner recession modification on coefficients of base moment and torque. The effects on power spectra of base moment and torque will be discussed in other future papers.

2 WIND TUNNEL TESTS AND RESULTS



(a) Mean wind speeds and turbulence intensity profiles
(b) PSD of turbulence at height of 60 cm in terrain B (c) PSD of Turbulence at height of 60 cm in terrain D
Fig.1. Simulated wind parameters of the terrain categories B and D

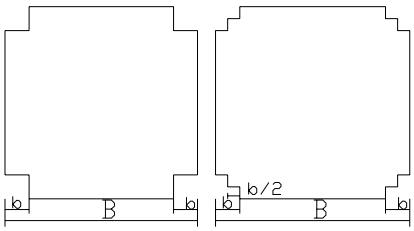
This test is carried out in TJ-1 Boundary Layer Wind Tunnel, whose working section is 1.8m in width and 1.8m in height, and the wind speed ranges continuously from 3 to 32m/s. With passive simulation method, i.e., different arrangement of three devices (turbulence generating spires, barrier and roughness element) in wind tunnel [11], the wind characteristics are achieved to simulate two kinds of wind conditions, corresponding to terrain categories B and D in the wind tunnel at a length scale of 1/300 in accordance with Chinese code [12]. Fig 1 shows simulated wind parameters of the terrain categories B and D where z is height; U stands for wind speed; U_g represents height for gradient wind; $S_u(n)$ is power spectra of wind speed, and σ^2 represents mean square value of wind speed; n is frequency. The turbulence intensity 60 cm above model is 12.6% and 16.5% for the two categories of terrain, respectively, and turbulent integral scale at the same height is according 34 cm and 36 cm (in wind tunnel), corresponding to actual turbulent integral scale 100 m and 110 m, respectively. Despite mean wind profiles at one-third height

for terrain categories D was larger than normative standard values, this error can be ignored since the contribution to base moment made by aerodynamic force below one-third height of this building is less than 5%.

The two types of cross-section modified by corner recession shown in Fig. 2 consist of type I and type II (double concave corner) developing from the fundamental type I. The corner recession ratio is defined as

$$\gamma_c = b / B \tag{1}$$

where B denotes section width, and b is cutting length of corner recession.



(a) type I (corner recession) (b) type II (double corner recession)
Fig. 2.Cross sections of the building models

Table 1 Testing cases

Types of corner recession	Corner recession ratio $\gamma_c = b / B$	Wind angle	Test wind speed(m/s)	Terrain
type I	0%,5%,7.5%,10%,12.5%,15%,20%,30%	0~45°	6, 8	B, D
type II	0%,7.5%,10%,12.5%,15%,20%,30%	0~45°	6, 8	B, D

The aluminum tube, whose cross-section area is 50mm×50mm, height is 600mm and thickness is 1mm, serves as mandrel to provide rigidity, and external foam was employed to satisfy different shape parameters for building simulation, ensuring little mass but large stiffness for models and enough high natural frequency for balance-model system. Additionally, in order to ensure the validity of the test data and precision of the measured signal, final test result is average of the two sets of test data under wind speed 6 m/s and 8 m/s, and all of the test data is used to fit the empirical formulae. Besides, the calculation program is employed to serve as automatic recognition of the modal parameters (free vibration frequency and damping ratio) for balance system according to output time-history data of high frequency force balance, and aerodynamic base moment decoupled from output of high frequency force balance signals is then revised, and the details of modified process is shown in paper [13]. The work cases is shown in table 1, and there exists totally 14 different models (13 model with corner recession modification and basic model with no corner recession modification whose dimension is 600mm×120mm×120mm) having been tested in terrain categories B and D. Owing to symmetry of square section 5° serves as a wind angle interval and wind range is from 0° to 45°. Moreover, the measuring range of base (torque) moments is 30 Nm, and the measuring precision is 0.004 Nm, and sampling frequency is 600 Hz, and sampling time is 60 s.

Non-dimensional coefficients of base aerodynamic force are defined as:

$$\bar{C}_{M_D} = \bar{M}_D / q_H BH^2, C'_{M_D} = \sigma_{M_D} / q_H BH^2, C'_{M_L} = \sigma_{M_L} / q_H BH^2, C'_{M_T} = \sigma_{M_T} / q_H B^2 H \tag{2}$$

where $q_H = 0.5\rho U_H^2$ is the dynamics pressure at the top of buildings, and B represents building width normal to the approaching flow, and H stands for the height of the building, and U_H is the wind velocity at the top of buildings. In addition, M_D is the mean base moment in along-wind;

σ_{MD}, σ_{ML} and σ_{MT} are the RMS values of the base moment for along-wind, across-wind and torsion direction, respectively; C_{MD} is the mean coefficients of along-wind base moment, C'_{MD}, C'_{ML} and C'_{MT} are the RMS coefficients of the base moment for the along-wind, across-wind and torsion direction, respectively.

To illustrate the effect of different corner recession ratio on coefficients of base moment, the correction factor is defined as:

$$\eta_{MD}(\gamma_c) = C_{MD}(\gamma_c) / C_{MD0} \tag{3}$$

$$\eta'_{Ml}(\gamma_c) = C'_{Ml}(\gamma_c) / C'_{Ml0},\ l = D,L,T \tag{4}$$

where $\eta_{MD}(\gamma_c)$ stands for correction factor for mean coefficients of along-wind base moment; C_{MD0} and $C_{MD}(\gamma_c)$ represent mean coefficients of along-wind base moment with corner recession and with no recession, respectively. Additionally, $\eta'_{Ml}(\gamma_c)$ represents correction factor for RMS coefficients of base moment (torque). C'_{Ml0} and $C'_{Ml}(\gamma_c)$ are RMS coefficients of base moment (torque) with corner recession and with no recession, respectively. Besides, subscript 0 represents basic square model with no corner recession and subscripts D, L, and T denote along-wind, across-wind, and torsional directions, respectively.

In order to facilitate the engineering application, empirical formulae for effect of corner recession modification on coefficients of base moment and torque are provided by using the nonlinear least-squares method. Moreover, error rate facilitating quantitative analysis is defined as follows:

$$\text{Error ratio=(Fitted result-Testing result)/Testing result} \times 100\% \tag{5}$$

3 EXPERIMENT RESULT

3.1 *Mean coefficients of base moment*

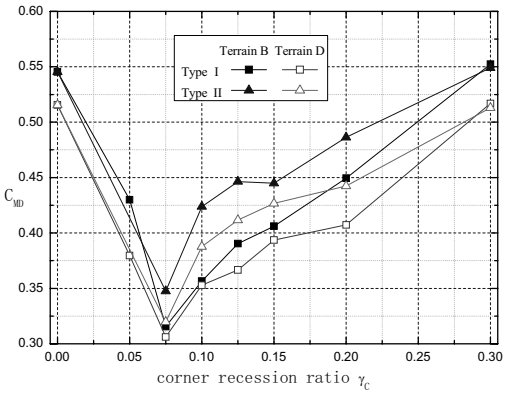


Fig. 3. Effect of corner recession ratio on the mean coefficient of along-wind base moment

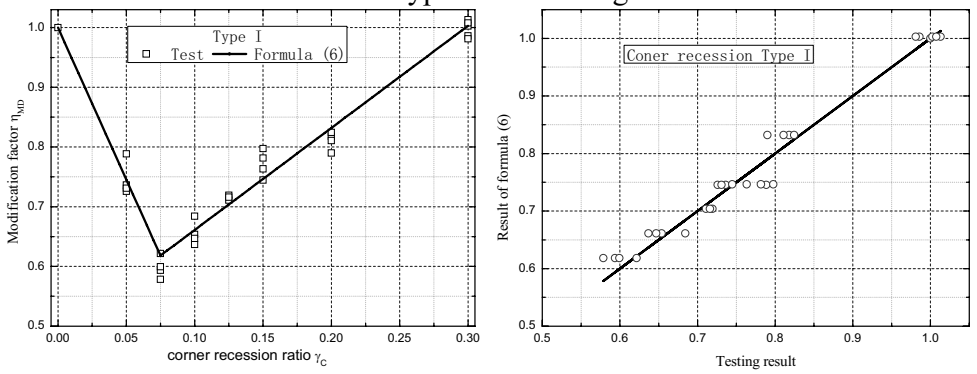
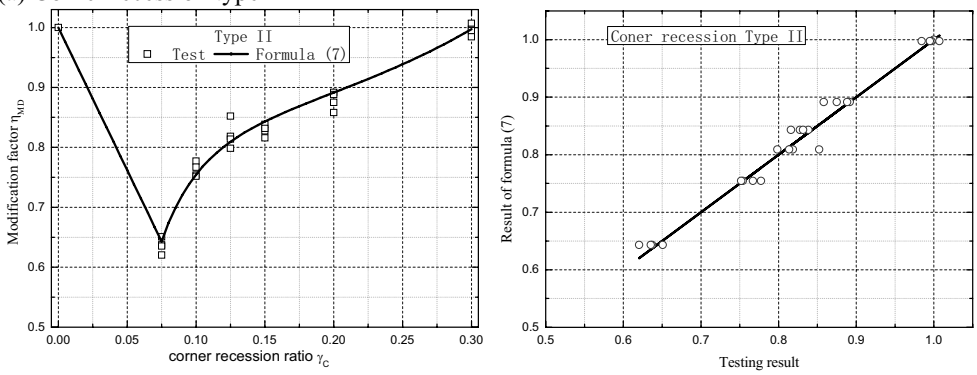
Fig. 3 illustrates the effect of corner recession ratio γ_c on C_{MD} of square model, where corner recession ratio 0 represents basic model with no corner recession. Seen from Fig.3, mean coefficients of base moment of models with no corner recession in terrain categories B and D are 0.55 and 0.52, respectively. With corner recession ratio increasing from 0% to 7.5%, C_{MD} decrease gradually and it reaches the minimum when γ_c is 7.5%. C_{MD}, however, would conversely increases if γ_c continues to grow over 7.5%, and processing to C_{MD0} when γ_c reaches 30%. In

sum, C_{MD} can be diminished when γ_c ranges from 0% to 30%, and reaches its minimum at the point 7.5%, roughly equivalent to 60% of C_{MD0}. Despite C_{MD} tested from terrain categories D is lower than the one from terrain categories B, effect of terrain categories B and D on C_{MD} is not obvious in error allow range. That regularity of the vortex shedding has been transformed and leeward negative pressure has been then reduced may explain for the phenomenon that the influence of two types of corner recession on C_{MD} is basically the same. Besides, type I corner recession is more effective than type II at reducing mean coefficients of base moment.



(a) Corner recession type I



(b) Corner recession type II

Fig. 4. Comparison of Modification factor η_{MD} between the testing results and corresponding fitted ones

Empirical formulae are derived by nonlinear least-squares method technique, expressed as:

$$\eta_{MD} = \begin{cases} 1.0 - 5.1\gamma_c, & 0 \le \gamma_c < 7.5\% \\ 0.49 + 1.7\gamma_c, & 7.5\% \le \gamma_c \le 30\% \end{cases}, \ Type\ I \tag{6}$$

$$\eta_{MD} = \begin{cases} 1.0 - 4.8\gamma_C, & 0 \le \gamma_C < 7.5\% \\ 0.89 + 4.55\gamma_C^3 - 0.0014\gamma_C^{-2}, & 7.5\% \le \gamma_C \le 30\% \end{cases}, \text{Type Ⅱ} \tag{7}$$

Fig. 4 portrays the distinction between test and calculation results obtained from formulae (6) and (7). The average of the error rate of calculation results obtained from formula (6) is 0.46% and RMS is 3.08%, and as for formula (7) the average and RMS of the error rate are 0.08% and 4.36%, respectively.

3.2 *RMS coefficients of along-wind base moment*

Fig. 5 illustrates the effect of corner recession ratio γ_c on C'_{MD} of square model. With corner recession ratio increasing, C'_{MD} firstly decreases, then increases, and finally decreases. C'_{MD} appears to be roughly equivalent to 80% of C'_{MD0} when γ_c=30%, and reaches its minimum when 7.5%, and probably equals 55% of C'_{MD0} when 7.5%. In brief, corner recession ratio ranging from 0 to 30% can reduce C'_{MD} and further increasing corner recession ratio over 7.5% is really ineffective at reducing C'_{MD}. Finally, effect of two types of corner recession on C'_{MD} is basically the same whether in terrain categories B or D.

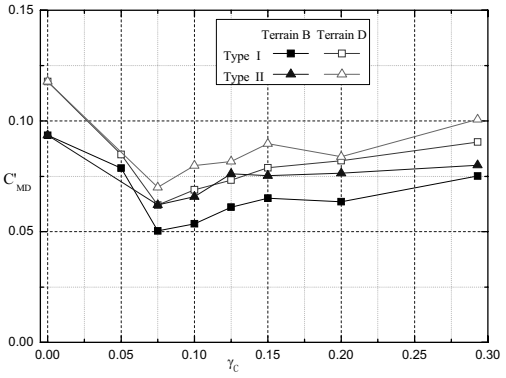


Fig. 5. Effect of corner recession ratio on the RMS coefficient of along-wind base moment

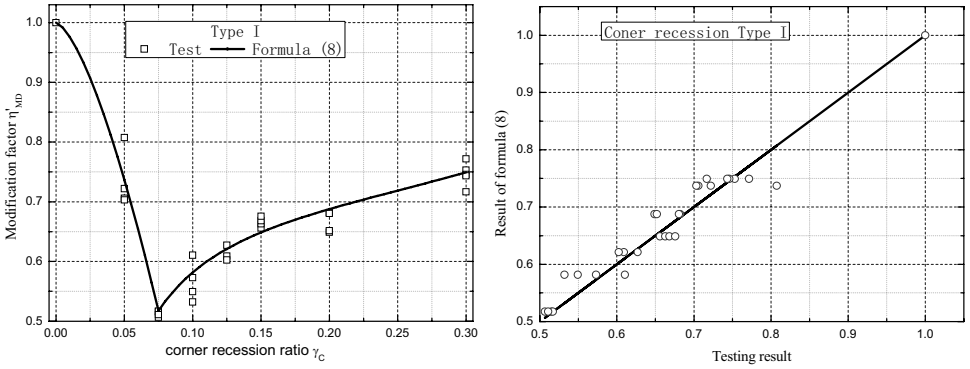
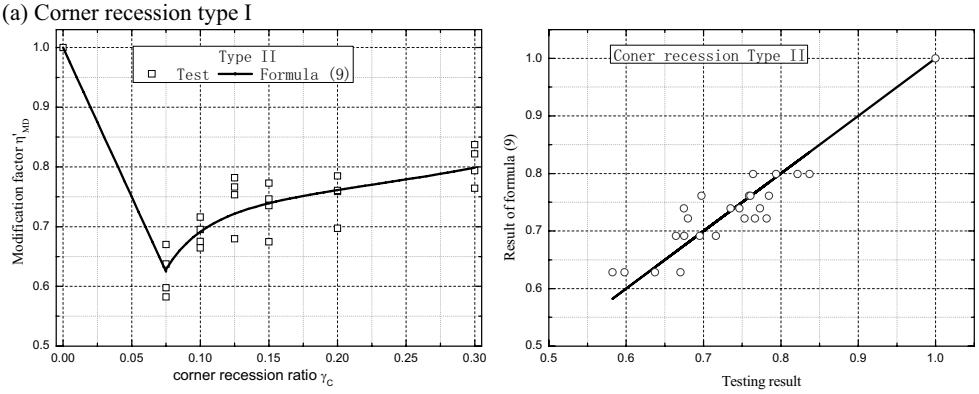


(a) Corner recession type I



(b) Corner recession type II

Fig. 6. Comparison of Modification factor η'_{MD} between the testing results and corresponding fitted ones

Piecewise function is adopted in fitting process because regular pattern of C'_{MD} in 0-7.5% is not consistent with that in 7.5%-30%. Empirical formulae reflecting the effect of two types of corner recession modification on C'_{MD} are shown as:

$$\eta'_{MD}=\begin{cases}1-24\gamma_c^{1.5}, & 0\le\gamma_c<7.5\%\\ 0.77+1.6\gamma_c^{3}-0.02/\gamma_c, & 7.5\le\gamma_c\le 30\%\end{cases},\quad \text{Type Ⅰ} \tag{8}$$

$$\eta'_{MD}=\begin{cases}1-5\gamma_c, & 0\le\gamma_c<7.5\%\\ 0.77+1.4\gamma_c^{3}-0.0008\gamma_c^{-2}, & 7.5\le\gamma_c\le 30\%\end{cases},\quad \text{Type Ⅱ} \tag{9}$$

Fig. 6 presents the comparison between testing results and the corresponding fitted ones obtained from formula (8) and (9). The average of the error rate of corresponding fitted results obtained from formula (8) is -0.18%and RMS value is 3.71%; the average and RMS of the error rate obtained from formula (9) are 0.21% and 4.86%, respectively.

3.3 *RMS coefficients of base across-wind moment*

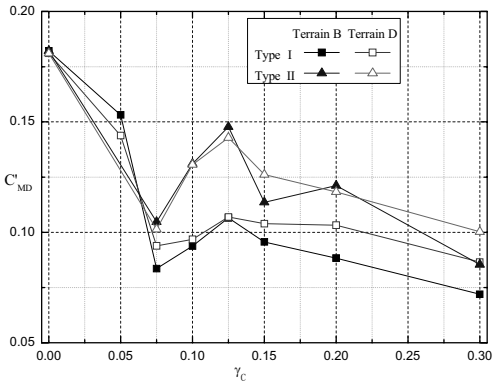


Fig. 7. Effect of corner recession ratio on the RMS coefficient of across-wind base moment

Fig. 7 illustrates the effect of corner recession ratio γ_c on C'_{ML} of square model. With corner recession ratio increasing, C'_{ML} firstly decreases, and then increases, and finally conversely decreases. C'_{ML} dramatically and sharply drops when γ_c=7.5%, and gradually increases with γ_c varying from 7.5% to 12.5%, and then decreases when γ_c grows over 12.5% whose decrease amplitude is relatively small. The essential change in vortex shedding would explain for this variation rule of C'_{ML} after γ_c grows over 7.5%. In brief, C'_{ML} can be diminished with γ_c varying from 0 to 30%, and appears to be roughly equivalent to 65% of C'_{ML0} when γ_c=7.5%. However, further increasing γ_c is really ineffective at reducing C'_{ML}. Besides, the effect of two types of corner recession on C'_{ML} are basically the same whether in terrain categories B or D, but decreasing amplitude of C'_{ML} induced by type I is larger than that of type II, whose usable area is larger than type I as for the same γ_c.

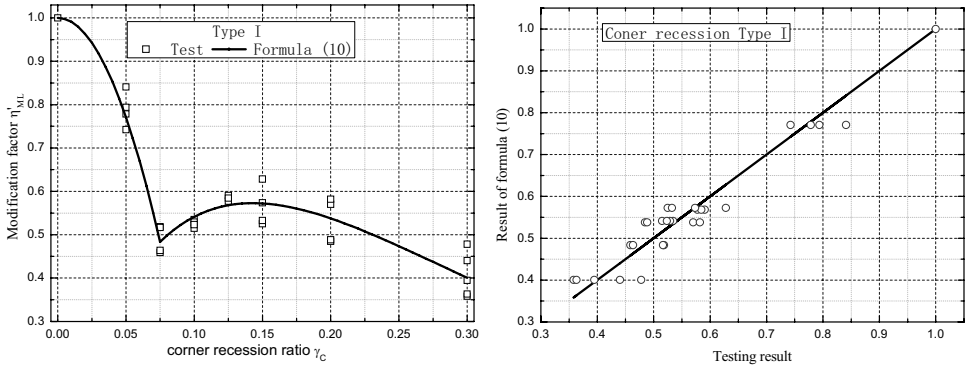
Despite the absence of test data on 5% for C'_{ML} of type II, linear function is adopted in fitting process for type II in 0~7.5% because the regularity in both types are similar.

Empirical formulae for the effect of corner recession modification on C'_{ML} are provided as:

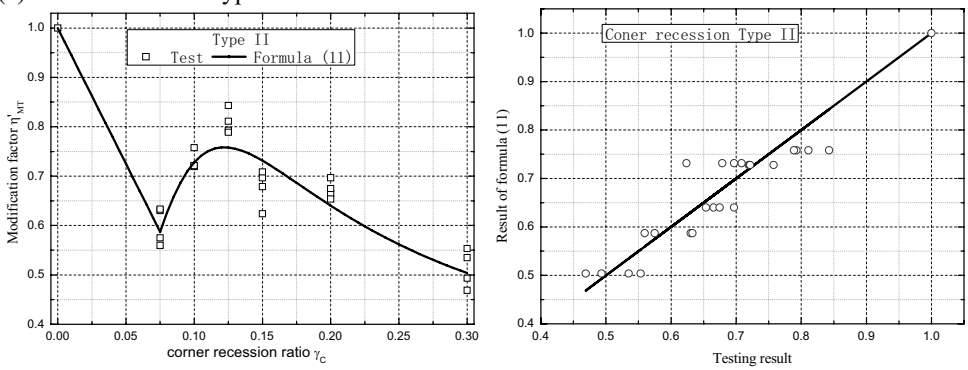
$$\eta'_{ML}=\begin{cases}1-92\gamma_c^{2}, & 0\le\gamma_c<7.5\%\\ 11\gamma_c e^{-7\gamma_c}, & 7.5\le\gamma_c\le 30\%\end{cases},\quad \text{Type Ⅰ} \tag{10}$$

$$\eta'_{ML}=\begin{cases}1-5.5\gamma_c, & 0\le\gamma_c<7.5\%\\ 1/(6.4-3.55\gamma_c^{-0.5}+0.62/\gamma_c), & 7.5\le\gamma_c\le 30\%\end{cases},\text{Type Ⅱ} \tag{11}$$

Fig. 8 presents the distinction between test and calculated results obtained from formula (10) and (11). The mean error rate of fitted results obtained from formula (10) is 0.16% and RMS is 7.1%, and as for formula (11) mean and RMS of error rate are -0.96% and 6.39%, respectively, demonstrating high precision of formula.



(a) Corner recession type I



(b) Corner recession type II

Fig. 8. Comparison of Modification factor η'_{ML} between the testing results and corresponding fitted ones

3.4 *RMS coefficients of base torque*

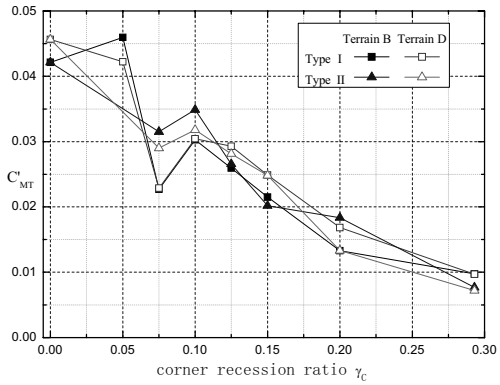


Fig. 9. Effect of corner recession ratio on the RMS coefficient of base torque

Fig. 9 illustrates the effect of two types of corner recession on RMS coefficients of base torque C'_{MT} of square model. Seen from Fig.9, if corner recession ratio varies between 0 and 5%, corner recession modification basically has no influence on C'_{MT}. However, C'_{MT} dramatically decrease with corner recession ratio increasing over 5%, and both of two types of corner recession have such effectiveness that C'_{MT} is less than 25% of C'_{MT0} when γ_c is 30%. Besides, effect of two types of corner recession on C'_{MT} are basically the same whether in terrain categories B or D.

Empirical formulae for the effect of corner recession modification on C'_{MT} are provided as:

$$\eta'_{MT} = e^{-5.6\gamma_c}, \qquad \text{Type I}, \quad 0 \le \gamma_c \le 30\% \tag{12}$$

$$\eta'_{MT} = 1 - 3.5\gamma_c + 7\gamma_c^3, \qquad \text{Type II}, \quad 0 \le \gamma_c \le 30\% \tag{13}$$

Fig. 10 presents comparison between test values and fitted ones obtained from formula (12) and (13), and calculation results evenly distributed in two side of test level, demonstrating these formulae both is concise and meet the requirements for engineering application.

4 CONCLUSIONS

This paper presents the test results of 14 rigid models with corner concession of square tall buildings with high frequency force balance (HFFB) technique in two simulated wind field conditions, and analyzes the effects of corner concession modification on the coefficients of base moment and torque. The main findings of the present study are summarized as follows:

(1) Both type I and type II corner recession measures can reduce the coefficients of base moment and torque of square high-rise building, and the corner recession rate of 7.5% is the most effective and optimal.

(2) Each of regularity in the coefficients of base moment and torque for along-wind, cross-wind and torsion direction is different. For any kind of aerodynamic coefficients two types of corner concession measures have the same regularity, insensitive to turbulence intensity of wind field condition.

(3) The precision and applicability of the empirical formulae for the coefficients of aerodynamic force were verified, which provides technical support for the revisions and supplements of load codes.

[b]*IIS, The University of Tokyo, 4-6-1 Komaba, Meguro-ku, Tokyo, Japan*

ABSTRACT: Bi-molecular reactions can affect the transport of air pollutants in urban street canyons. In numerical simulations, we need to evaluate the correlation between the concentrations of the reactants to know the reaction rate. In this paper, we examine the effects of the subgrid scale (SGS) on the reaction rate in large-eddy simulations (LESs). LESs coupled with an SGS variance model are used to study the dispersion of both inert and reactive pollutants in a simulated street canyon. First, we conduct simulations of an inert pollutant at different grid resolutions. The results of these simulations demonstrate the validity of our model for calculating the variance of concentration at the SGS. Second, we apply the model to the dispersion of reactive pollutants. The correlations of the SGS variances become relatively large in a free shear layer at the height of the canyon. However, the SGS variance is very small and has a negligible impact on the mean concentrations of pollutants within the canyon.

Pollutant dispersion; Street canyon; Chemical reaction; LES; Subgrid-scale variance

1 INTRODUCTION

To address an increasing number of air quality issues, many previous studies have evaluated pollutant flow and dispersion in urban areas. Street canyons are a common component of urban areas, and numerous studies have used CFD (computational fluid dynamics) simulations to explore the fundamental characteristics of air pollutant dispersion in street canyons. Additionally, recent increases in computing power have allowed for the development of numerical simulations with high computational loads. In response, engineers and scientists have started to employ large-eddy simulations (LESs) to study the urban atmospheric environment.

Some attempts have been made to extend CFD simulations to the transport of reactive pollutants. For example, Baker et al. [1] and our group [2] have applied LESs with reaction rate models to the dispersion of reactive pollutants in urban street canyons. In these studies, the variance of pollutant concentrations was not considered at the subgrid scale (SGS), which means that the authors assumed perfect mixing of pollutants at the SGS. However, additional studies have reported the influence of the segregation of pollutants at the SGS on the reaction rate [3].

This study aims to assess the influence that the variance of the concentrations at the SGS has on the dispersion of reactive pollutants in an urban street canyon. To evaluate this system, an LES model was coupled with an SGS variance model. To confirm the performance of our model, we initially studied the dispersion of an inert pollutant in an urban street canyon. We then ap-

plied the model to the dispersion of a pollutant that undergoes a bi-molecular reaction in the canyon.

2 MODEL DESCRIPTION AND NUMERICAL METHOD

2.1 *LES model of the flow field*

We employed a one-equation model for LES proposed by Yoshizawa and Horituti [4]. The model simultaneously solves the transport equation for the kinetic energy at the SGS k_{SGS} and the filtered velocities $\bar{u}_i\ (i=1,2,3)$. The equations of the model become

$$\frac{\partial \bar{u}_i}{\partial x_i} = 0, \tag{1}$$

$$\frac{\partial \bar{u}_i}{\partial t} + \frac{\partial \bar{u}_i \bar{u}_j}{\partial x_j} = -\frac{\partial \bar{p}}{\partial x_i} + \frac{\partial}{\partial x_j}\left(-\tau_{ij} + \frac{2}{Re}\bar{D}_{ij} \right), \tag{2}$$

$$\tau_{ij} - \frac{1}{3}\delta_{ij}\tau_{kk} = -2\nu_{SGS}\bar{D}_{ij}, \tag{3}$$

$$\nu_{SGS} = C_1 \Delta k_{SGS}^{1/2}, \tag{4}$$

$$\frac{\partial k_{SGS}}{\partial t} + \frac{\partial \bar{u}_j k_{SGS}}{\partial x_j} = 2\nu_{SGS}\bar{D}_{ij}^{\,2} - C_2\frac{k_{SGS}^{3/2}}{\Delta} + \frac{\partial}{\partial x_j}\left[\left(\frac{1}{Re} + C_3 \Delta k_{SGS}^{1/2} \right)\frac{\partial k_{SGS}}{\partial x_j} \right]. \tag{5}$$

In these equations, τ_{ij} is the Reynolds stress at the SGS; D_{ij} is the strain-rate tensor; Re is the Reynolds number; ν_{SGS} is the eddy viscosity coefficient at the SGS; Δ is the grid width; and C_1, C_2 and C_3 are the model coefficients.

2.2 *SGS variance model*

The filtered mass conservation of pollutants becomes

$$\frac{\partial \bar{c}_m}{\partial t} + \frac{\partial \bar{u}_j \bar{c}_m}{\partial x_j} = \frac{\partial}{\partial x_j}\left[\left(\frac{1}{ReSc} + \frac{\nu_{SGS}}{\sigma_{tc}} \right)\frac{\partial \bar{c}_m}{\partial x_j} \right] + \bar{R}_m, \tag{6}$$

where Sc is the Schmidt number, σ_{tc} is the turbulent Schmidt number at the SGS, and R_m is the source/sink term due to the reactions.

In this study, we considered the following bi-molecular reaction:

$$c_1 + c_2 \rightarrow c_3. \tag{7}$$

Reaction rates for the reduction of c_1 and c_2 and the corresponding production of c_3, are defined as

$$\bar{R}_1 = \bar{R}_2 = -\bar{R}_3 = -D_{a1}\overline{c_1 c_2}, \tag{8}$$

where D_{a1} is the first Damköhler number. The filtered product of c_1 and c_2 can be approximated by the following equation:

$$\overline{c_1 c_2} = \bar{c}_1 \bar{c}_2 + \overline{c_1'' c_2''}, \tag{9}$$

where x" is the SGS variance of x. Following Meeder and Nieuwstadt [3], we employed the transport equation of the SGS correlation described in Equation (10). We numerically integrated it with the governing equations for the flow and the grid scale (GS) concentration fields

$$\frac{\partial \overline{c_1"c_2"}}{\partial t}+\frac{\partial \bar{u}_j \overline{c_1"c_2"}}{\partial x_j}=2\frac{\nu_{SGS}}{\sigma_{tc}}\frac{\partial \bar{c}_1}{\partial x_j}\frac{\partial \bar{c}_2}{\partial x_j}+\frac{\partial}{\partial x_j}\left[\left(\frac{1}{ReSc}+\frac{\nu_{SGS}}{\sigma_{tc}}\right)\frac{\partial \overline{c_1"c_2"}}{\partial x_j}\right]-C_4\overline{c_1"c_2"}\frac{k_{SGS}^{1/2}}{\Delta}, \tag{10}$$

where C_4 is a model coefficient.

To validate the performance of the SGS variance model, we carried out a numerical experiment to evaluate the dispersion of a sole scalar without reaction. In this case, $D_{a1} = 0$ and Equation (10) reduces to

$$\frac{\partial \overline{c"^2}}{\partial t}+\frac{\partial \bar{u}_j \overline{c"^2}}{\partial x_j}=2\frac{\nu_{SGS}}{\sigma_c}\left(\frac{\partial \bar{c}}{\partial x_j}\right)^2+\frac{\partial}{\partial x_j}\left[\left(\frac{1}{ReSc}+\frac{\nu_{SGS}}{\sigma_c}\right)\frac{\partial \overline{c"^2}}{\partial x_j}\right]-C_4\overline{c"^2}\frac{k_{SGS}^{1/2}}{\Delta}. \tag{11}$$

For this simulation, we set $c_1 = c_2 = c$.

2.3 *Computational details*

Figure 1 shows an illustration of the street canyon model with an aspect ratio of unity. It has a uniform shape along the y-axis, and the computational domain has a size of $2H$ (x) x $2H$ (y) x $2H$ (z). A line source of c or c_2 is set at the bottom of the canyon along the center. For the case involving the reactive pollutant, the inflow supplies a constant concentration of c_1 into the domain.

Periodic boundary conditions are applied for all components of the flow fields, both in the stream-wise and span-wise directions. This means that infinitely long street canyons line up continuously along the x-axis. A constant pressure difference is imposed between the inflow and outflow of the computational domain. The upwind wind direction is set to be perpendicular to the street canyon. We carried out the simulation under an isothermal condition.

Calculation conditions are listed in Table 1. The Reynolds number is approximately 1.5×10^5 and is defined with a building height of H and reference velocity of U_{upw}. We set the model constants to be $Sc = 1.0$, $\sigma_{tc} = 0.5$, $C_1 = 0.05$, $C_2 = 1.0$, $C_3 = 0.1$ [4], and $C_4 = 1/Sc$ [5]. Table 2 shows the grid resolutions used in the simulations. We used all of the resolutions for the simulations of the inert pollutant dispersion, whereas only GR32 was employed for the reactive pollutant dispersion. All of the statistics in this paper were averaged along the y-axis because of the uniform shape along the street canyon.

3 RESULTS AND DISCUSSION

3.1 *Grid resolution and flow field*

We initially checked the dependency of the flow field on the grid resolution. Statistics relating to the velocities are normalized by the mean velocity at z/H = 2.0 (U_{upw}) in each case.

Figure 2 shows the profiles of the mean stream-wise velocities at three locations. An increase of grid resolution results in high wind-speeds just above the canyon, which makes the cavity eddy stronger in the high resolution case. The difference between the stream-wise velocities for GR128 and GR64 is smaller than the difference between GR64 and GR32. This means that the sensitivity of the flow field to the grid resolution becomes low at a resolution of approximately H/128.

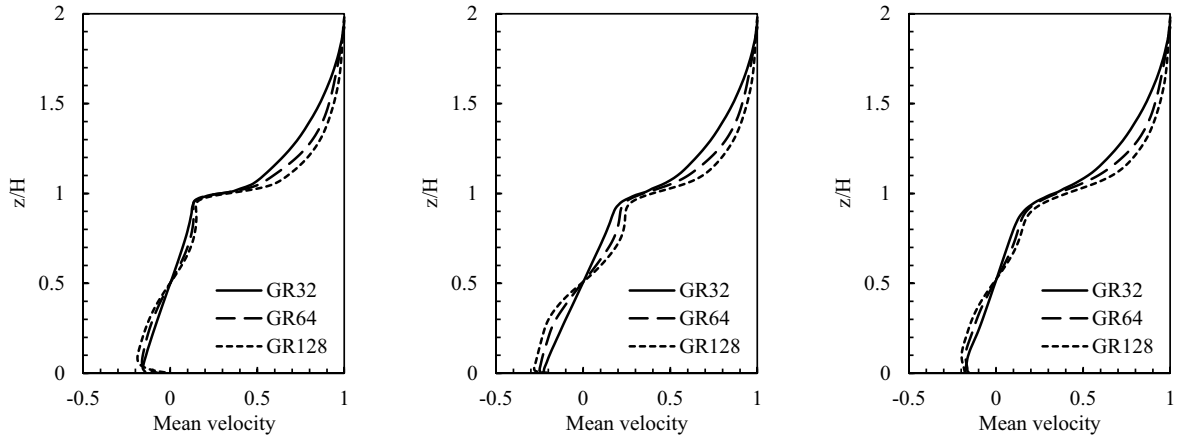

Figure 2. Mean velocity in the stream-wise direction. All variables are normalized by U_{upw}.

The higher resolution enables a larger amount of kinetic energy to be contained in the GS. Therefore, RMS (root-mean-square) values of the filtered velocities become high in GR128 and low in GR32 (Figs 3 i) and ii)). Consequently, the kinetic energy at the SGS (k_{SGS}) is the lowest in GR128 (Fig. 3 iii)).

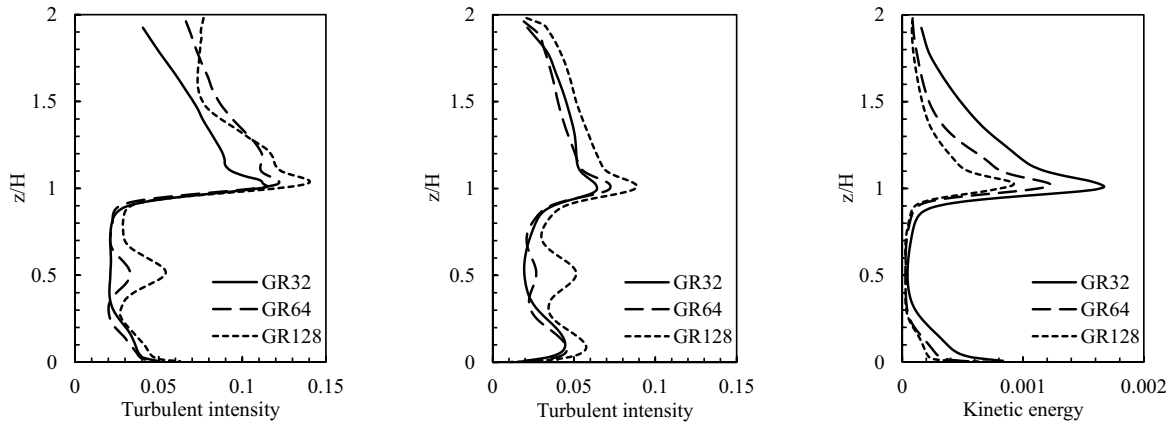
3.2 *Grid resolution and inert scalar field*

Before accounting for the reactivity of pollutants, we conducted dispersion simulations for an inert pollutant at the three different grid resolutions. Concentrations presented in this section are normalized by C_n:

$$C_n = Q_e / U_{upw} HL, \tag{12}$$

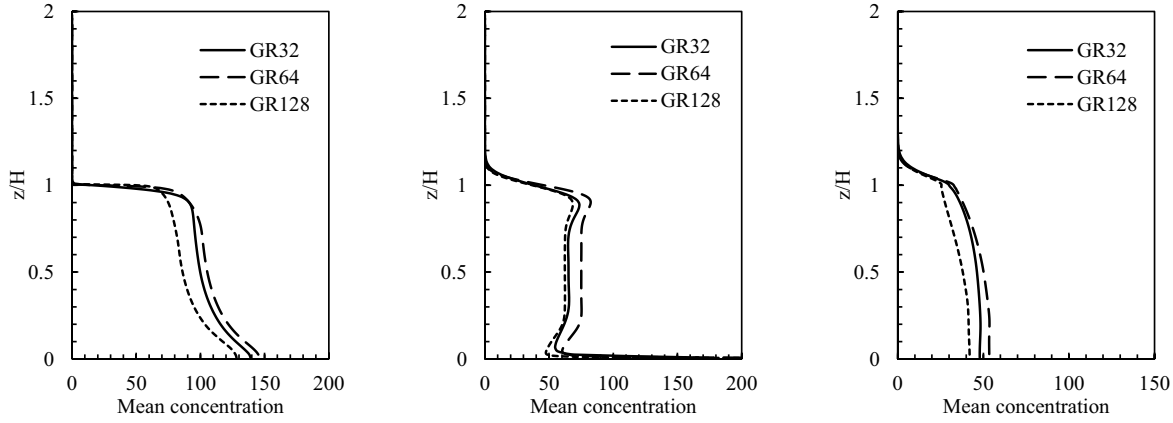
where Q_e is the emission rate of the pollutant and L is the length of the street canyon.

Figure 4 shows the mean concentration profiles for the inert pollutant. The mean concentration is high along the lower part of leeward wall because it is in the direct downwind region of the line source. Some differences of the mean concentrations are apparent for the different grid resolutions; however, the trend of the dependency on the grid resolution is not clear compared to the flow field in the previous section.



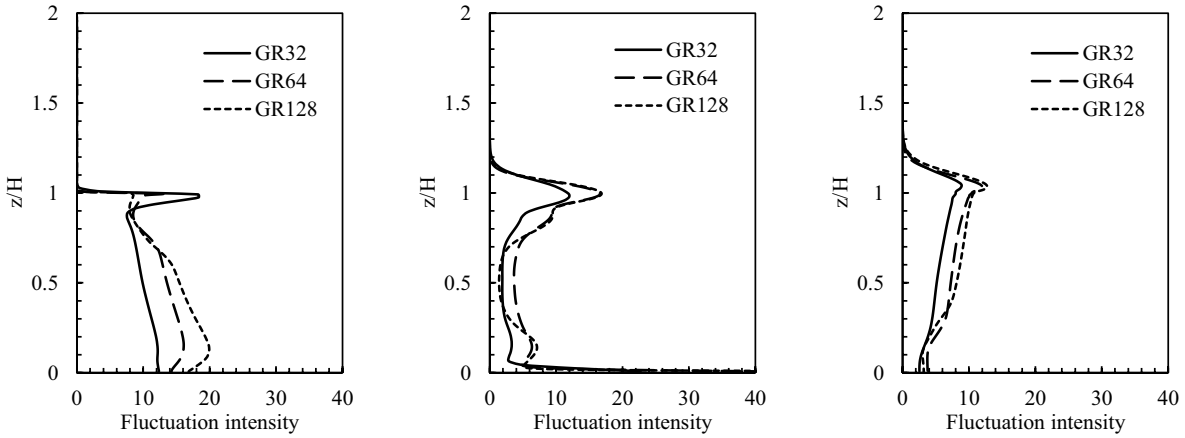
i) RMS $\overline{u}$ ii) RMS $\overline{w}$ iii) k_{SGS}

Figure 3. Turbulent intensity at the GS and kinetic energy at the SGS at x/H = 0.0 (Center). All variables are normalized by U_{upw}.



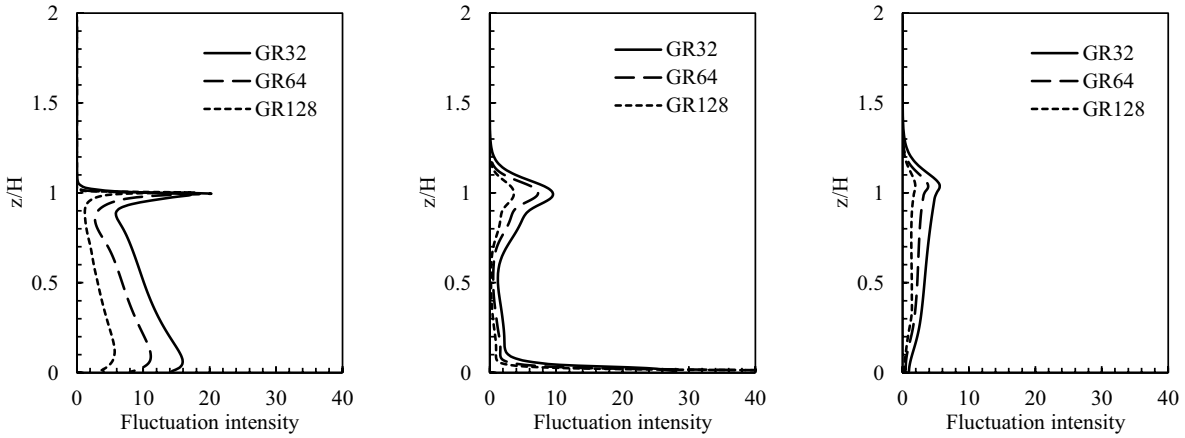
i) x/H = -0.5 (Leeward wall) ii) x/H = 0.0 (Center) iii) x/H = 0.5 (Windward wall)

Figure 4. Mean concentration normalized by C_n.



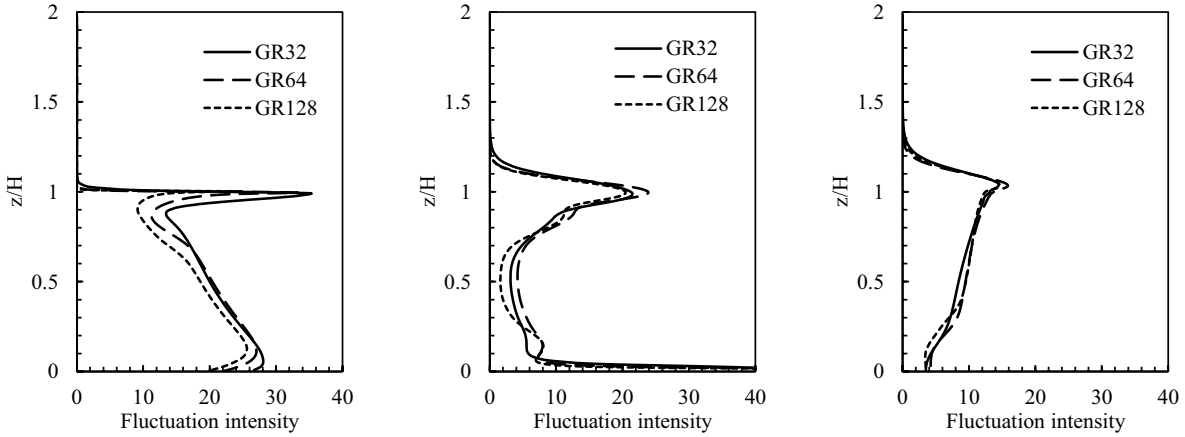
i) x/H = -0.5 (Leeward wall) ii) x/H = 0.0 (Center) iii) x/H = 0.5 (Windward wall)

Figure 5. Concentration fluctuation intensity at the GS ($\sigma_{c,GS}$) normalized by C_n.



i) x/H = -0.5 (Leeward wall) ii) x/H = 0.0 (Center) iii) x/H = 0.5 (Windward wall)

Figure 6. Concentration fluctuation intensity at the SGS ($\sigma_{c,SGS}$) normalized by C_n.



i) x/H = -0.5 (Leeward wall) ii) x/H = 0.0 (Center) iii) x/H = 0.5 (Windward wall)

Figure 7. Total concentration fluctuation intensity at the GS and SGS normalized by C_n.

Figures 5 and 6 show the concentration fluctuation intensities at the GS $\sigma_{c,GS}$ and SGS $\sigma_{c,SGS}$, respectively. Here, $\sigma_{c,GS}$ is the RMS of the filtered concentration, and $\sigma_{c,SGS}$ is the mean value of $\overline{c''^2}^{1/2}$. The higher resolution also makes it possible to have more concentration fluctuation energy at the GS. Therefore, $\sigma_{c,GS}$ is highest in GR128 and lowest in GR32, and $\sigma_{c,SGS}$ shows the opposite behavior. Additionally, $\sigma_{c,SGS}$ is greater than $\sigma_{c,GS}$ on the leeward wall for GR32 because the region is near the line source.

We defined the total fluctuation intensity of the concentration σ_c as the sum of $\sigma_{c,GS}$ and $\sigma_{c,SGS}$. Although some discrepancies remain near the top of the leeward wall, Figure 7 shows that σ_c becomes comparable for the three grid resolutions. This means that our SGS variance model worked well to evaluate the variance of the concentration field at the SGS.

3.3 *Influence of SGS variance on the dispersion of reactive pollutants*

To evaluate the effect of the reaction between c_1 and c_2, we compared two different cases. The first case accounts for the SGS correlation of c_1 and c_2 to calculate the reaction rates using Equation (10), and the second case neglects it. Concentrations are normalized by C_0, or the concentration of c_1 in the inflow. D_{a1} has a value of approximately 1.3, and it is defined using U_{upw}, H and C_0. This value of D_{a1} agrees well with the actual values reported for the reaction between ozone and nitrogen monoxide in urban canyons [2]. The results described in the previous sections demonstrate that sensitivity to the grid resolution remains high for GR32. However, we elected to use this resolution for this portion of the study because we expected that the influence of the SGS variance model would be largest in the case of the lowest resolution.

Figure 8 shows the distributions of the mean concentrations of c_1 and c_2 for the case that includes the SGS variance model. As the reaction proceeds, the concentrations of c_1 and c_2 are reduced in the canyon (Eq. (7)).

The presence or absence of the SGS variance model resulted in small differences between the mean concentrations, as shown in Figure 9. This is because the contribution of the SGS correlation to the reaction rate is very small relative to the product of the filtered concentrations (Eq. (9)). Figure 10 shows that the SGS correlation becomes large at a value of approximately z/H = 1.0 due to the strong mixing of c_1 and c_2. However, the correlation is a small percentage of the product of the filtered concentrations in most regions in the canyon.

4 CONCLUSIONS

To study the dispersion of both inert and reactive pollutants in an urban street canyon, we used LESs that were coupled with an SGS variance model. The model solves the transport equations of the variance or the correlation of pollutants at the SGS with the equations of the filtered concentrations.

First, we validated the performance of the model by evaluating the concentration fluctuations at the SGS for changing grid resolutions. Three resolutions of averaged grid widths (H/32, H/64 and H/128) were employed, where H is the height of the canyon. The concentration fluctuation intensity at the GS was small for the coarse grid case. This was due to the expansion of the filtering width. However, the SGS variance model could estimate the variance lost in the filtering operation. From this result, we concluded that the model could reliably calculate the SGS variance of the concentrations.

Second, we investigated the effect of the SGS variance of concentrations on dispersion for the case of bi-molecular reactions. We carried out simulations at a grid resolution of H/32 and either included or excluded the SGS variance model. The correlations of concentration variations at the SGS of reactive pollutants became relatively large at the height of the canyon. This was because

ABSTRACT: Air pollution is a global phenomenon which has been the subject of study for several years. Pollutants released from rooftop stacks have a tendency to re-enter the same building or an adjacent building in the near vicinity. Complexities in airflow and pollutant transport due to terrain conditions, local topography and buildings make it very difficult to assess plume concentrations. This paper will analyse the role of the unsteady flow and its influence on pollutant dispersion. The effect of a building located upstream to an emitting building which has a roof stack, will be tested in a boundary layer wind tunnel and compared with computational fluid dynamics simulation (CFD). The most used approach for turbulent flow simulation is the Reynolds-averaged Navier-Stokes (RANS) equations. However, it was confirmed that important inaccuracies for dispersion prediction especially in the near-field of an emitting building are usually obtained by RANS. The reason is attributed to the RANS incapability to capture the inherent unsteadiness of flow in the wake of buildings. The influence of different turbulence models was evaluated but no clear improvement to compensate the mentioned inaccuracy was noticed. The effect of unsteady RANS (URANS) was also analyzed in an exploratory way.

KEYWORDS: CFD, Dispersion; Multiple buildings; Pollutants re-ingestion; Schmidt number; Wind tunnel.

1. Introduction

Air pollution is a global phenomenon which has been the subject of study for several years. Complexities in airflow and pollutant transport due to terrain conditions, local topography and buildings make it very difficult to assess plume concentrations (Saathoff et al., 2009). In the built environment increasing exhaust emissions from institutional, industrial buildings and vehicular traffic are inevitable. Toxic and odorous emissions affecting the urban environment and degrading human health are present in every city. One on the most common urban pollution phenomenon is associated with contaminants released from rooftop stacks. Depending on the average airflow, the turbulence of flow and the building-generated turbulence, pollutants can be trapped in recirculation zones and affect sensitive areas as, for example, fresh air intakes. This closed circuit path is known as re-ingestion of pollutants.

In the past, studies performed by Wilson et al., 1998 and Stathopoulos et al., 2008 showed that the presence of a taller upstream building produces higher concentrations on the rooftop of the emitting building. Currently, ASHRAE 2007 gives guidelines for determining plume dilutions for an isolated building without considering the effects of adjacent buildings and local turbulence. Studies performed by Hajra et al., 2010 have shown that ASHRAE 2007 predicts rather unrealistic and overly conservative dilutions. More recently, CFD has been a useful tool in as-

sessing plume dilutions in the built environment. However, CFD simulations require validations with field and wind tunnel measurements.
This paper presents wind tunnel data for tracer gas released from rooftop stack 0.005 m height (full scale equivalent to 1 m) and exhaust momentum ratio M = 1.7. The spacing between the buildings, for a two-building configuration, was fixed to 0.1 m (20 m) and the stack location placed in the middle of the symmetry plan on the roof of downstream building. Results are compared to CFD simulations using different turbulence models.

2. Wind tunnel simulation of building exhaust and dispersion

The wind tunnel experiments were carried out in the open circuit boundary layer wind tunnel at Concordia University, Montreal, Canada. The wind tunnel is 1.8 m by 1.8 m in cross-section and 12.2 m in length. The buildings tested in the wind tunnel were made of timber on a 1:200 scale. According to Snyder, 1981 while modelling non-buoyant plume exhaust, certain criteria should be satisfied:

· Geometric similarity
· Building Reynolds Number > 11.000
· Stack Reynolds Number > 2.000
· Similarity of wind tunnel flow with atmospheric surface layer
· Equivalent stack momentum ratio.

Tracer gas consisting of a mixture of Sulphur hexafluoride (SF_6) and Nitrogen was released from a roof stack of an emitting building named B1. A multi-syringe pump was used to collect the gas samples to determine the concentration of effluents at various receptors with a sampling time of 2 minutes. A Gas Chromatograph (GC) was used to assess the gas concentrations that were collected using syringe samplers. The velocity at building height was measured to be 6.2 m/s in the wind tunnel. The buildings were considered to be in an urban terrain with a power law exponent of 0.31 (Simiu and Scanlan, 1996). Additional details on the experimental conditions used in this study are described in Stathopoulos et al., 2008.

The pollutant dispersion was evaluated in terms of normalized dilution following the formulation suggested by Wilson (1979):

$$D_N = (D_r Q)/(U_H H^2) \quad (1)$$

where $D_r = C_e / C_r$ is the dimensionless concentration coefficient at the coordinate location (receptor), C_e = contaminant mass fraction in exhaust (ppm), C_r = contaminant mass fraction at the coordinate location (ppm), Q is the flow rate at the exhaust (m^3/s), H is the B1 height (H=0.075 m) and U_H the wind speed at the B1 height. The momentum ratio at the stack outflow is $M=V_e/U_H = 1.7$ (where V_e is the exhaust velocity). Receptors for concentration measurements were distributed on the roof of the emitting building along and across wind direction, as shown in Figure 1.

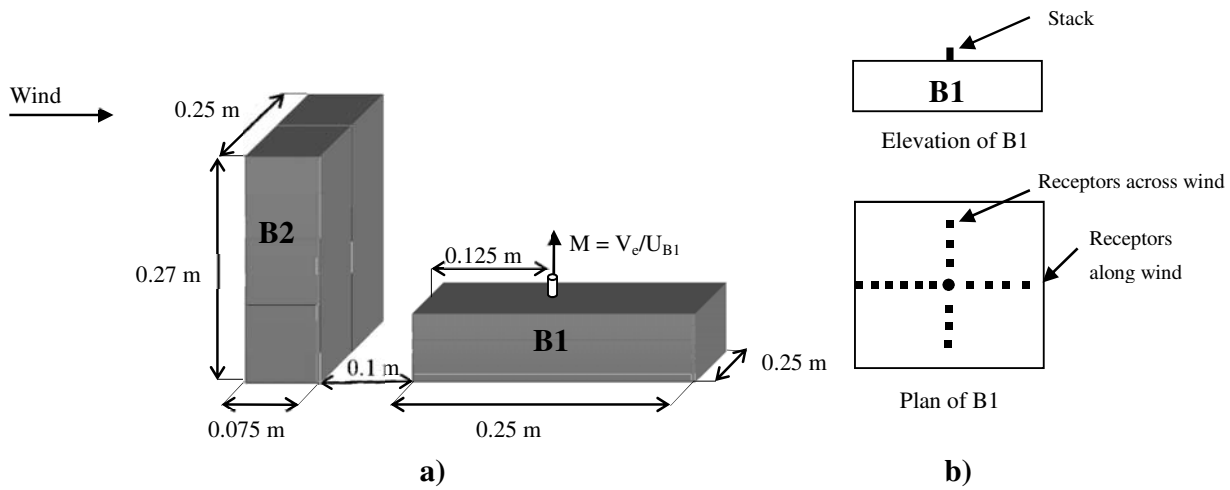

Figure 1: a) Schematic representation of an emitting builng (B1) with an upstream building (B2). b) Location of receptors on roof of the emitting building.

Figure 2 shows the profiles of mean velocity (a) and turbulence intensity quantities (b) measured at the wind tunnel. These profiles will be used to specify the inlet condition in the numerical model. The mean velocity profile was approximated by power law exponent of 0.31, which corresponds to an urban terrain. The velocity at the building B1 height (H = 0.075 m) was $U_H = 6.2$ m/s.

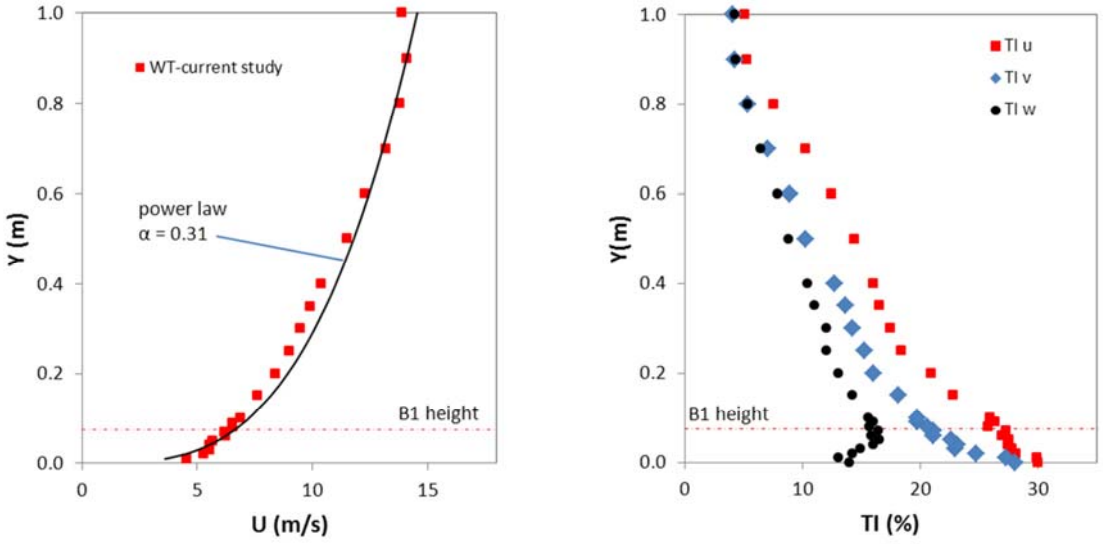

Figure 2. Atmospheric boundary layer profiles from wind tunnel. a) mean velocity b) turbulence intensity

The measured turbulence intensity profiles are converted in a turbulent kinetic energy (k) profile using two approaches. Option-1: k is calculated from turbulent intensity measurements in the wind tunnel considering the three components of fluctuating velocities $\langle u' \rangle, \langle v' \rangle$ and $\langle w' \rangle$ assuming $\langle u' \rangle = TI_u U/100$. Option-2: k is calculated assuming isotropic turbulence and only x component, $\langle u' \rangle$, of the measured component is used (van Hooff and Blocken, 2010). In order to

specify these profiles in the numerical model, a function of height (Y(m)) k defined as polynomial of degree 5 was developed for each option. The impact of this difference will be evaluated in the next section. The two options of k are as follows:

Option 1: $k = \frac{1}{2}(\langle u' \rangle^2 + \langle v' \rangle^2 + \langle w' \rangle^2)$ (2)

Option 2: $k = \frac{3}{2}\langle u' \rangle^2$ (3)

As shown in Figure 3 option-2 presents a relatively high value of k in the low level of the boundary layer, as compared with option-1. The dissipation rate profile (ε) was defined as $\varepsilon = u^{*3}/\kappa y$ where κ is the von Karman constant (0.42) and u* is the friction velocity obtained from the equation $u(y)/u^* = 1/\kappa(\ln(y/y_o)$ with roughness length $y_o = 0.0033$ m. At the model scale of 1:200, the equivalent full-scale roughness length is 0.66 m, which is at the low end of the expected range for an urban environment ($0.5 \text{ m} < y_o < 1.5$ m) (Stathopoulos et al. 2004).

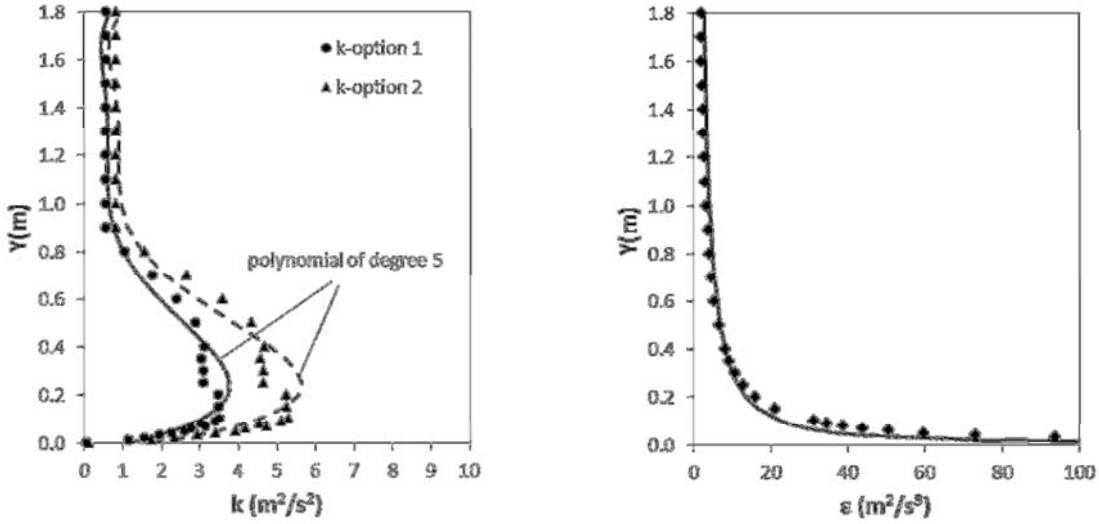

Figure 3. Turbulence kinetic energy and dissipation profiles evaluated from wind tunnel data.

3. CFD simulations

3.1 Description of cases considered

Dispersion was evaluated using two cases: an isolated emitting building (B1) and a two building configuration (B2 upstream of B1). A schematic representation of the latter was presented in Figure 1. The dimensions of each building used are provided in Table 1.

Table 1. Building models for CFD and wind tunnel experiments

Building	Height (m)	Width (m)	Length (m)
B1	0.075 (15)	0.25 (50)	0.25 (50)
B2	0.27 (54)	0.25 (50)	0.075 (15)

NB: Width refers to across wind dimension

3.2 Computational model and boundary conditions

The numerical model was constructed principally using structured hexahedra grids since it has been proved that this mesh style provides the best computational results (Hefny and Ooka, 2009). Due to the circular section of the stack an unstructured wedge grid was used in its vicinity. Three meshes were tested: mesh 1, 2 and 3 with 885,044, 2,388,057 and 3,398,121 cells respectively. The near wall region was modeled using the semi-empirical formulation called "wall function" which requires a y^+ between 30 and 300 (Fluent, 2006). Figure 4 shows dilution comparisons obtained by the three meshes. No difference in dilution at the roof level of B1 was detected using mesh 2 and 3. In consequence, mesh 2 was selected to continue the study. The inlet profile of turbulence intensity, k, was tested using the two options shown previously. Figure 5 shows no relevant impact on the dilution values at the roof level of B1. Therefore, option-1 was used in this study since it provides more physically correct prediction of k.

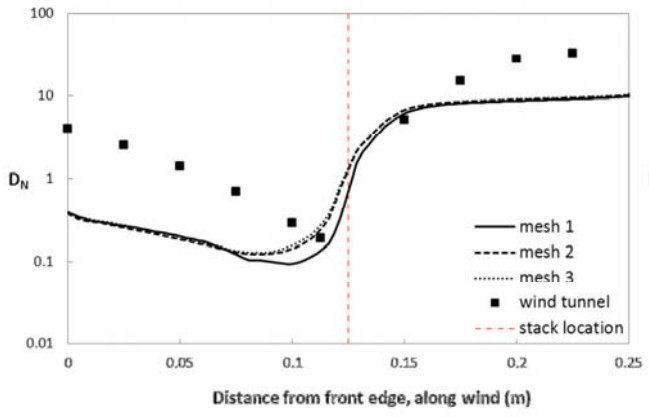

Figure 4. Effect of mesh on D_N

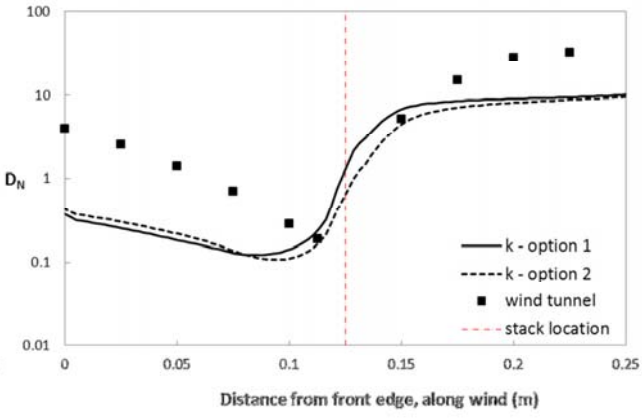

Figure 5. Effect of turbulence intensity profile on D_N

The bottom surface (i.e ground) is specified as a rigid plane with an aerodynamic roughness length y_o defined previously. In Fluent this roughness length is implemented by the sand-grain roughness height k_s (m) which can be defined using the function developed by Blocken et al. (2007): $k_s = 9.793y_o/Cs$, where Cs is a roughness constant. Considering the default value of Cs equal to 0.5, k_s should be specified as 0.0646 m. However, this value is limited to the distance z_p of the centroid of the first cell to the bottom domain (e.g $z_p = 0.00187$ m) as imposed by Fluent. The effect of this limitation is translated as streamwise changes in the inlet vertical profile. However, these effects are minimized considering the significant turbulence induced by the upstream building.

Top and sides of the domain were modelled as no slip walls in order to respect the wind tunnel conditions. At the outlet an outflow (zero gradient) condition was specified, to generate a fully-developed flow.

Turbulent Schmidt number (Sc_t) is necessary to solve the transport mass equation in CFD prediction of dispersion with RANS and is defined as the ratio of turbulent momentum diffusivity (eddy viscosity) to the turbulent mass diffusivity ($Sc_t=\nu_t/D_t$). In Fluent Sc_t must be declared as an input before any calculation or else the default value is 0.7. Past studies have shown the depend-

ence of Sc_t on simulation of pollutant dispersion from isolated buildings (Tominaga and Stathopoulos, 2007; Chavez et al., 2011) and hence the present work pays special attention to Sc_t values.

4. Results and discussion

This section has three parts:
1. Dilution prediction at the roof of B1 using RANS when it is isolated.
2. Dilution prediction at the roof of B1 using RANS when a tall building (B2) is placed upstream of B1.
3. Flow simulation for a single cube in a fully developed channel flow. This simulation was inspired on the work carried out by Iaccarino et al. (2003) and is presented in this study to confirm that it is possible to capture the vortex shedding in the wake of buildings using unsteady RANS (URANS).

In the following subsections, different turbulence models will be evaluated in order to compare their performance for dispersion prediction in the near-field of a source.

4.1 B1 isolated

Firstly a flow and dispersion around an isolated building with a roof stack (B1) was performed. The results were compared with experimental data obtained by the authors for an identical configuration. The computations were carried out using different turbulence models: the standard k-ε (std), the standard k-ε with modified constants proposed by Yan et al. (2009) (std-modified), the realizable k-ε using two turbulent Schmidt numbers, Sct = 0,1 and 0,3 (rlz-sct = 0.1, rlz-sc t = 0,3), the renormalization group (rng) and the Reynolds stress-model (rsm).

Figure 6 a) and b) compares the dilution values streamwise and spanwise from the roof stack of B1. Firstly, it is observed that in general no significant difference on dilution values among all turbulence models tested is registered. Thus, for this case, no clear statement can be made against or for a particular turbulence model. The computed dilutions are similar very near the stack but are mostly underestimated downstream the stack and overestimated upstream the stack. Clearly the computed values become completely out of range near the windward edge. This indicates that practically no species is trapped in the front edge recirculation zone, as it seems to happen with the experimental results. In the crosswind plotting line, dilution is also overestimated by all turbulence models. Only the rlz turbulence model when using Sc_t different from the default value (0.7) shows relatively better results, especially downstream the stack and in the crosswind direction where $Sc_t = 0.3$ seems to be appropriated. It is interesting to notice that upstream the stack a low Sc_t tries to correct the predicted dilution by reducing diffusion of species whereas downstream the stack a low Sc_t increase diffusion. This is exactly what it is needed to improve the agreement with experimental data; however calibration of numerical dispersion simulations using different Sc_t cannot be generalized because it is highly case dependent. The effect of reducing Sc_t for dispersion when using RANS has already been presented in various previous publications (Di Sabatino et al. 2007; Tominaga and Stathopoulos, 2007; Blocken et al. 2008; Chavez et al. 2011).

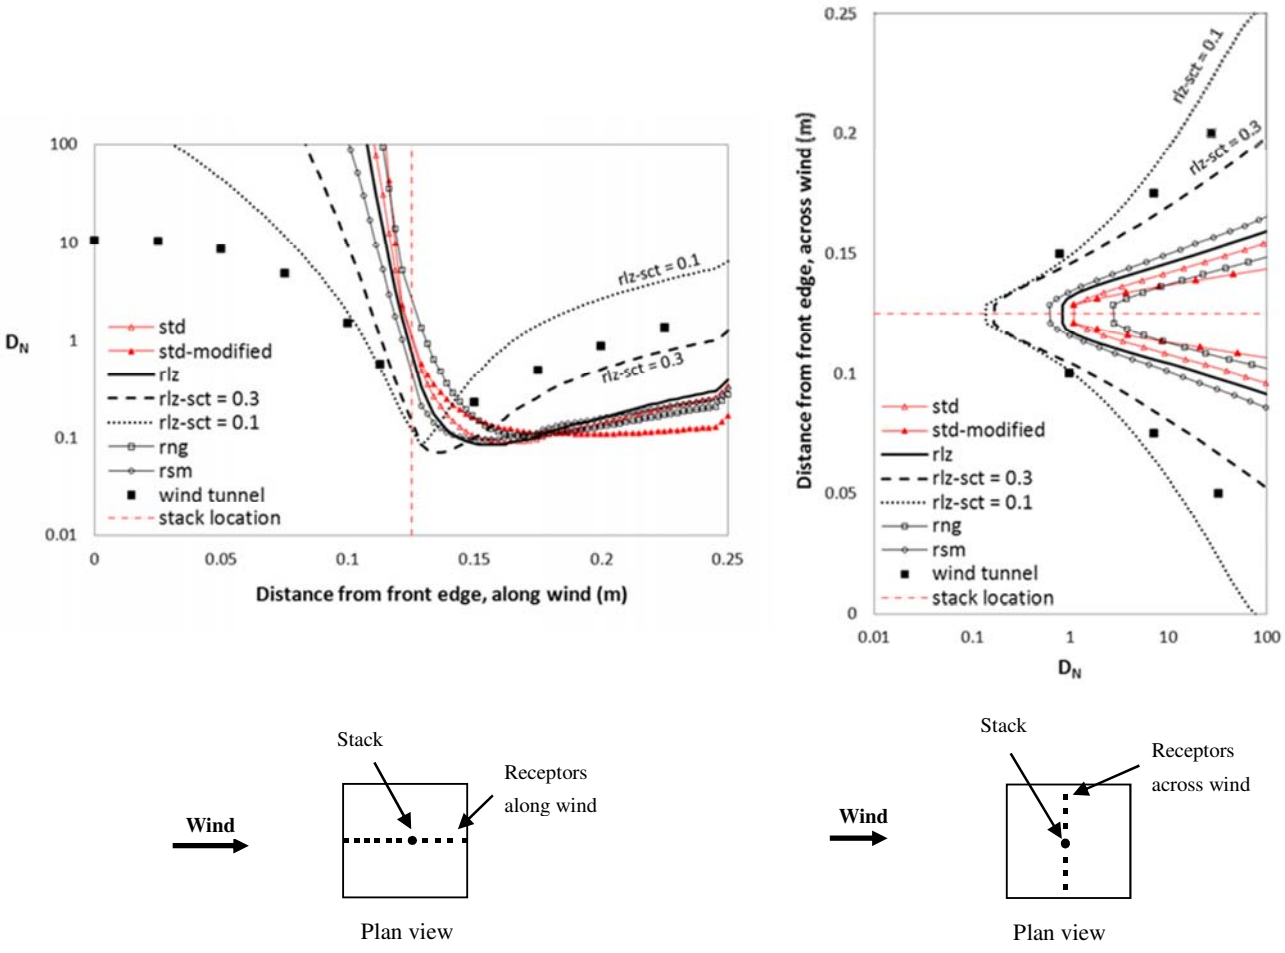

Figure 6: Steady simulations for an isolated building (B1) using different turbulence models. Dilution values at roof level a) along direction b) across wind direction.

4.2 B1 with an upstream building (B2)

The present case considers the emitting building B1 with an adjacent building (B2) placed upstream. The streamwise and spanwise distribution of dilution at the roof of B1 is presented in Figure 7 a) and b). Observing only the experimental results, and comparing with the isolated case, it can be seen that the presence of the upstream building changes significantly the dilution field in the near field. Downstream the stack the values of dilution increase almost two orders of magnitude and upstream the stack dilution decrease less than one order of magnitude. Dilution distribution spanwise from the stack also change and relatively low values are registered when B2 is added. This shows that the velocity field, which is characterized by a predominant upwind flow, tends to trap the species between the two buildings instead of dragging them downstream with the mean stream. This was also observed in previous cases (e.g. Chavez et al. 2012).

In terms of computed dilution values, similarly to the isolated case, no significant differences are registered among the turbulence models tested. In general, the computed dilution values have

better agreement downstream the stack but it remains significantly underestimated upstream the stack. The specification of a low Sc_t value produces an interesting improvement in terms of predicted values upstream the stack; however it has a very little effect downstream the stack. It is observed that along the crosswind plotting line Sc_t = 0.1 and 0.3 present practically same results on dilution values.

The discrepancies found on dilution values at roof level of B1, when B2 is placed upstream are probably due to the inherent fluctuations in the wake of B2, which are not detected by RANS as mentioned by Tominaga and Stathopoulos (2009). These fluctuations are characterized by unsteady vortical structures which interact with each other and with the surroundings playing a fundamental roll in the transport mechanism of pollutants. Consequently, steady RANS will reproduce poor prediction accuracy of dilution in regions where mixing is caused by the advection of generated eddies into the wake.

4.3 URANS simulation

To gain insight into the numerical modelling of flow around bluff bodies using the unsteady RANS approach (URANS), a basic literature case represented by a cube in a channel flow was

reproduced and analyzed. One of the well-known experimental results for such idealized problem is that developed and documented by Hussein and Martinuzzi (1996).
The model corresponds to a surface-mounted cube (0.25x0.25x0.25 m) in a fully-developed channel flow. The dimensions of the channel were specified as 10h x 7h and 2h height, where h is the height of the cube (0.25 m). The inlet conditions correspond to a fully developed channel velocity profile as the measured by Hussein and Martinuzzi (1996). The channel walls were specified as walls with no slip condition. The grid was built using hexahedral elements only with strong clustering close to the walls to capture the near-wall turbulent regions. The y+ for all walls was kept below 4 in order to apply the "enhanced wall treatment" available in Fluent (Fluent, 2006). Initially, a very large time step was specified until convergence condition (10^{-5}) was reached. Then a very small time step (t = 10^{-3}s) combined with a small unsymmetric perturbation in the velocity field was imposed to perform the simulation. The latter condition is suggested to "trigger" the unsteadiness, since otherwise the symmetric geometry and flow would not allow the formation of vortices (Iaccarino et al. 2003).

Figure 8 shows the existence of unsteadiness in the wake of the cube. Four instances within T, which is the time period for a complete cycle of vortex generation, are presented as streamlines at the cube half height. The side-to-side oscillations of flow are characterised by vortical structures interacting with each other within the wake of the cube but with a limited time life because they vanish after detaching. These results support the idea that URANS can capture coherent vortex shedding that occur in a flow around cubic obstacles.

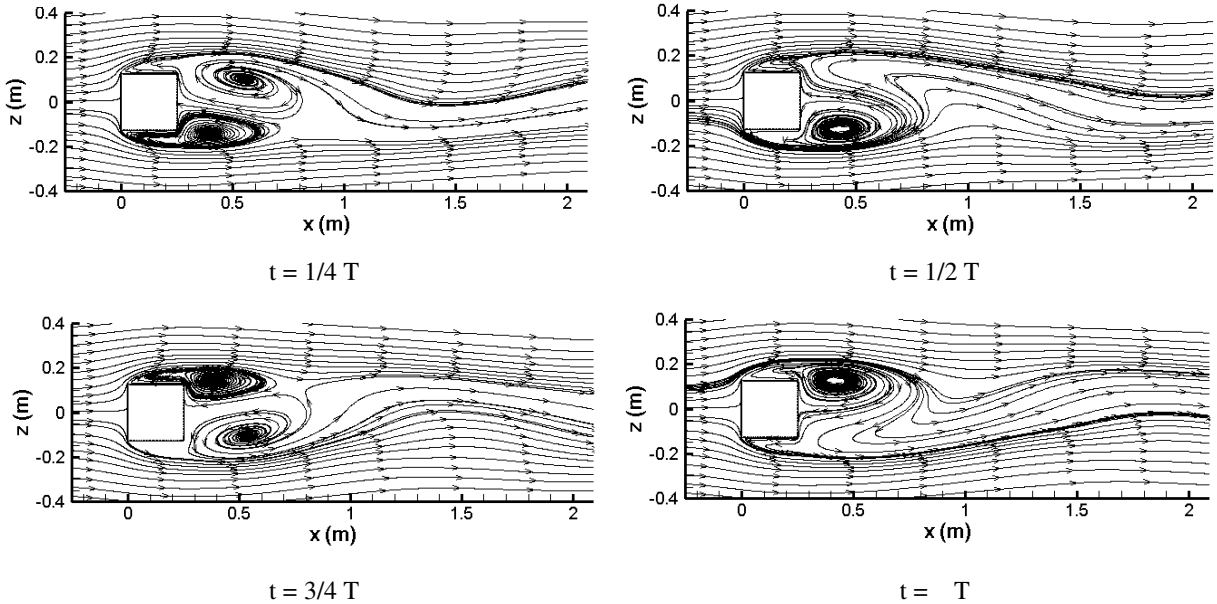

Figure 8. Planview of streamlines for a flow around a cube using URANS approach.

Figure 9 a) and b) shows the distribution of velocity Ux (streamwise) and Uz (spanwise) in the wake of the cube. Practically no change is experienced with either steady or unsteady simulation for Ux. On the other hand, an oscillation is noticed for Uz within the wake of the cube, as expected. These fluctuating velocities, which are not captured by steady RANS simulation, probably explain the inaccuracy experienced in preceding comparisons. The next step of this study is

to apply same methodology as it was carried for the cube but for the two-building configuration. It is expected to find significant flow unsteadiness, which could explain the underestimation of dilution registered using RANS.

5.- Conclusions

This work has investigated the distribution of dilution of pollutants at roof level of an emitting building. Two cases were considered: the emitting building as isolated and with a taller upstream building. Comparisons between wind tunnel data and CFD simulations confirmed that in general RANS underestimate dilution in the near field of a source in both cases. For the isolated building case dilution prediction is characterized by an overestimation upstream the stack and an underestimation downstream the stack. It was confirmed that low values of Sc_t can partly compensate the mentioned inaccuracy by increasing species diffusion upstream and in the lateral direction. For the two-building configuration, dilution is generally underestimated along the streamwise and lightly overestimated in the lateral direction. The "calibration" using low Sc_t is also confirmed. Discrepancies may be explained by the inaccuracy of steady RANS to capture unsteadiness in the wake of the taller building. In order to gain insight into unsteady simulation of flow around an obstacle, URANS approach confirmed the existence of coherent vortical structures in the wake of a building.

ABSTRACT: This paper reviews recent studies pertaining to flow and pollutant dispersion around buildings and complex geometries (real cities). Field/laboratory experiments and numerical simulations (mainly Computational Fluid Dynamics, with attention to Large Eddy Simulation approach) performed by us as well as by other researchers who have looked at flow, turbulence, dispersion and ventilation around bluff bodies are considered. We attempt to review state of the art results considering that the urban complexity is not only due to the packing density, but also spatial building-height variability, thermal properties, the presence of vegetation. These findings are discussed in light of recent advances of operational urban dispersion models.

KEYWORDS: flow and dispersion, modelling, experiments, city breathability, urban models

1 INTRODUCTION

Health risks associated with exposure to pollutant concentrations in cities have motivated research to improve numerical models for local air quality. One of the difficulties arises from the complexity of the urban form which continues to be a challenge for modellers. An urban canopy consists of a large collection of buildings, trees and other obstacles affecting transport and distribution of scalars (pollutants, temperature, humidity etc.). A large number of experiments and simulations of flow around bluff bodies has been performed to understand the wide range of complex flow phenomena. This has led to the development and improvement of obstacle resolving models, such as Computational Fluid Dynamics (CFD) models.

Most of the studies have been performed separately depending on the specific application and a comprehensive overview is still missing. In this context, the paper reviews and summarizes some of the most recent advances in numerical (with attention to the Large Eddy Simulation techniques) and experimental findings obtained by us as well as by other researchers who have looked at flow and turbulence around single and groups of bluff bodies to adequately predict pollutant dispersion at the micro-scale. These advances are examined in light of the development of recent operational dispersion models, which are commonly used to determine the exposure of the population to pollutants in urban areas and to develop strategies for its reduction.

2 BUILDING AND STREET SCALE

2.1 *Flow and dispersion around isolated buildings*

Several studies, both numerical and experimental, were carried out in the past analyzing flow and dispersion in flat terrain and around bluff bodies (buildings). Among the pioneering studies,

Riddle et al. (2004) considered the simulation of the dynamics of the basic atmospheric boundary layer using a CFD code and an integral, operational model for the prediction of gas dispersion for neutral stability and flat terrain situations. Overall, they proposed to artificially increase the plume dispersion by reducing the typical turbulent Schmidt number Sc_t value in order to increase the turbulent diffusion near the ground in the Reynolds-averaged Navier–Stokes (RANS) k-ε model. Similar analyses and results were performed by Di Sabatino et al. (2007, 2008a). The work by Tominaga & Stathopoulos (2009) is one of the more systematic attempt to examine prediction accuracy of flow and dispersion around a cubic building for several wind directions using various k-ε models, comparing numerical results with wind-tunnel data. As for the flat terrain cases, the standard k-ε model provided inadequate results for the concentration field, because it cannot reproduce the basic flow structure, such as the reverse flow on the roof.

Only very recently, there has been an increasing interest in using Large Eddy Simulation (LES) models which, although computationally expensive, have the advantage over RANS in that they explicitly resolve the majority of the energy carrying eddies and the internally or externally induced periodicity involved, whereas only the universal small scale eddies are modelled. Following Tominaga & Stathopoulos (2010), Gousseau et al. (2011a, 2012) compared the convective and turbulent mass fluxes predicted RANS and LES for isolated buildings and analyzed the turbulent mass transport mechanism by unsteady concentration and velocity statistics. They showed that RANS models predict erroneous convective fluxes and are largely outperformed by LES in terms of prediction accuracy of mean concentration. Calculated results by Yoshie et al. (2011) confirmed better agreement of LES results with experiments.

2.2 *Flow and dispersion within urban street canyons*

Several works have been performed to understand flow and dispersion in urban street canyons. Most of the researches focused on the idealized case of an infinitely long street, within which a recirculating flow develops, driven by an external wind blowing perpendicularly to the street axis. These studies have provided fundamental knowledge on flow dynamics and pollutant dispersion in presence of obstacles for several engineering applications and for the optimization of the urban comfort. Moving from this basic knowledge, recent studies have been focusing on more complex phenomena. Among these we focus here on the effects induced by varying wind directions on the flow within a street canyon and at the intersection of two or more canyons. The effect of vegetation and buoyancy is also taken into account.

Reviews of recent progress in CFD and operational modelling of wind field and pollutant transport can be found in Vardoulakis et al. (2003) and Li et al. (2006). More recently, Blocken et al. (2011) and Chavez et al. (2011) reviewed various aspects of outdoor air pollution modelling through CFD in the urban environment which included isolated buildings, airborne particles in dense urban areas etc. Recent studies pertaining to CFD modelling techniques to assess pollutant dispersion in different street canyons have been reviewed by Hajra (in press), who discussed modeling technique advantages and demerits. This study shows that the future of CFD is bright and in the coming years LES model is more likely to be used due to its computational preciseness despite increased computer simulation time (Tominaga & Stathopoulos, 2011).

2.2.1 *Wind direction and street intersections*

Most of the studies have been devoted to the case of a wind blowing perpendicularly to the street axis since it is widely believed to maximize the retention time of pollutants. However, field experiments and numerical simulations have demonstrated that if the street is sufficiently long, the wind blowing along the street causes an accumulation of pollutants and the resulting concentra-

tion at the downwind end of the street can exceed that produced when a similar wind blows perpendicular (e.g. Berkowicz et al., 1996; Soulhac & Salizzoni, 2010; Hang et al, 2012). The evaluation of the advective fluxes along the canyon is then essential to predict and model the wide range of dispersion conditions that can occur within a street canyon.

A review of experimental studies of the flow induced in a street by an external wind blowing at an arbitrary angle is given in Ahmad et al. (2005) and described as a complex 3D helicoid. Soulhac et al. (2008) have shown that certain aspects of the flow can be obtained from the linear superposition of two asymptotic cases - flow parallel to the street and flow perpendicular to the street - providing an analytical model wind velocity along the street axis spatially averaged over the transverse street section. This result is the basis for finer parametric modeling approach for the exchange phenomena of pollutant, heat or momentum between the urban canopy and the overlying atmosphere (Cantelli et al., 2011; Soulhac et al., 2011).

Advective transfer along the street axis within a street of finite length causes dynamical effects within a street intersection. A detailed review on the state of the art has been given by Tiwary et al. (2011). Numerical simulations, wind tunnel and field experiments have provided a detailed picture of some of the major flow mechanisms that occur (e.g. Soulhac et al, 2009, Carpenitieri et al, 2019) showing that, even for simple configurations, the flow structure is very complicated, with significant variation of local averages of pollutant concentrations and even larger instantaneous variations, due to both wind direction variations and local smaller scale turbulence.

2.2.2 *Thermal effects*

To date relatively few studies investigated the role of heat fluxes in urban canyons, which are generated by temperature difference between the canyon walls and the air within the canyon. The temperature difference is typically induced by the direct solar radiation and can reach over tens of degrees in summer (Offerle et al., 2007). Thermal fluxes generate buoyancy forces within the canyon which have a relevant influence on the flow within it, especially in low wind conditions.

First studies were performed numerically by Sini et. al. (1996) and Kim & Baik (2001) and experimentally by Kovar-Pankus et al. (2002). Full scale experiments were performed in central Nantes (France) by Idczac et al. (2007) and in central Gothenburg (Sweden) by Offerle et al. (2007). Recently, numerical studies of these phenomena have captured increasingly interest. Memon et al. (2010) developed a two-dimensional k-ε turbulence model with a Renormalization Group (RNG) closure scheme to assess the impact of the street canyon aspect ratio and wind speed on the intensity of heat. The street canyon model was validated by comparing results with reported wind tunnel data and similar numerical models (e.g. Uehara et al., 2000; Kim & Baik, 2001; Xie et al., 2007). Results uncovered the importance of street canyon aspect ratio and wind speed on urban heating and that urban cool island (i.e., daytime lower temperatures in an urban area) may be associated with direct ground heating. Another recent contribution was given by Defraeye et al. (in press) who proposed an adjusted wall function for temperature intended for forced-convective heat transfer at surfaces of bluff bodies. Finally Cheng & Liu (2011) performed LES simulations to examine characteristics of flows and pollutant dispersion in two-dimensional urban street canyons of aspect ratio equal to one in neutral, unstable, and stable thermal stratifications. While pollutants tend to be well mixed in street canyons in neutral and unstable conditions, improved pollutant removal in unstable conditions was observed due to the enhanced roof-level buoyancy-driven turbulence. Similar results were found by Cai (2012).

2.2.3 *Effects of vegetation*

To complete the picture, one should also consider how urban vegetation affects urban canopy flows, the microclimate and air pollution levels. Although particle deposition on plant surfaces removes pollutants from the atmosphere, thus reducing their concentration, it also should be noted that trees themselves act as obstacles to airflow decreasing air exchange with the above roof level atmosphere. Many research studies are underway to determine the role of vegetation in urban microclimates (e.g CODASC Database, 2008; Mochida et al., 2008; Buccolieri et al., 2009; 2011). In numerical simulations using CFD models, trees have been modelled as porous media to which is associated a pressure loss according to the specific tree porosity. Typically, a modification to the governing equation is done by adding a momentum sink term. The interpretation of concentration results is done by looking at modifications that the flow undergoes in presence of trees. Though numerical studies using LES type of models should be employed (Salim et al., 2011; Park et al., 2011), RANS CFD simulations suggest that the presence of trees in the canyon break the main vortex structure expected in the tree-free cases and modifies the corner vortices at the street ends thus reducing mass exchanges with the various openings, therefore in first approximation dilution is much reduced. Real-city applications have further complications and both buildings and trees have to be considered together (Buccolieri et al., 2011).

3 DISTRICT SCALE

3.1 *The influence of building geometry and arrangements on pollutant dispersion*

When the urban rough surface interacts with the atmospheric flow above it, the disturbed flow field can become extremely complex depending on the obstacles' geometry, spacing and the spatial arrangement. Nowadays, several high-quality experimental and numerical data sets are available in the literature. Street-level pollutant concentrations have been proven to be attributable to several factors such as wind direction and velocity, street canyon aspect ratios, the presence of street intersections and upstream buildings, building roof geometry (Yassin, 2011), building packing density etc. In this context, a recent contribution has recently been made by the COST Action 732 (2005-2009, http://www.mi.uni-hamburg.de/Home.484.0.html) numerical team which has highlighted current potential and pitfalls of CFD models using data from the Mock Urban Setting Test (MUST) wind tunnel experiments (Bezpalcova, 2007). In addition, the CEDVAL dataset (2006-2009) have been recently studied by several authors in the context of model validation (e.g. Di Sabatino et al., 2008a; Franke et al., in press).

Even though different attempts were made to improve the capability of RANS models by modifying model parameters to improve their capability to reproduce real wind flow fields, turbulence and concentration patterns (e.g. Solazzo et al., 2009), interest in LES is increasing. Spatial distribution of the turbulent scalar flux inside building arrays by comparing the numerical results obtained by LES and RANS computations have confirmed what found for simple street canyon model, that is RANS underestimates turbulence diffusion in the building canyon when compared with LES due to the difference in the representation of turbulent scalar flux (Tominaga & Stathopoulos, in press). Another recent comparison between LES and RANS (Gousseau et al., 2011b) has further shown by comparison with wind tunnel experiments in Montreal that the performance of the standard k-ε model strongly depends on the turbulent Schmidt number, whose optimum value is case-dependent and unknown a priori. In contrast, LES showed a better performance without requiring any parameter input to solve the dispersion equation. As an example

Figure 1 (left) shows that even in presence of symmetrical geometry, the instantaneous concentrations can be asymmetric, which can be captured only by using the LES approach.

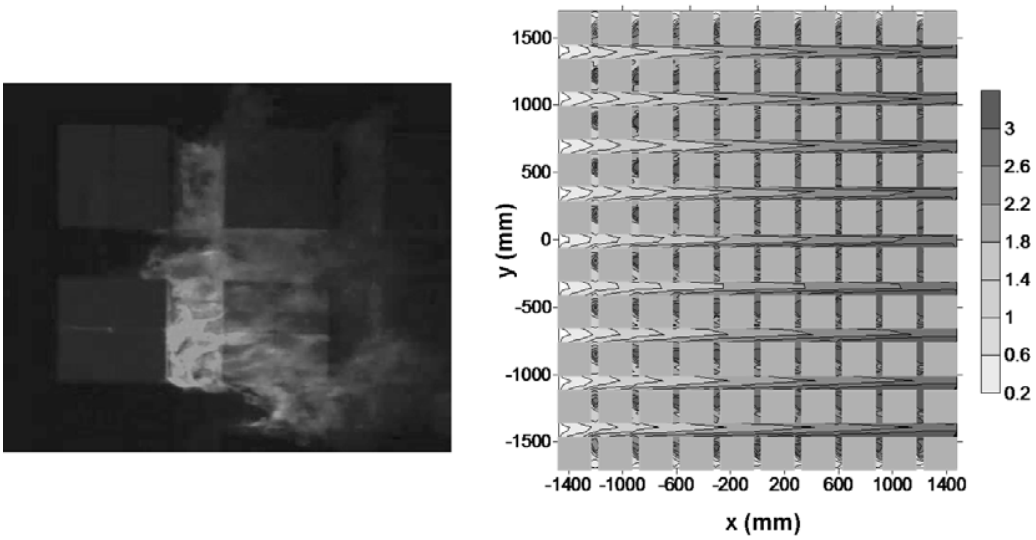

Figure 1. Visualization of a passive scalar injected by a line source at ground level within a regular obstacle array (left) and example of a map of normalized mean age of air (right). The wind blows from the left.

3.2 *City breathability*

An approach to determine street level pollutant dilution has recently been offered by the implementation of building ventilation concepts previously used to evaluate indoor exposure (Chen, 2009). Among the most recent studies, Hang et al. (2012) analyzed the nature of the flow being advected into the city from its surrounding rural areas using the concept of local mean age of air (Etheridge & Sandberg, 1996), which intuitively represents the time taken by an air parcel to reach a given place after it enters the city. A poorly ventilated region, as occurs at the end of the array (Figure 1, right) implies a large mean age, i.e. air mass takes a long time to reach a given region and therefore pollutant removal will be slower. Buccolieri et al. (2010) introduced the expression city breathability to describe this effect. Those authors set a conceptual frame to interpret pollution concentration levels in urban-like geometries using a bulk flow balance approach to calculate flow rates by means of RANS CFD simulations. Wind tunnel and numerical simulations analyses suggested a way to classify city's neighbourhoods into three groups: sparse, compact and very compact cities. Further, the presence of a low spatial building-height variability (a negative effect with respect to city breathability) and a low value of built-up area index (positive effect) together with the intracity variability of city morphometry is expected to be relevant for city breathability and still needs to be quantified (Di Sabatino et al., 2010).

4 URBAN DISPERSION MODELLING

As discussed above, CFD codes have been proven to be successful in predicting flow and dispersion at city scale by resolving the flow and dispersion down to the building scale. However, when a district of hundreds of streets and a large amount of the pollutant emissions have to be considered, CFD requires still unfeasible computational costs for operational purposes. Alterna-

tive approaches have then to be adopted and operational dispersion models are commonly used to determine the population's exposure to pollutants and to develop strategies for its reduction. We discuss here four different simulation strategies: Coupling dispersion models with diagnostic flow models, Street network models, Canopy models and Adapted Gaussian models. The models are hereafter presented for decreasing computational costs, which is strictly associated to the accuracy adopted in the description of details the urban geometry and of the velocity field within it.

4.1 *Coupling dispersion models with diagnostic flow models*

This method aims in reproducing the local urban geometry with high accuracy. The modeling chain can be directly fed with Geographic Information System (GIS) data of the buildings. Pollutant concentrations are obtained by coupling a Lagrangian dispersion model with velocity field predictions obtained by diagnostic models. These can be eventually modified using analytical corrections to better simulate the recirculation zones developing in the wakes of buildings and obstacles (Kaplan & Dinar, 1996). Examples of this approach are given by Moussafir et al. (2004) and Tinarelli et al. (2007), which present simulations of pollutant dispersion around isolated buildings or in groups of buildings in domains with lengths scales of few hundreds of meters. The computational cost are significantly lower than those needed to run simulations with prognostic CFD codes but not sufficiently low to use this model for simulations of multiple sources over a whole district or to run simulations over a whole year.

At larger scales, that span between the district and the city scale, when it is not possible to represent the details of recirculation zone developing within canyons and building wakes, the velocity field within the urban area can be reconstructed by correcting the output of a mass-consistent diagnostic model with analytical solution of the spatial averaged velocity within the urban canopy (Cionco, 1965; Macdonald et al., 1998). These velocity fields can then be used to run Gaussian puff dispersion models (e.g. Chang et al, 2005).

4.2 *Street network models*

Further reduction of the computational costs can be achieved adopting a street network approach. These are box models at heart but formulated with explicit modelling of the exchange of flow and pollutant fluxes at urban intersections and capable of providing a detailed concentration field at the street scale over a whole urban district. These models adopt a simplified description of the urban canopy. The streets in a district are modelled as a simplified network of connected street segments represented by boxes, whose mass exchanges are modelled by means of parametric laws. The flow within each street is driven by the external wind and the pollutant is assumed to be uniformly mixed over the street. In order to compute the mean concentration within each street, these models account for three transport mechanisms: the convective mass transfer along the streets (Soulhac et al., 2008) due to the mean wind along their axis, the turbulent transfer across the interface (Salizzoni et al., 2009) between the streets and the atmosphere, the convective transport at street intersections (Soulhac et al., 2009). An example of implementation of this approach is provided by Soulhac et al. (2011). Recent studies have evaluated the performances of this approach both against laboratory experiments (Carpentieri et al, in press) and field experiments (Soulhac et al, 2012). These approaches provide reliable results for high density canopy, and the width of the building blocks exceeds that of the streets separating them, as for most central part of European cities. Their performances decrease in case of sub-urban districts, when the spacing between the buildings increases, the physical limits of the street volume becomes unclear and the flow field within the street is strongly coupled with that of the atmosphere just above.

4.3 *Canopy models*

Much effort has been done in order to relate mass, heat and momentum exchanges between an urban canopy and the overlying atmosphere to spatially averaged characteristics of the urban geometry. As an example we cite here Di Sabatino et al. (2008b) who have recently proposed a modelling approach for the computation of the spatially-averaged flow field, where the average is defined at the neighbourhood scale, between 0.2 up to 10km. The novel idea is the description of the drag forces in terms of height dependent morphological parameters based on detailed knowledge of building geometry. This is nowadays available in digital format (Digital Elevation Models) which can be easily analyzed using image processing techniques (Di Sabatino et al., 2010). The goal is the development of a fast model for the prediction of the flow and pollutant concentration fields at the neighbourhood scale taking into account building arrangement in terms of porosity parameters and spatial building height variability. In terms of computational costs canopy models are similar to street network models. However, canopy models loose details in the spatial resolutions of the concentration fields, since they are not able to grasp the flow details in the streets at the local scale or the channelling effect occurring along the axes of the street canyons. Their application can be however particularly interesting in sub-urban areas or in general in district with mow density of buildings, which have proven to be critical for street network approach.

4.4 *Adapted Gaussian models*

For short-range local problems (up to about 5km), simple Gaussian models are used. It is accepted that in urban areas these models can still be applied when pollutants disperse above the buildings or when the dimensions of the cloud are much bigger than the dimensions of the obstacles. Under such conditions classical Gaussian models may still play a role as screening tools but lack the potential for realistic predictions (COST Action 732).

The performances of these models can however be significantly improved by accurately correcting the plume spreading parameterizations implemented in it with specific semi-empirical relations. In particular, at the micro-scale the retention of pollutant within the recirculating flow structures in building wakes and street canyons, that inhibit street ventilation and enhances ground level concentrations, can be computed as the sum of two components: the background concentration due to street canyon trapping effect and the concentration related to the direct contribution of vehicles emissions within the street (e.g. Hertel & Berkowicz, 1989; Schuluman et al., 2000). Further, at slightly large scales the enhanced lateral spreading of a pollutant plume due to increased plume meandering in the buildings wakes can be efficiently simulated with simple parametric relations linking the intensity of the turbulent fluctuations to the time averaged later spread of the plume (e.g. Venkatram et al., 2004). At the district scale, similar corrections for the parameterization of the plume can be taken into account to model the enhanced diffusivity within the roughness sub layer (Raupach et al., 1991; Rotach, 1993; Salizzoni et al., 2009), taking advantage of the fact that turbulent characteristics have proven to be almost uniform with height (Venkatram et al., 2005). It is worth mentioning however, that these approaches are reliable mainly in case of sparse obstacle arrays, and not in dense packed obstacle array, where the channelling of pollutant along the street axes is one of the main transfer process (Garbero, 2010).

5 CONCLUSIONS

This short review tried to show recent advancement from flow and dispersion studies around bluff bodies for urban environment applications. The focus was to select some very recent works in this area. Until now a large number of experiments and simulations of flow around bluff bod-

ies has been performed to improve fluid dynamics around obstacles and to understand the wide range of complex flow phenomena. Physical simulation studies in wind tunnels show a high potential since the influence of bluff body's geometry, presence of obstacles etc. can be investigated by controlling each parameter independently. This has also led to the development and improvement of obstacle resolving models, such as CFD, with LES more likely to be used in future owing to its accuracy.

Up to now computational dispersion models have been proven to be successful in predicting flow and dispersion at city scale by resolving the flow and dispersion down to the building scale. However, when a district of hundreds of streets is considered and a large amount of the urban pollutant emissions has to be taken into account, the application of CFD codes requires computational costs that are still unfeasible for operational purposes. In this context, operational dispersion models are commonly used to determine the exposure of the population to pollutants in urban areas and to help develop strategies for its reduction.

ABSTRACT: We examine some statistical properties of the concentration field, developing from the steady release of tracer gas at street level in an urban street canyon. To that extent, detailed time-resolved numerical simulations of coupled flow and dispersion are conducted. The numerical model was extensively validated by comparing the predicted time-averaged concentrations to wind tunnel measurements. In this paper, we employ the validated model to assess the time-averaged concentration, the variance and the probability density function (PDF) at various locations in the urban street canyon. The PDF in the mid-plane of the street canyon was found to be wider and more uniform at near-ground locations close to the leeward wall, and narrower and more pronounced at locations higher above the ground and closer to the windward wall. A wider PDF implies that both the mean concentration and the variance are higher, and that longer time periods are needed to determine these quantities at a given confidence level. This observation has an immediate impact on the sensor location and averaging time for siting monitoring networks, and affects the assessment and planning of pollutant mitigation strategies.

KEYWORDS: Computational Fluid Dynamics (CFD), Large Eddy Simulation (LES), dispersion, statistical analysis, average, variance, probability density function (PDF).

1 INTRODUCTION

Thus far, pollutant dispersion studies have mainly focused on mean concentrations and their spatial distribution for a wide range of configurations and emission scenarios. Studies providing statistical information on air pollutant concentration are rare. Nevertheless, their significant added value was demonstrated in a wind tunnel study by Pavageau and Schatzmann (1999), and discussed again in e.g. Schatzmann and Leitl (2011). They showed that statistical information can help to improve our understanding of dispersion mechanisms, and can assist to suggest specifications regarding e.g. sensor location and averaging time for siting monitoring networks. Compared to wind tunnel studies, performing numerical simulations has the advantage that full-field data of all quantities of interest are available over the considered period of time.

In Moonen et al. (2012a), we assessed the performance of a numerical model to accurately simulate pollutant dispersion in an urban street canyon with tree planting. Detailed time-resolved numerical simulations of coupled flow and dispersion were conducted and compared to corresponding wind tunnel measurements (Gromke and Ruck 2007, 2009). The model performance was assessed in several steps, ranging from a qualitative comparison to measured concentration

profiles, over statistical data analysis by means of scatter plots and box plots, up to the calculation of objective validation metrics, and was found to be excellent.

The goal of the current study is to employ the validated model to assess the statistical properties of the concentration field. We focus on an isolated urban street canyon with near-ground released traffic emissions, under perpendicular approach flow. The numerical model is described in Section 2. Section 3 summarizes the main conclusions of the validation study. In Section 4, the statistical properties of the concentration field are analyzed. We concentrate on three quantities of interest, namely the time-averaged concentration field, its variance and corresponding probability density function.

2 NUMERICAL MODEL

2.1 *Domain dimensions*

We perform detailed unsteady simulations of a dispersion experiment, conducted in the atmospheric boundary layer wind tunnel of the University of Karlsruhe, Germany. We focus on a 1:150 scaled isolated street canyon under perpendicular approach flow conditions. The street canyon consists of two parallel buildings of 0.12 x 0.12 x 1.2 m (L_x x L_y x L_z), and positioned 0.12 m apart in streamwise direction (x). In this way, a street canyon with $W/H = 0.12/0.12 = 1$ and $L/H = 10$ is formed ($H = 0.12$ m), see Figure 1. The cross sectional dimensions of the numerical domain are taken equal to the dimensions of the wind tunnel, namely 2 m wide by 1 m high, hereby accurately reproducing the experimental blockage ratio of 7.2%. The total streamwise length of the domain is 25 H (3 m), and consists of an approach flow region of 7 H (0.84 m), a model region of 3 H (0.36 m) and a wake region of 15 H (1.8 m). The position of the upstream domain boundary coincides with the entrance of the wind tunnel test section, i.e. where velocity profiles have been measured. The downstream distance is chosen in accordance with the best practice guidelines, formulated as outcome of COST Action 732 (Franke et al. 2011).

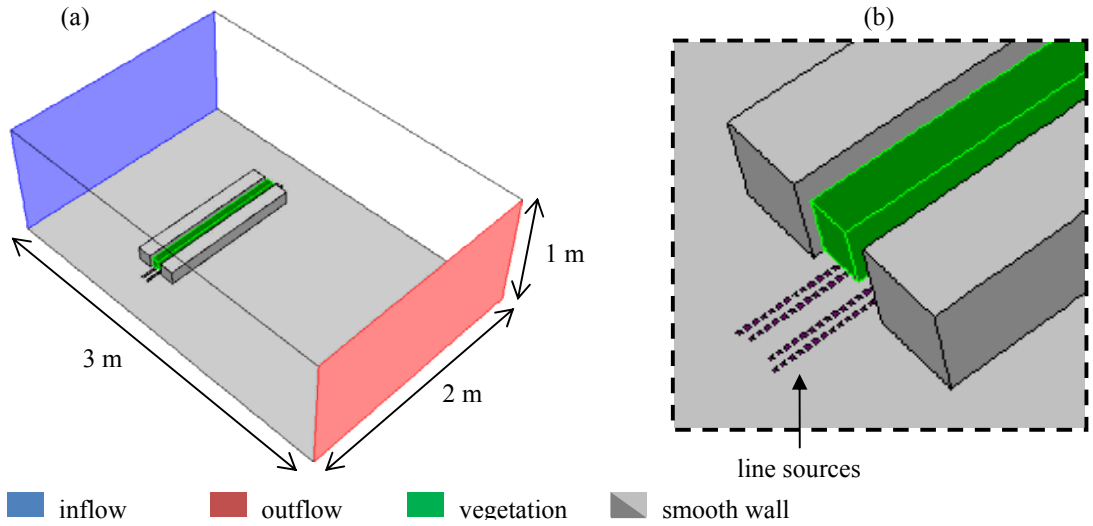

Figure 1. Layout of the computational domain.

2.2 *Boundary conditions*

We simulate the flow in an atmospheric boundary layer wind tunnel, in absence of temperature effects. Boundary conditions (BCs) are chosen accordingly.

No-slip conditions are imposed along the *top, bottom and lateral boundaries* of the domain, corresponding to flow along the smooth wind tunnel walls. The same BC is applied for the surfaces of the canyon model. All walls are considered impermeable for species transport.

At the *inflow boundary*, the measured vertical profiles of mean flow speed $u(y)$ and turbulence intensity $I(y)$ can be well approximated by power-law correlations with exponents $k_u = 0.3$ [-] and $k_I = 0.65$ [-], respectively (Moonen et al. 2012a):

$$\frac{u(y)}{u(y_H)} = \left(\frac{y}{y_H}\right)^{k_u} \tag{1}$$

$$\frac{I(y)}{I(y_H)} = \left(\frac{y + y_d}{y_H}\right)^{k_I} \tag{2}$$

with $u(y_H) = 4.65$ m/s the mean flow speed and $I(y_H) = 16.3\%$ the turbulence intensity at reference height $y_H = H$ and $y_d = 0.02$ m a parameter representing the peak in turbulence intensity at the top of the roughness elements. Time-dependent inlet conditions are generated from the measured mean profiles by means of Ansys' inbuilt spectral synthesizer (Ansys Inc. 2009). In this method, the fluctuating velocity components are computed by synthesizing a divergence-free velocity-vector field from the summation of (100) Fourier harmonics. The inflowing fluid is dry air at 293.15 K with zero background tracer concentration.

On the *outflow boundary*, a zero diffusive flux is imposed for all flow variables in the direction normal to the exit plane. This means that the conditions of the outflow plane are extrapolated from within the domain and have no impact on the upstream flow. This assumption is valid for fully-developed flows.

The *line source* is modeled as a series of equidistantly-spaced point sources at ground level, as in the experiment. The individual hypodermic tubes have been approximated by square inflow boundaries, each 0.005 x 0.005 m^2. The imposed flow rate and concentration are equivalent to the experimental conditions, namely a mixture of 7000 cm^3/min dry air ($\rho = 1.225$ kg/m^3, $\mu = 1.7894\ 10^{-5}$ kg/(m·s), molecular weight of 28.966 kg/kgmol) and 6.5 cm^3/min SF_6 ($\rho = 6.164$ kg/m^3, $\mu = 1.42\ 10^{-4}$ kg/(m·s), molecular weight of 146.05499 kg/kgmol). The properties of air are taken from the inbuilt material database (Ansys Inc. 2009). The ones of SF_6 are compiled from various literature sources. SF_6 is considered as an inert gas (i.e. chemical reactions are not modeled). Because of the larger surface area of the individual point sources in the CFD model, the exhaust momentum is lower than in the experiment. This is compensated by adding a source term to the vertical momentum equation in the cells in direct contact with the source. Note that other researchers (Gromke et al. 2008, Salim et al. 2011a,b) proposed more simplified modeling strategies for the line source and reported a qualitatively good agreement with the experimental results. Since SF_6 is about 6 times heavier than air, gravitational effects need to be included in the model.

2.3 *Computational grid*

In LES, the computational grid acts as a filter. The turbulent structures larger than the grid size (i.e. the large eddies) are resolved, while the smaller ones are modeled. Small eddies are more isotropic. Cubic elements have an equal filter length in the three principal directions, and are

thus the -optimal element type for resolving turbulent structures with LES. The grid employed in this study is therefore entirely built up with this element type.

Since uniform grid refinement rapidly results in a prohibitively large number of elements for grids consisting of cubic elements, we developed and validated an algorithm that systematically refines the grid – in all three dimensions – towards regions of interest (Moonen et al. 2012b). The final grid consists of 1'226'062 perfectly cubic elements. The element size gradually reduces from $H/3$ (= 0.04 m) in the bulk up to $H/24$ (= 0.005 m) in the region of interest. The employed element size in the region of interest is about 2 times smaller than the one obtained by sensitivity analysis (Salim et al. 2011a) and about 2.5 times smaller than the recommended maximal grid size for isolated buildings (Franke et al. 2011) and street canyons (Bartzis et al. 2004).

2.4 *Solution method*

The three-dimensional Navier-Stokes equations, the continuity equation and the species transport equation were solved using the commercial CFD code Ansys Fluent 12.1 that employs the control-volume technique. The staggered pressure-based solver was selected. For the unsteady LES simulations, closure was obtained by means of the dynamic Smagorinsky-Lilly subgrid-scale model (Lilly 1992). The subgrid-scale turbulent Schmidt number was dynamically updated, obviating the need to prescribe a default value. Near-wall modeling was performed using the law-of-the-wall. It was verified that the instantaneous $y+$ values in the region of interest did not exceed 60, i.e. the limit of validity of the selected near-wall modeling approach (Ansys Inc. 2009). Pressure-velocity coupling was taken care of by the SIMPLEC algorithm (Vandoormaal and Raithby 1984). Pressure interpolation was performed by means of the PRESTO! scheme (Peyret 1996). Green-Gauss cell-based gradient evaluation was employed. The third-order MUSCL discretization scheme (Van Leer 1979) was used for the convection terms of the governing equations. By default, second-order accuracy is used for the viscous terms. Second order implicit time integration is employed.

2.5 *Initialization, solution and termination criterion*

The simulations were initialized from a preliminary RANS simulation. An LES time step of 0.00125 s was selected, resulting in cell Courant numbers below 2.5. Typically 100 iterations were required per time step, until the desired level of convergence was reached, i.e. constant residuals of 10^{-4} or less for all equations (Franke et al. 2011). The residuals are defined as the imbalance of the conservation equations, summed over all elements. These values are scaled and the scaled values are used in the code as a measure of the iteration convergence (Ansys Inc. 2009). We reached 10^{-4} for the species transport equation, 10^{-9} for the continuity equation and machine precision ($<10^{-12}$) for the three momentum equations.

All simulations were run on the ETH Brutus cluster (17'000 cores, peak performance 180 TF). Typically, one time step (0.00125 s) required 1.6 hours of CPU time. A stable flow pattern is reached after 10 s (8000 time steps), corresponding to more than 15 domain flow-through times. Statistics were collected during the subsequent 8000 time steps (10 s). In section 4, we will show that the considered time period (10 s in the reduced-scale model, or 25 minutes in full scale) is sufficient to obtain converged statistics in the largest part of the domain. We will show that, for specific locations and applications, even longer averaging times are required.

3 MODEL VALIDATION

The model performance was analyzed in detail in Moonen et al. (2012a). In this section, we only summarize the main conclusions of the comparison between the results, based on the model described in Section 2, and the corresponding wind tunnel measurements by Gromke and Ruck (2007, 2009). The comparison focused on the mean near-wall pollutant concentration, normalized according to:

$$c^+ = \frac{cu_H H}{Q/\ell} \tag{3}$$

with c [-] the measured concentration, u_H [m/s] the mean streamwise flow velocity at height H [m] in the undisturbed approach flow and Q/ℓ [m^2/s] the tracer gas source strength per unit length, with Q being 6.5 cm^3/min SF_6 mixed with 7000 cm^3/min dry air and ℓ = 1.42 m.

Figure 2a and b depict scatter plots of the mean normalized concentration at the leeward and windward wall of the street canyon, respectively. Predicted and observed data have been paired in space and are plotted against each other. Information on the spatial location is retained, and is represented by the different marker types (*, x, + and . for z/H = 0, ±1.25, ±3.75 and ±4.9, respectively). Points on the diagonal indicate a perfect match between simulations and measurements. The two dotted lines bound the region where measured and simulated data differ by less than a factor two.

Figure 2a shows a good degree of correlation between model results and measurements at the leeward wall. A detailed analysis of the different datasets reveals that the simulated mean normalized concentration in the center of the street canyon ('*'; $z/H = 0$) is consistently higher than the observations, while the simulated concentrations at the edges of the street canyon ('.'; $z/H = \pm 5$) are consistently lower than the observations. The mean normalized concentrations at the windward wall are significantly lower than at the leeward wall, and are systematically overpredicted by the model (Figure 2b). Note that this discrepancy does not necessarily imply poor model performance. As will be shown in the next section, the specific temporal flow features in the areas where the largest discrepancies occur necessitate the acquisition of extremely long time series in order to arrive at statistically relevant quantities. The latter condition applies both to measurements and to time-resolved simulations.

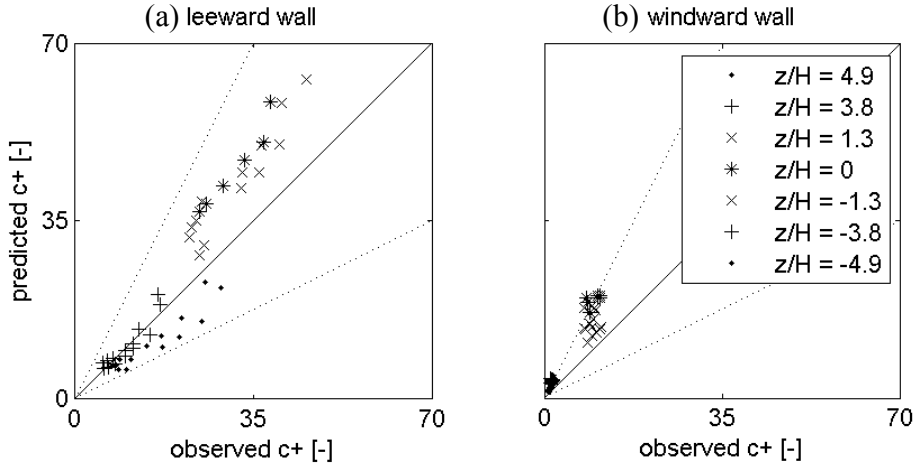

Figure 2. Predicted versus observed mean normalized concentration near (a) the leeward wall and (b) the windward wall of a street canyon. Marker types indicate the spatial location.

4 ANALYSIS OF TEMPORAL FLOW FEATURES

4.1 *Time series*

Figure 3 depicts the temporal evolution of the normalized concentration at a typical near-ground location in the street canyon (solid line). Periods characterized by a relatively low scalar concentration alternate with sudden peaks of high concentration. The short duration of these peaks, i.e. on the order of a few milliseconds, necessitates employing small time steps in the simulation (in this case $\Delta t = 0.00125$ s). The intermittent time between two high-concentration events does not seem to follow a regular pattern. The concentration history at a specific point is the result of the contaminated fluid parcels that reach that point over time. The peak concentrations originate from fluid parcels whose trajectory passed through the scalar source. The lower intermediate concentration is representative for the background concentration after mixing.

Two additional statistical quantities are shown on Figure 3, namely the cumulative mean (dashed line) and the cumulative standard deviation (dotted line). The cumulative mean is calculated according to:

$$c^+_{avg}(t) = \frac{1}{t - t_0}\int_{t_0}^{t} c^+(t)dt \tag{4}$$

and the cumulative standard deviation is obtained as:

$$c^+_{std}(t) = \sqrt{\frac{1}{t - t_0}\int_{t_0}^{t} \left(c^+(t) - c^+_{avg}(t)\right)^2 dt} \tag{5}$$

where the onset of the averaging period (t_0) is taken 10 s after the start of the simulation, to avoid including transitional affects.

From Figure 3, it is clear that both quantities gradually strive towards a constant value. The true mean and standard deviation theoretically require considering an infinitely long time series. In practice however, it can be noticed that their magnitude hardly changes after $t = 16$ s. The considered time interval of 10 s (25 min in full scale) is therefore sufficiently long to study the concentration fluctuations at this spatial location. As will be shown in Section 4.3, points at different spatial locations have different requirements regarding the time period to reach representative statistical quantities. Considering higher order moments generally also implies acquiring longer time series.

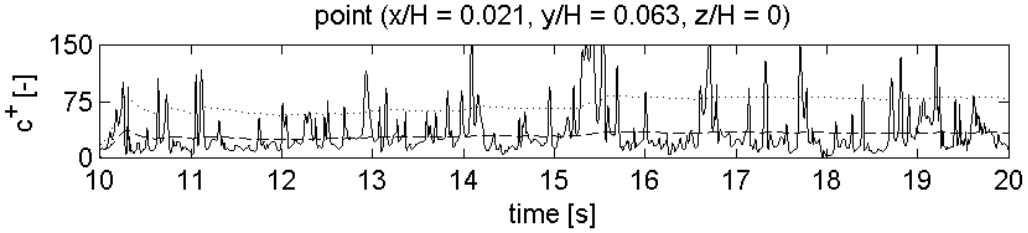

Figure 3. Temporal evolution of the mean normalized concentration at a point in the street canyon (solid line) and the corresponding cumulative mean (dashed line) and cumulative standard deviation (dotted line).

4.2 *Mean and standard deviation*

Figure 4 depicts the ten-second mean (left) and standard deviation (right) of the normalized concentration in every cell along the mid-plane ($z/H = 0$) of the urban street canyon. The flow direction of the standing vortex is schematically indicated as well. The tracer sources are pairwise clustered around $x/H = \pm 0.2$, leading to a locally increased mean normalized concentration in the cells above the sources. The tracer sources around $x/H = -0.2$ receive already contaminated air from the tracer sources around $x/H = +0.2$, explaining the location of the maximum tracer gas concentration. The concentration rapidly decreases with increasing distance from the tracer sources (along a streamline) due to mixing and dilution. The highest mean normalized concentrations are found near the ground and at the lower part of the leeward wall.

Although the source strength is uniform in time, the standard deviation of the concentration fluctuations in the air above the sources is larger than at any other place in the considered cross section (Figure 4). This clearly demonstrates the unsteadiness of the flow. Since the line source is composed of a series of point sources, turbulent fluctuations can easily cause a fluid parcel to travel either above the source or immediately next to it. The local instantaneous concentration therefore varies between zero and the source strength, resulting in a high standard deviation.

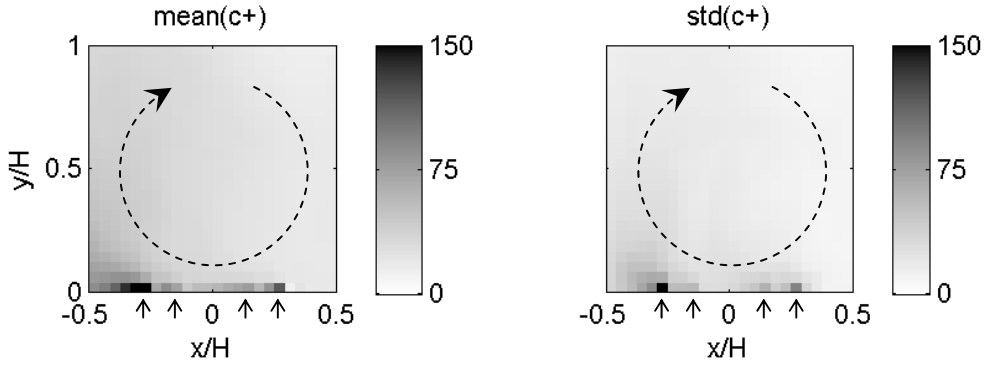

Figure 4. Mean and standard deviation of the normalized concentration in the mid-plane of the street canyon (z/H = 0). The standing vortex and the position of the tracer sources are schematically depicted as well.

4.3 *Probability density function*

Time-resolved simulations can offer interesting information beyond first order statistics. Figure 5 depicts probability density functions (PDFs) at 9 locations in the center plane of the urban street canyon ($z/H = 0$). The PDF gives the relative likelihood that a certain normalized concentration is found at that specific location. From Figure 5, it is clear that the shape of the probability density function is highly location-dependent. Distributions near the leeward wall are consistently wider than distributions near the windward wall, and the width of the PDF decreases with increasing height above the ground. Moreover, the normalized concentration with the highest likelihood is higher for wider distributions. These observations are in agreement with the observed patterns of mean concentration and standard deviation (see Section 4.2, Figure 4).

Statistical principles state that the width of the PDF, or more precisely the variance, is proportional to the required sampling time for determining a statistical quantity such as the mean, with a given level of confidence. In other words, a long time period needs to be considered at locations where the variance is high. The observed spatial variability of the variance of the PDF im-

plies that very long time series are required at locations near the ground and near the leeward wall, while locations higher above the ground and closer to the windward wall require shorter time series for the same level of accuracy. These observations have important consequences when comparing CFD results to full-scale field data: the turbulent time scales governing dispersion might exceed the time period over which quasi-stable conditions can reasonably be expected to occur in the field. Measurement sensor locations should therefore be selected with care, preferentially avoiding regions characterized by a high variance.

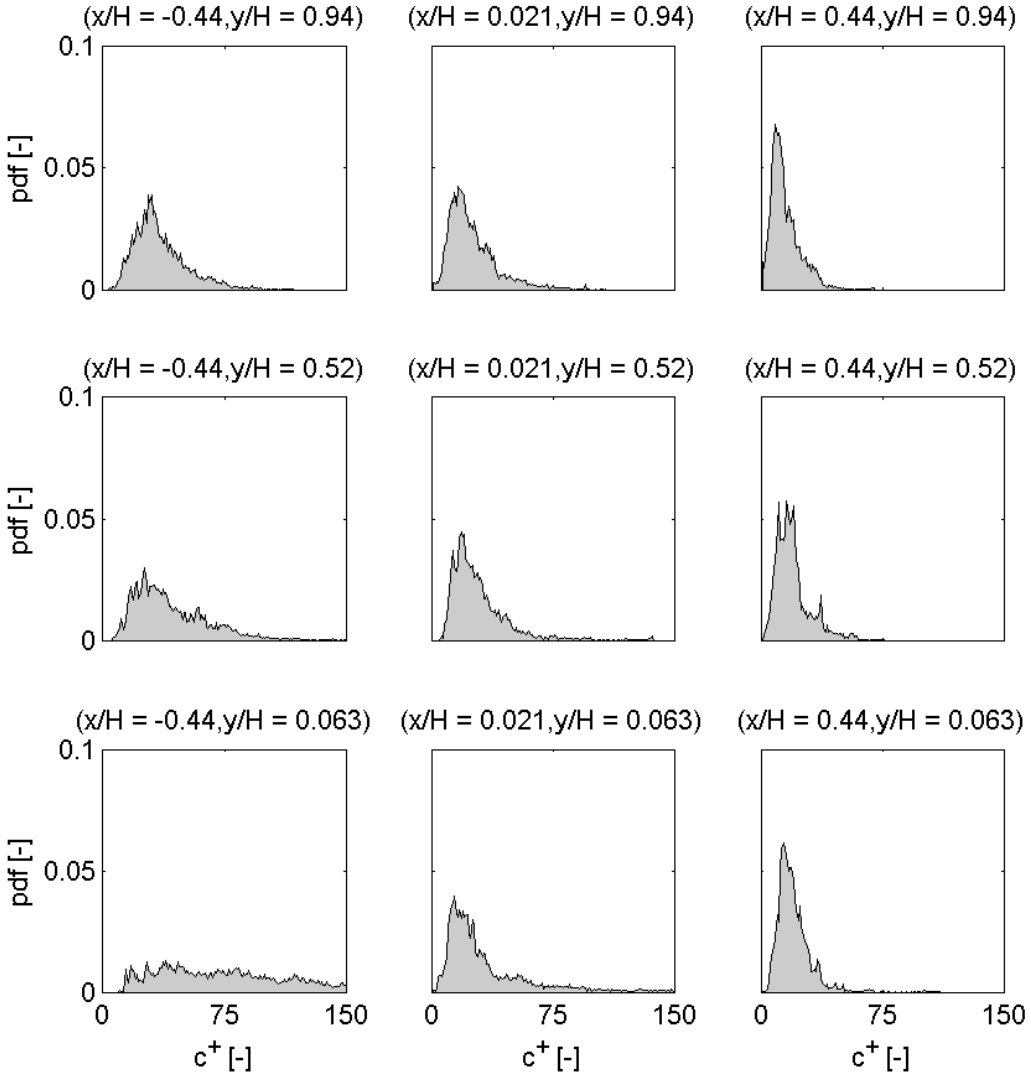

Figure 5. Probability density function (PDF) of normalized concentration at several location along the mid-plane of the street canyon (z/H = 0). Bin size is one unit of normalized concentration.

5 CONCLUSIONS

Unsteady simulations of coupled flow and dispersion inside a street canyon were performed and some statistical properties of the concentration field were analyzed. We focused on the time-averaged concentration, the variance and the probability density function (PDF) at various locations in the urban street canyon. The following observations were made:

- The region in the immediate neighborhood of the pollutant source is not only characterized by a high mean concentration, but also by a large variance.
- The PDF in the mid-plane of the street canyon was found to be wider and more uniform at near-ground locations close to the leeward wall, and narrower and more pronounced at locations higher above the ground and closer to the windward wall.
- At locations characterized by a wide PDF, long time periods are needed to determine statistical quantities, such as the mean and the variance, at a given confidence level.

We have shown that carefully conducted numerical simulations are capable to provide accurate and detailed information on concentration fluctuations in urban street canyons, at high spatial and temporal resolution. The results in this paper clearly illustrate the need for sufficiently long averaging times in unsteady numerical simulations, and, by analogy, also in wind tunnel tests and during field campaigns. We believe these observations are relevant to all modelers and experimentalists, involved in pollutant dispersion research.

Physical and numerical modelling of dust dispersion in the leeward zone of two single-standing buildings

Cornelia Wevers, Rüdiger Höffer

Wind Engineering and Fluid Mechanics, Ruhr-Universität Bochum,
Universitätsstraße 150, Bochum, Germany

ABSTRACT: The aim of this work is to define a model setup for a suitable and economical prediction of dust/particle dispersion and deposition around buildings driven by an atmospheric boundary layer (ABL) flow. The dispersion behind two different single buildings is modelled physically and numerically. The numerical simulations with gas and particle dispersion show different results in comparison to the physical tracer gas experiments. The normalised concentrations behind the single cube are overpredicted and underpredicted behind the single-standing hall with an open leeward side. The used wind tunnel technique does not allow the simulation of particle settling, in contrasts the numerical simulation is able to model particle deposition using different particle diameters in the gravity field, which is shown in a pre-study.

KEYWORDS: dispersion, particle transport, CFD, wind tunnel, Eulerian, Lagrangian

1 INTRODUCTION

To model dust/particle dispersion and deposition from diffuse sources in the atmospheric flow physical and numerical simulations were combined and used together in this study. In the past, several researchers investigated numerical simulation approaches for urban pollution dispersion in comparison to physical models [1], either for gaseous pollutants [2,3,4] or for particle dispersion [5,6]. Numerical CFD calculations need to be compared to physical experiments to ensure a proper prediction of the target values and to proof the suitability of the numerical model and the dispersion characteristics. But before adopting a physical model for validation purpose it needs to be validated and tested itself. For this reason first a geometrically simple test case, namely a cubic building with a pollution source on the building top is used to validate the experimental set up for dispersion modelling (cf. Fig. 1 Case1). The dispersion process itself depends on the flow field and in detail on the existent turbulence quantities. In a previous work the validation of the computed wind field around bluff buildings using the commercial code ANSYS CFX and the same simulation setup compared to this study were performed with the VDI Guideline 3783-9 (VDI = The Association of German Engineers), [7]. This validation shows a suitable agreement between the experimental and numerical predicted velocity components within a given range [8,9]. The target values of this work are the nondimensional concentration distributions. For that reason the validation test case from the wind tunnel model, the cube, is also used for CFD calculations in order to compare the computed concentration values with the performed experiments. As idealised case of use a leeward open industrial hall (Case 2 in Fig. 1) with a source inside was placed in the ABL-flow. In real live such buildings dusty goods like construction or soil materials are handled and storage. Due to the wind around and through the halls emitted particles are transported outwards and interact with the environment. The other way around, numerical calculations were used to find appropriate and optimal measurement positions in the wind tunnel for detect the concentration distribution behind the buildings.

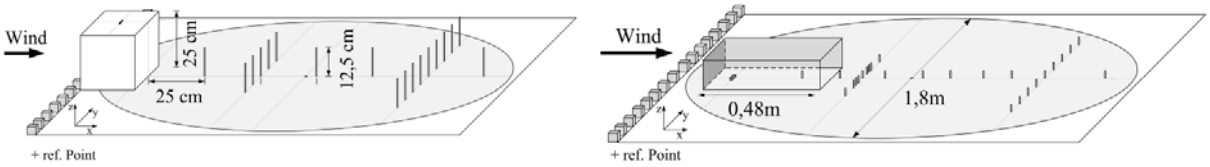

Figure 1. Left: cube with source on the top (Case 1), right: leeward open hall with source inside (Case 2).

One main disadvantage of the physical approach is the difficulty of modelling particle tracking because of the scaling requirements (see Chapt. 2.1.2). Thus, the physical experiments were performed using a tracer gas, assuming that very small dust particles are suspended in air and not affected by gravity. The same tracer gas approach (EULERIAN model) is then used in the numerical calculation for comparison. In contrast the advantage of the numerical model is the possibility to simulate particle transport in real scale while using a LAGRANGIAN model approach. Therefore, at first, gravity-free dispersion simulations with uniform particles were performed and compared to the tracer gas approach. Afterwards, simulations with gravity and different particle diameters were done in order to model particle deposition. The physical plausibility of the simulated particle behaviour is analysed heuristically in a first step.

2 DESCRIPTION OF THE PHYSICAL AND NUMERICAL MODELS

2.1 *Physical model*

2.1.1 *Boundary conditions and measurement techniques*

The physical tracer gas experiments are performed in the boundary layer wind tunnel of the Ruhr-Universität Bochum. The oncoming turbulent flow is generated using a COUNIHAN-setup [10] and corresponds to an atmospheric wind over urban terrain with a real roughness length z_0 = 0.1m (geometrical scale 1:200). In Figure 2 the dots show measured flow characteristics, like vertical velocity profile and turbulence quantities in x-direction [11].

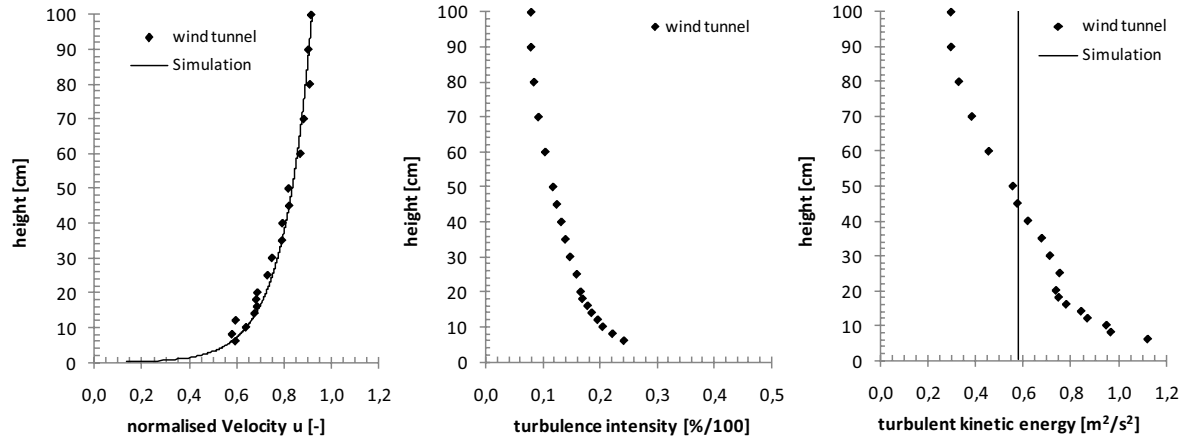

Figure 2. Characteristics of the turbulent boundary layer flow in the wind tunnel [11] and used inlet conditions for the numerical approach, left: velocity profile, middle: turbulence intensity, right: turbulent kinetic energy (all in x-direction).

The dust phase is modelled with Sulfurhexafluorid (SF6) diluted in Nitrogen (N2) to achieve the same fluid capacity like air. The source is geometrically modelled in such a way, that the mo-

mentum flux densities of the tracer and of the air flow in source height are almost equal. For both cases, the concentrations were measured along three axes, two laterals and one longitudinal (see Figure 1) in certain heights with an Electron Capture Detector (ECD). Under consideration of all fluid parameters the local concentrations $\rho_{SF6,i}$ are measured and normalised with a reference velocity u_{ref}, height z_{ref} and the source mass flow $\dot{m}_{Q,SF6}$ to a nondimensional concentration coefficient C_i:

$$C_i = \left(\rho_{SF6,i}\, u_{ref}\, z_{ref}{}^2\right) / \dot{m}_{Q,SF6} \tag{1}$$

For testing the repeatability and independency from the measured values of the parameters variations of the experiments were made with different flow velocities, source strengths and measurement times.

2.1.2 *Scaling requirements for particle simulation*

The basic principle of a boundary layer wind tunnel test is to scale the wind field so that a certain similarity of wind velocity profile, turbulence intensity and turbulent length scales exists compared to the real wind [12]. One measure for similarity between real and model scale flow is the Flow-REYNOLDS-Number $Re_F = \rho_f\, u\, L/\eta_f$, using a reference velocity u, a characteristic building length L and the fluid density ρ_f as well as the dynamic fluid viscosity η_f. It is usually not possible to match the real Re_F-Number in the experiments, but to ensure a similarity of the flow around bluff buildings $Re_F \geq 10\,000$ is recommended in the literature for the experiments [13].

Physical experiments with particles were done in the past either for saltation of scaled snow [14,15] or for analysis of real sand motion [16,17,18]. In case of modelling aeolian particle motion requirements for particle scaling in a wind tunnel simulation are summarized e.g. by Kind [19], White [20] and Durán et al. [21]. Kind performed a similarity analysis and stated out, that "it will often be impracticable to simultaneously satisfy all the simulation requirements […]", therefore compromises are necessary [19, p. 219]. There are three particle movement modes which develop due to the wind shear stress on the grain surface and due to atmospheric turbulence: suspension (free flight), saltation (short jumps on a surface) and creep or reptation [22]. The main influence on the mode is given by the ratio between particle size, particle settling velocity, particle spin, wind shear stress and turbulence intensity. Therefore, as scaling requirement, e.g. the ratio between the particle settling velocity and a reference velocity should be equal in real and model scale [19]. The similarity of the aerodynamic behaviour of the free flying particles is characterized amongst others by the Particle-REYNOLDS-Number $Re_p = \rho_f\, u_P\, d_P/\eta_f$, which describes the inertial and viscous effects at the scale of a grain. In case of fine sand (quartz, $d = 300\mu m$) the deposition velocity is $u_p = 3m/s$ [21] and the corresponding Particle-REYNOLDS-Number is $Re_p = 58.3$ ($\gg 1$, turbulent regime).

The consideration of all requirements can make it nearly impossible to find a proper material, which matches all requirements for modelling suspension, deposition and saltation simultaneously in a scaled physical wind tunnel experiment. Therefore, in general, only physical gas simulations are performed and then in the numerical approach discrete particles are considered. The development of the numerical set up is still progressing.

2.2 *Numerical model*

2.2.1 *Meshes, flow boundary conditions and simulation settings*

For both Case 1 and Case 2, the geometries and meshes were build regarding the used wind tunnel models and following the recommendations of Franke et al. [23]. In Case 1 the height of the cube is $H_{C1} = 25cm$, the width (W_{C1}) and the length (L_{C1}) are equal. For Case 2 the building height is $H_{C2} = 12cm$ and the size ratio is $H_{C2} : W_{C2} : L_{C2} = 1:2:4$. Block-structured hexahedral

volume meshes are generated with a maximum cell-growing ration of 1:1. The meshes were refined iteratively until the target values did not change much anymore. For the particle simulation in real scale the mesh was exported with a building height H_{C2} = 24m. Therefore Case 1 has c.a. 1.4Mio cells and Case 2 has c.a. 5.3Mio cells. The inlet profiles for velocity, turbulent kinetic energy (TKE) and its dissipation are modelled according to the method proposed by Richards et al. [24] to match the results of the performed physical simulations, see Figure 2. The lateral sides, the bottom and the building surfaces are defined as walls. The top boundary has a constant shear velocity in order to keep the vertical velocity profile as much as possible constant in horizontal direction [25]. The outlet has a relative static pressure of 0Pa. All numerical simulations were performed as REYNOLDS-Averaged NAVIER-STOKES (RANS) simulations with the Standard k-ε turbulence model using the commercial code ANSYS CFX 12.1. For the approximation of the convective terms the High-Resolution scheme is used, and the truncation error is set for the maximum residuals to 10^{-6} within 1000 iteration steps. The iteration convergence is observed using monitor probes behind the buildings.

2.2.2 *Modelling the dust dispersion*

The physical experiments for modelling the transport of the dust material use a tracer gas method as mentioned before. In order to use these experiments for comparison the dust in the numerical simulations is modelled in two ways. The first way describes the tracer as gas, like in the physical model, using an additional transported scalar variable (EULERIAN approach) and the standard gradient-diffusion-hypothesis (SGDH) for the scalar fluxes [26]. They are modelled amongst others using the turbulent eddy viscosity ν_t and the turbulent SCHMIDT-number Sc_t. The latter one describes the scale between the turbulent viscosity and turbulent diffusivity, thus the scale of transport values between momentum exchange and mass exchange [27]. Although Sc_t is not a constant [28,29], it is used as a constant in the gradient-diffusion-hypothesis. A proper value choice is an actual discussion of research [3,4,29,30]. The choice should be made case dependent. In this study the turbulent SCHMIDT-number is Sc_t = 0.9 and will be not vary for this study. The transport properties for the scalar are the same like for air at 25°C, which is defined as fluid for the whole domain. The source mass flow and velocity of the tracer are set with respect to the wind tunnel experiments. For analysis the nondimensional concentration is calculated with Equation (1). The second way to model the tracer is to track discrete particles in the continuous air phase using the RANS-calculated flow field (LAGRANGIAN approach). With EULER-forward integration of the particle velocity in discrete points the particles are moved along paths through the domain. The particle velocity itself is calculated from an analytical solution of the particle momentum equation, which sums all forces acting on a spherical particle [31]. The most relevant force is the drag force, which is calculated using STOKES-law in Equation (2). This includes the velocities of the fluid u_f and of the particle u_P as well as the particle diameter d_P, the dynamic viscosity η and the correction factor C_{cor}, which depends on the Particle-REYNOLDS-Number, used model from SCHILLER & NAUMANN in [32,31].

$$m_P \frac{du_P}{dt} = 3\pi\eta d_P C_{cor}(u_F - u_P) \tag{2}$$

Additionally the stochastic “discrete droplet” model from Gosman and Ioannides [33] is used to calculate the turbulent diffusion of each particle due to turbulent eddies with a characteristic fluctuation velocity u_i', length ℓ_e and lifetime τ_e:

$$u_i' = \Gamma\left(\overline{u_i'^2}\right)^{1/2} = \Gamma(2k/3)^{1/2} \quad ; \quad \ell_e = \left(C_\mu^{3/4} k^{3/2}\right)/\varepsilon \quad ; \quad \tau_e = \ell_e/(2k/3)^{1/2} . \tag{3}$$

The variable Γ denotes a normal distributed random number, k the local TKE, its dissipation ε and C_μ a constant [31]. For suspension modelling 80,000 numbers of positions with particles of diameter d_p = 2.5µm (quartz ρ_P = 2650kg/m^3) and a mass flow of $m_{Q,P}$ = 0.2kg/s were injected inside the hall (real scale sized). The maximum tracking time was set to 24 hours with an integration time step per particle of Δt = 1s. The nondimensional concentration C_i (Equ. (4)) is calculated comparable to Equation (1) using the averaged volume fraction from Equation (4). The summation is performed over all particles and time steps in a control volume CV and stored in each vertex; Δt is the particle integration step, N_P is the particle number rate, m_P is the particle mass and Φ_P the volume fraction [31].

$$C_i = \left(\overline{\Phi}_{P,i}\, u_{ref}\, z_{ref}{}^2\right) \Big/ \left(m_{Q,P}/\rho_P\right) \quad \text{with} \quad \overline{\Phi}_{P,i} = \sum\left(\Delta t\, m_P\, N_P\, \Phi_P\right) \Big/ \sum\left(\Delta t\, m_P\, N_P\right) \tag{4}$$

3 RESULTS AND DISCUSSION

3.1 *Independency of the flow-REYNOLDS-number and of the model scale*

The dependency of the inflow velocity, more precisely of the flow-REYNOLDS-number *Re*, and of the model-scaling was tested and analysed. The physical experiments were performed with a *Re* - number around *Re* = 42000 with $u_{ref} \approx$ 5m/s (> 10000, cf. 2.1.2). The normalised numerical results for gas and particle dispersion are not affected by different inlet velocities above a critical minimum velocity (e.g. model scale: $u_{ref} \approx$ 2,5m/s results in an undeveloped flow field). The normalised results of the gas dispersion are also not influenced by different scaling (model scale = wind tunnel scale and real scale). But, as expected, the particle simulations show clearly the necessity of particle scaling. When using the same particles (size and material) the normalised concentration distributions show higher values in model scale simulations compared to the real scale simulations. The particle size is too huge in the ratio to the model scale domain size and yields to higher concentrations by calculation of the volume fraction in Equation (4). Therefore, all numerical simulations were performed in real scale and not in wind tunnel model scale.

3.2 *Comparison of the normalised concentrations*

3.2.1 *Cubic building (Case 1)*

The flow and dispersion around the cubic building is one of the benchmark geometries in the German VDI Guideline 3783-12 for physical wind tunnel tests. Figure 3 demonstrate the concentration distributions behind the cube along the measurement axes, and Figure 4 shows the normalised concentration contours in the middle vertical plane. The conducted physical experiments give almost satisfying results compared to this guideline. It can be stated that the physical wind tunnel set up is able to reproduce the dispersion process behind the cube. In contrast to this, the numerical approaches overestimate the concentration by far in longitudinal direction and underestimate the lateral dispersion. Similar results were also found for isolated sources e.g. by Blocken et al. [4] and Gousseau et al. [34] and seem to be characteristically for a RANS SGDH approach. On the one hand several researchers found a high dependency of such results on the turbulent SCHMIDT-number Sc_t, as discussed in Chapter 2.2.2, so that a variation of Sc_t could lead to some improvement of the results. But on the other hand, to vary this number is not always a solution. For example Rossi et al. [29] pointed out, that the discrepancies "may reflect the inadequacy of the SGDH model in capturing the complex features of the scalar dispersion process, which cannot be compensated by adjusting the Schmidt number value." [29, p. 3]. In addition, the source on the top lies in a highly turbulent zone where an unsteady recirculation bubble influences the source, which cannot be captured by a RANS model.

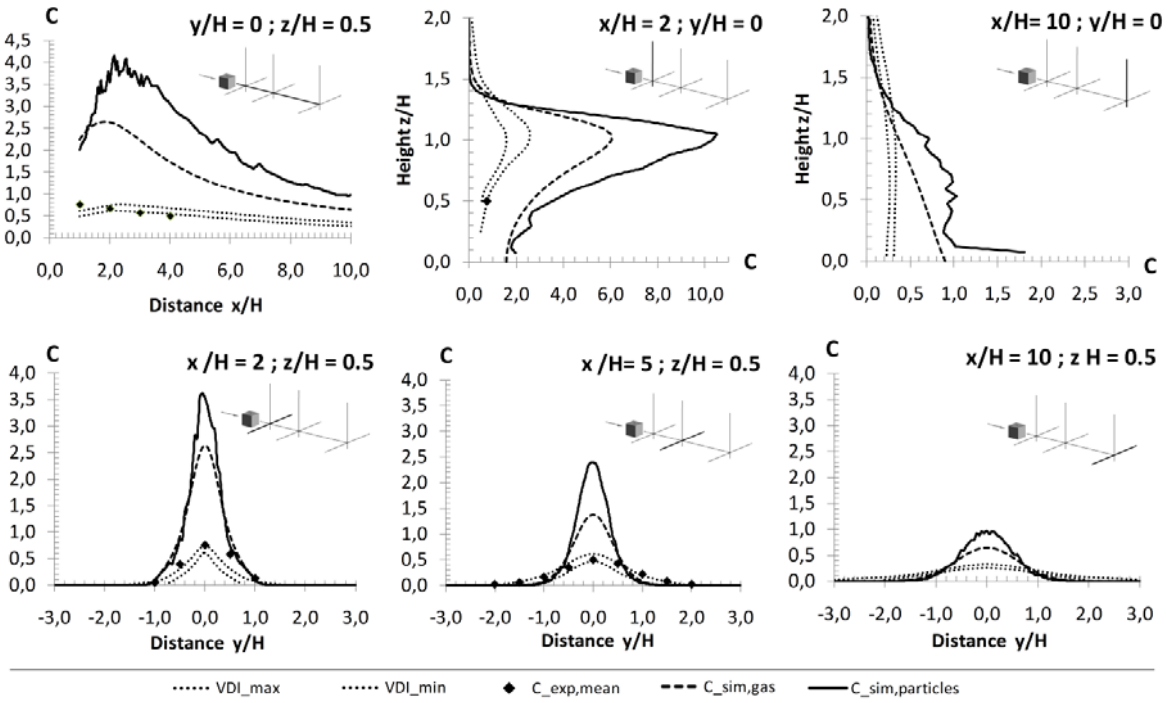

Figure 3. Longitudinal, vertical and horizontal concentration distribution behind the cube.

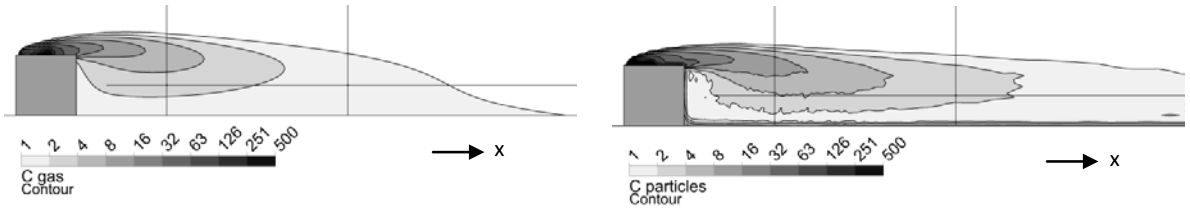

Figure 4. Simulated normalised concentration in the middle vertical plane, left: gas concentration, right: particle concentration; the straight lines determine the position of measurement axes.

3.2.2 *Leeward open hall (Case 2)*

Behind the hall with an open leeward side the normalised concentrations are compared along the three axes. Figure 5 shows in the first row the concentrations at height z = 0.5H and in the second row at height z = 0.25H. In general, the quantitative concentration distribution characteristics can be predict by the numerical approaches, but the gas simulation as well as the particle simulation underestimates the concentration values of the physical experiment, particularly inside the building (Figure 5 first column, negative x direction). This is strongly in contrast to the results of Case 1, where all numerical results are overpredicted compared to the physical measurements.

The dispersion in and outside the hall is mainly influenced by the recirculation zone behind the building, which leads to an interaction of the outer and inner flow field. Inside the hall the velocity and the pressure is low compared to the outer regime. The wake is pulling the dust out from the interior along the building walls (Fig. 6) and most of the dust (gas or particle mass) escapes the hall in the upper corners as well as close to the bottom (Fig. 7).

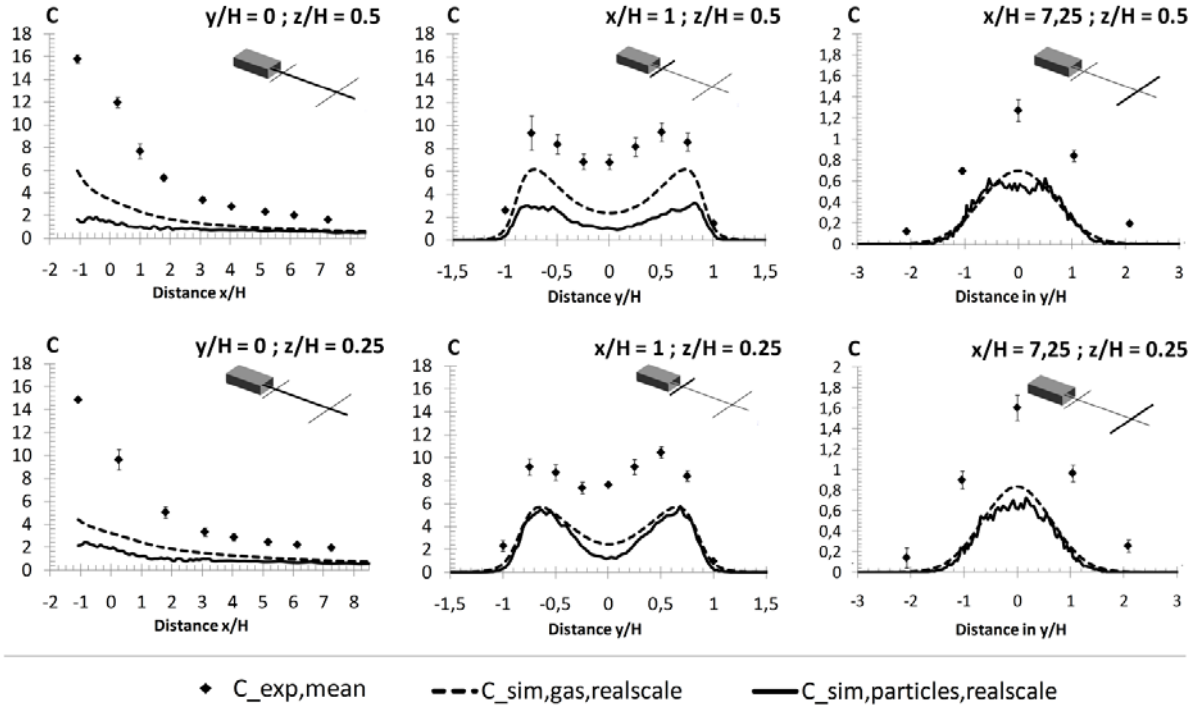

Figure 5. Comparison of normalised concentration distribution behind building "Case 2" along three measurement axes in two different measurement heights; all numerical simulations are run in real scale.

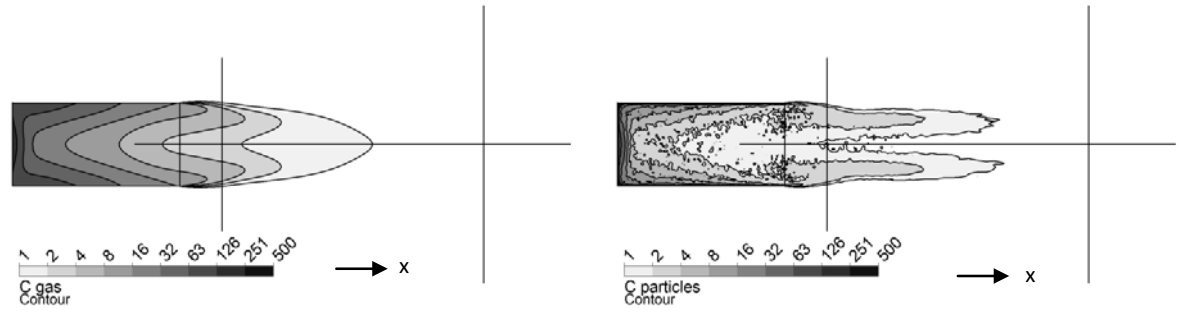

Figure 6. Bird eyes view on simulated normalised concentration contours in horizontal plane in height z/H=2, left: gas concentration, right: particle concentration; the straight lines determine the position of measurement axes.

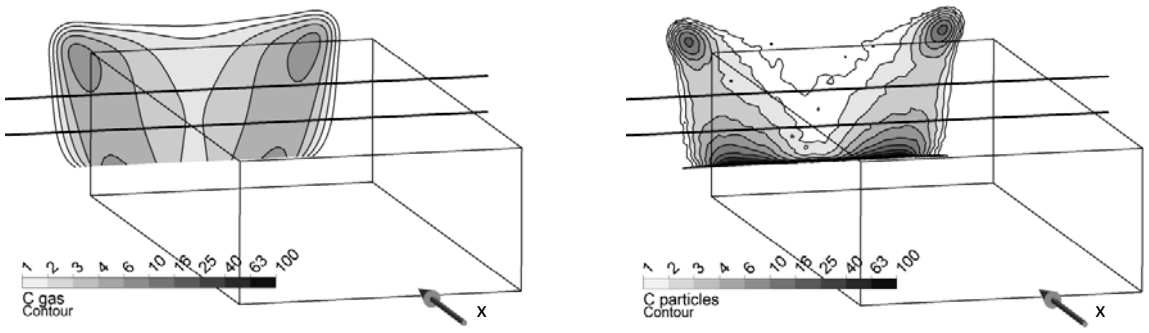

Figure 7. Simulated normalised concentration contours in vertical plane x/H = 1 behind the opening, left: gas concentration, right: particle concentration; the straight lines determine the measurement axes z/H = 0.5 and z/H = 0.25.

The wake re-enters the building from all sides in the middle and lower area of the opening and transports air and partially dust back into the hall. Inside of this recirculation, particulary in the two lateral vortices, the dust is stored and the concentration is higher, see middle column in Figure 5. This recirculation is a highly turbulent and non stationary process, occurring and collapsing or meandering, as could be seen in laser light sheets during the physical experiments. This unsteadiness may cause the high discrepancies, especially along the lateral axes, between the physical and numerical approach, because in the performed RANS simulation the recirculation is of steady state. So there is less lateral mixing and more dilution of the concentration from the building interior to the outer region compared to the physical results.

3.3 *Retention time of the particles and particle deposition*

The Lagrangian approach is able to provide information about the time resolved particle motion and particle deposition, when gravity is acting on the particles. In Case 2 the particles moves from the source to the opening in about 10 minutes, for u_{ref} = 10m/s. The longest retention time is about 30 minutes. In the presented results no gravity was activated and all particles had the same size. Figure 8 shows particle tracks of a performed numerical sand simulation with gravity and different particle diameter. Particles in suspension mode are usually smaller than 20µm and are kept aloft by turbulent eddies, grains between 20-70µm develop short term suspension which reaches distances of tens to hundred meters [35]. Sand grains with a size of 70-100µm are transported mainly in a series of short jumps (saltation) in a layer close to the bottom, in which the vertical component of wind velocity due to turbulence has no effect on the particle trajectories [36]. If the particle size is larger than 500µm the grains are moved in contact with the surface by reptation and creep. This physical behaviour was reproduced in a first numerical approach and shows acceptable results compared to literature (Fig. 8 right).

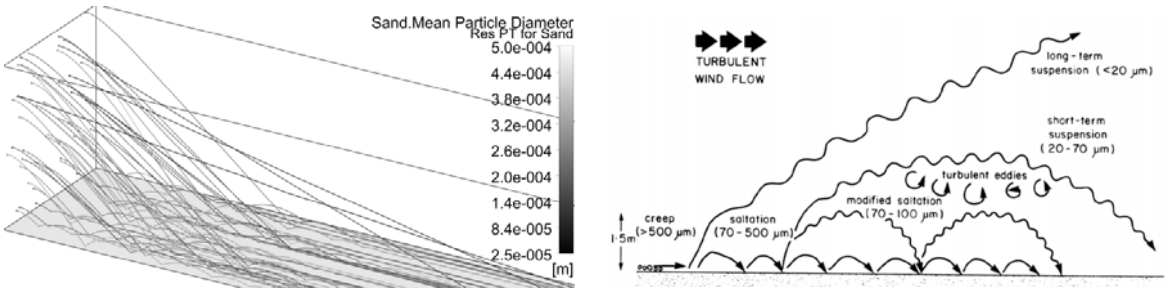

Figure 8. Particle tracks of aeolian sand, left: numerical simulation of sand particles in an empty domain (light = small 50µm – dark = large 250-500µm diameter, right: scheme of aeolian particle transport [Pye, 1987].

4 CONCLUSION AND OUTLOOK

The comparison of the numerically calculated concentration distributions in the leeward zones of two different buildings with results from wind tunnel measurements indicates a completely different behaviour of the models while using almost the same simulation settings. In case of a cubic building with one local source on the top a high overestimation of the concentrations in longitudinal direction and an underestimation of the lateral dispersion are found. In contrast to this, the numerical results of the concentration distribution behind the open hall show better agreement but underestimate the concentration distribution in longitudinal direction. It can be stated that the dispersion behind an idealised geometry with a locally placed source in a highly turbu-

lent zone is more difficult to predict than the dispersion behind a more complex case. Such results were also found by other researchers, e.g. [4]. In case of an open hall the source itself is diffuse and the dispersion process is affected mainly by the recirculation behind the hall. It is not possible to generalise the suitability of a RANS model for dispersion modelling. It depends on the type, location and surrounding of the source. Large Eddy Simulation gives better results compared to physical experiments for pollution dispersion [37,38], but it is not a useful alternative until today because of the required high expenses in calculation time and computer power. The comparison of the flow field and turbulence quantities is matter of future works in order to define more precisely the transport mechanisms. The time resolved LAGRANGIAN particle model provides more detailed information about the particle transport compared to the EULERIAN approach, like tracking time or particle-wall interaction. In future work, the deposition and interaction of the particles with the walls shall be modelled/improved, to analyse e.g. the retention effect of dust in such a hall. But particle erosion and accumulation is difficult or rather impossible to model. One alternative to the LAGRANGIAN approach could be the use of an EULERIAN Multiphase model, like the Algebraic Slip Model, which is commonly used for snow modelling [39,40].

CFD simulations of pollutant gas dispersion with different buoyancies around an isolated building

Yoshihide Tominaga and Lin Guo-Cheng

Department of Architecture and Building Engineering, Niigata Institute of Technology, Kashiwazaki, Niigata, Japan

Abstract

CFD simulations are performed for flow and dispersion fields around an isolated cubic building model with tracer gases exhausted behind it. The tracer gases have three different buoyancies due to density differences with ambient air. Therefore, they behave as neutral, buoyant and dense gases. Two modeling approaches, steady RANS and LES, are adopted and compared. For the neutral gas case, all the RANS computations show very large concentrations near the floor, which did not appear in the experimental and LES results. The same tendency is observed for the buoyant gas case. These high concentrations are mainly caused by underestimation of turbulent diffusion behind the building. On the other hand, since the density gradient is negative (stable) in the dense gas case, the discrepancy in steady-RANS is not noticeable. The difference between the two modeling approaches for the dense gas case is relatively small compared with those for the neutral and buoyant gases.

Keywords: CFD, Dispersion, Buoyancy, Building, Turbulence model

1 INTRODUCTION

Prediction of contaminant dispersion around buildings is one of the most important subjects in the fields of wind engineering, air-conditioning engineering, etc. A number of investigations have been carried out for predicting turbulent diffusion around buildings using wind tunnel tests. However, there are several difficulties and limitations with wind tunnel tests in comprehending the very complicated turbulent diffusion process around buildings located in atmospheric boundary layers.

Numerical methods based on CFD (Computational Fluid Dynamics) for simulating flow and diffusion fields have developed rapidly as a new analysis tool for wind engineering. Much research has been conducted on pollutant dispersion around buildings using the CFD technique (e.g. Blocken et al., 2008; Tominaga and Stathopoulos, 2010). Most of these previous studies have treated tracer gases as neutrally buoyant (passive) scalar (e.g. Hanna et al., 2004). Even when using a lighter or heavier tracer gas than air in an experiment, buoyancy effect of pollutants on a dispersion field has not been explicit in many cases. However, negative or positive buoyancies in pollutants have a large influence on flow and dispersion fields (Gavelli et al., 2008; Meroney, 2010; Hu et al., 2011).

In the present study, CFD simulations are performed for flow and dispersion fields around an isolated cubic building model, where the tracer gases are exhausted from behind the building. The tracer gases are treated as neutral, buoyant or dense compared with ambient air. Various turbulence models including two modeling approaches, steady Reynolds-averaged Navier-Stokes (RANS) and Large-Eddy Simulation (LES), are used and compared. Effects of pollutant buoyancies on the prediction results by various models are investigated by comparison with wind tunnel experiment results.

2 FLOW AND DISPERSION FIELD

2.1 *Target configuration*

The target configuration was determined based on the experiment reported in Tominaga et al. (1992, 1997). Figure 1 illustrates the flow situation analyzed here. A cubic building model 0.2m high was located in the turbulent boundary layer. Here, x_3 is the vertical direction. The Reynolds number based on $<u_b>$ and H is 5.7×10^3. It was confirmed in preliminary experiments that Reynolds number effect is small. A square-shaped gas source with a side length of 0.025H was set at ground level in the recirculation region behind the cube. Exit gas speed $<w_s>$ was $0.5<u_b>$. The cases compared in this study are listed in Table 1. The densimetric Froude numbers Fr_d, defined by Eq. (1), for the buoyant and dense gas cases were determined so that their absolute values were identical.

$$Fr_d = \frac{g\Delta\rho H}{\rho_a < u_b >^2} \qquad (1)$$

where ρ_a is ambient air density; ρ_s is gas density; $\Delta\rho = \rho_s - \rho_a$.

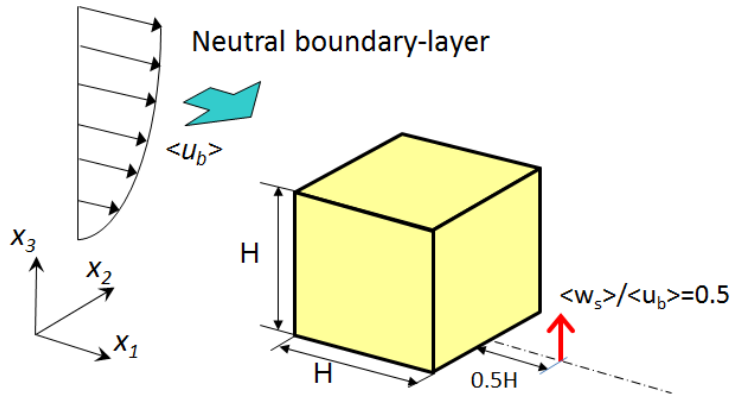

Figure 1. Model flowfield.

Table 1. Cases investigated.

Case	ρ_s/ρ_a	Fr_d	
1	1.0	0.0	neutral gas
2	0.3	-8.6	buoyant gas
3	1.7	+8.6	dense gas

2.2 *Experimental setup*

Experiments were carried out in the boundary layer wind tunnel at the Institute of Industrial Science, the University of Tokyo. The power law exponent of the vertical profile of the inflow velocity was 0.25. The streamwise turbulent intensity at building height H was approximately 20%. The upwind mean velocity at building height H was 0.4 m/s. The neutral gas C_2H_4 was used as a tracer gas. In order to take into account negative and positive buoyancies shown in Table 1, a mixture of He and C_2H_4 and of SF_6 and C_2H_4 were used for the buoyant and dense gases, respectively. Concentration measurements were performed using a high-speed total Hydro-Carbon Analyzer (Technica; H-THCA-01). Wind velocity was measured by a split fibre probe (Dantec Dynamics; 55R55) and a CTA module, which can discern the three-dimensional components of velocity vector. Sampling frequency was set to 10Hz to obtain 4,096 data for each measuring point.

3 COMPUTATIONAL SETUP

3.1 *Numerical methods*

The commercial software ANSYS FLUENT 13.0 was used for both RANS and LES computations based on a control volume approach for solving flow and concentration equations (FLUENT Inc., 2010).

1) RANS: Three types of turbulence models were used and compared: the standard k-ε model (SKE), the RNG k-ε model (RNG) (Yakhot et al., 1992) and the realizable k-ε model (RLZ) (Shih et al., 1995). All model constants were set to be the default values in the software. All the transport equations were discretized using a second-order upwind scheme. The SIMPLE algorithm was used for pressure-velocity coupling. The generation of turbulent kinetic energy due to buoyancy was included in the k equation by default of the software. Although the buoyancy effect on ε was also included, it was confirmed that its effect on the results was negligible.

2) LES: Two types of sub-grid scale (SGS) eddy viscosity models were used: the standard Smagorinsky model (SS; Smagorinsky 1963) with the empirical constant C_S=0.12 (Tominaga 2008a) and the dynamic Smagorinsky SGS model (DS; Germano et al. 1991). The filtered equation was discretized using a bounded central-differencing scheme. Time integration was second-order implicit. The computations were conducted for 800 non-dimensional time units t* (=t×<u_b>/H), which corresponds to 400 s in real time scale, to determine the time-averaged values. It was confirmed that the statistical results were almost repeatable over a longer averaging period.

3.2 *Domain, computational grid and boundary conditions*

The boundary conditions were set following basic guidelines (Tominaga et al., 2008b). The computational domain covered a volume of 21H(x_1)×13H(x_2)×6.5H(x_3). This domain was discretized into 1,112,200 hexahedral grids. These conditions were the same in both computations. Turbulence in the exhaust outlet flow was not considered.

1) RNG: The vertical distributions of <u_1>, k and ε at the inflow boundaries were based on the experiment. For the ground surface, the wall functions were modified for roughness, specified by an equivalent sand-grain roughness height k_s and a roughness constant C_r. k_s was defined using the function proposed by Blocken et al. (2007): k_s=9.793z_0/C_r. The value of z_0 was estimated by the velocity profile obtained by the experiment.

2) LES: A time-dependent inlet profile was generated by using the vortex method with a number of vortices N_v=190 (Gousseau et al., 2011). For the boundary condition at the solid walls (floor and building surfaces), a logarithmic-law was assumed.

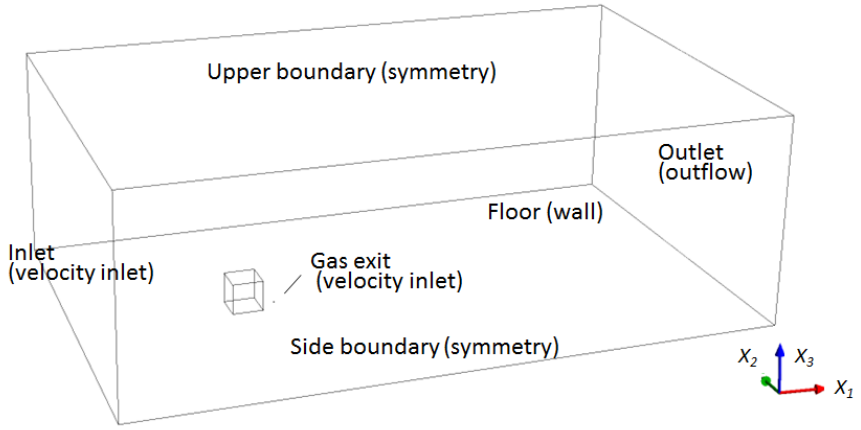

Figure 2. Computational domain.

4 RESULTS AND DISCUSSION

4.1 *Neutral gas case*

Figure 3 compares the contours of the time-averaged velocities of streamwise component ($<u_1>$) at the central section. Three computational results by the RANS approach show stronger reverse flow and longer reattachment length behind the building than those by two LES computations. In the RANS computations, the strongest recirculation flows are predicted by RNG and the weakest by SKE. The choice of SGS model in LES hardly influences the velocity predictions. The small recirculation region behind the building in the LES cases are mainly due to the fact that the periodic velocity fluctuation behind the building is well reproduced in comparison with RANS, as pointed out in previous studies (e.g. Tominaga et al. 2008a).

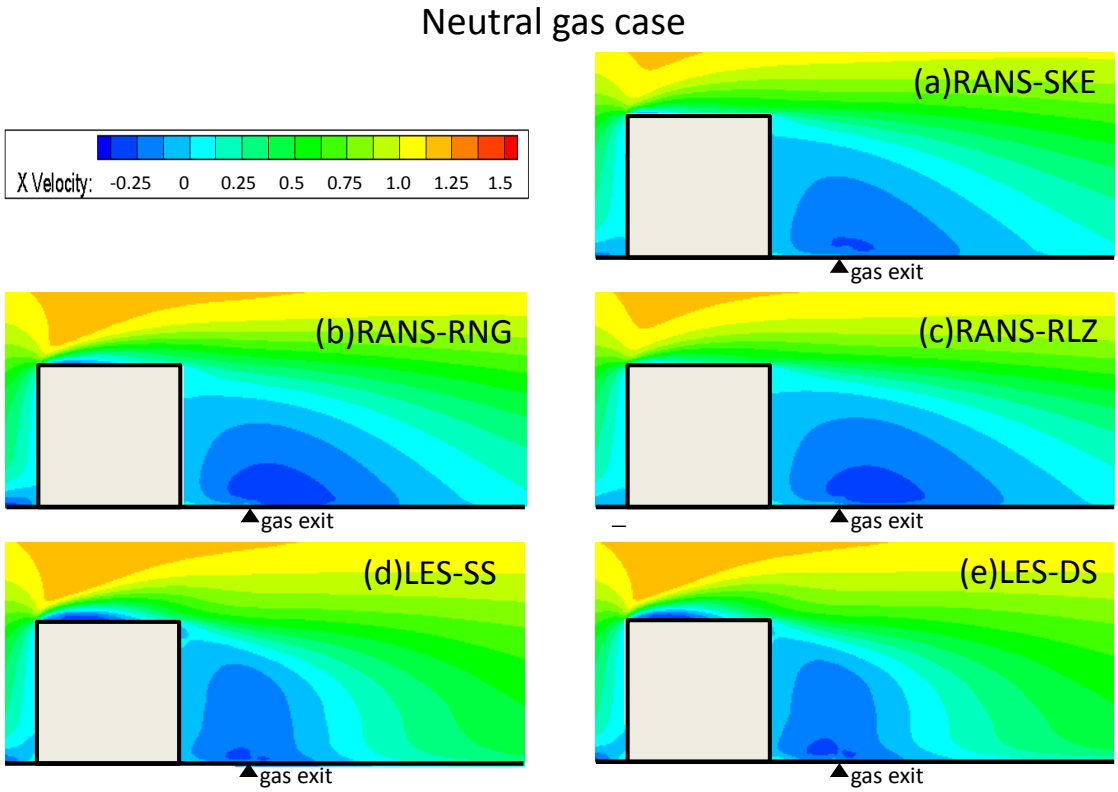

Figure 3. Contours of time-averaged streamwise velocity $<u_1>/<u_b>$ at center section: (a) RANS-SKE; (b) RANS-RNG; (c) RANS-RLZ; (d) LES-SS; (e) LES-DS.

Figure 4 shows the time-averaged concentrations at the center section. There is no significant difference among the general distributions of all models. It should be noted that the contour obtained by the experiment may give different expression from those of CFD because the experimental measuring pitch was coarse. In all the results, concentrations from the source exit are advected by the recirculation flow behind the building, and a high concentration region appears windward of the exit. The two LES cases predict smaller spread of concentration leeward of the exit in comparison with RANS. This difference between LES and RANS is mainly caused by the fact that the turbulent diffusion in the wake region is underestimated and the convective transport is dominant in RANS, as previously mentioned.

Figure 5 compares the vertical distributions of concentration at the mid-point between the building and the exit. All RANS computations show extremely large concentrations near the floor, which differs from the experiment and LES. The concentrations obtained by the two LES cases are lower and are closer to that of the experiment than those by RANS.

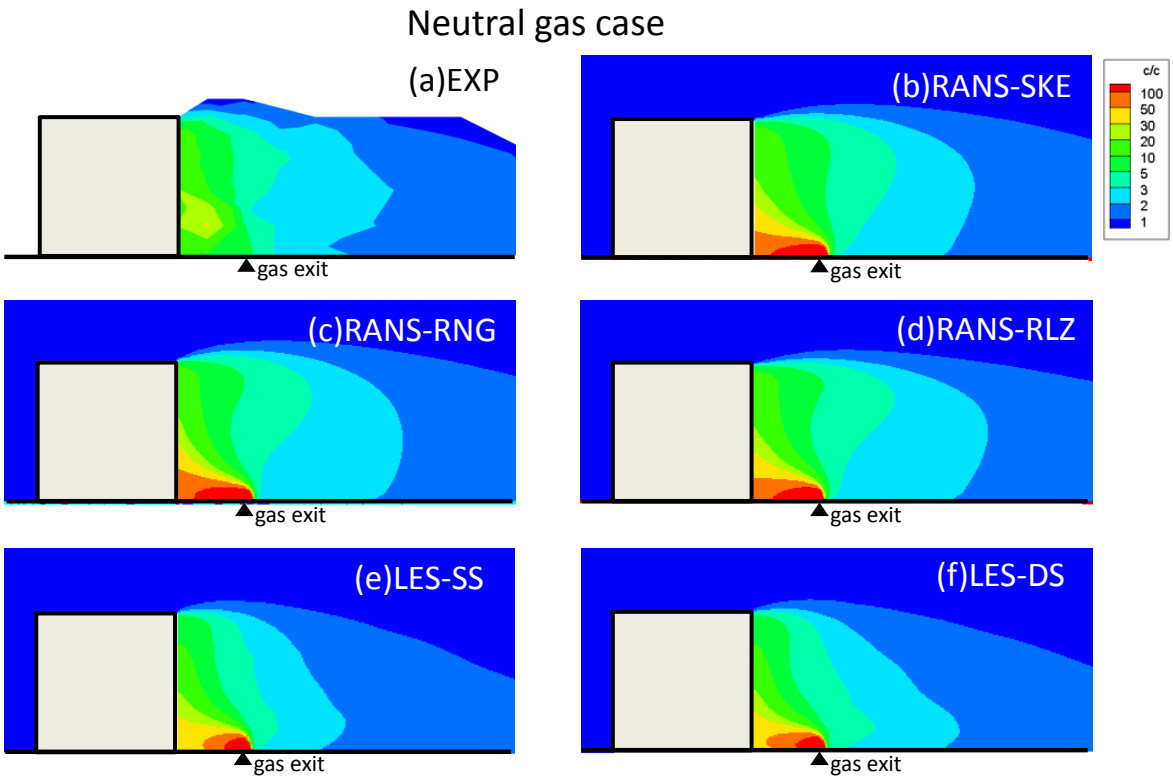

Figure 4. Contours of time-averaged concentration <c>/<c_0> (at center section): (a) experiment; (b) RANS-SKE; (c) RANS-RNG; (d) RANS-RLZ; (e) LES-SS; (f) LES-DS.

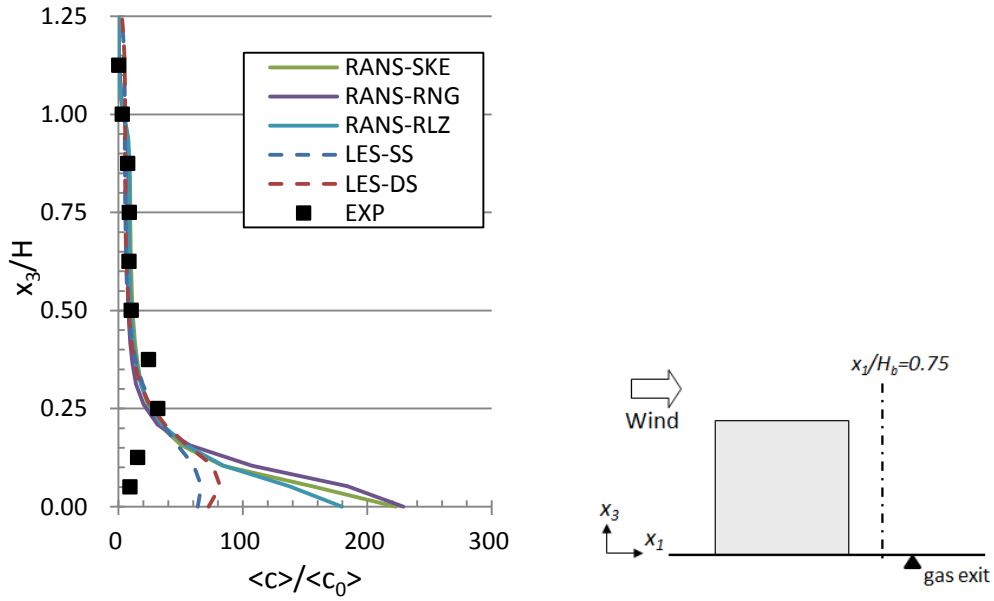

Figure 5. Vertical distributions of time-averaged concentration <c>/<c_0>.

4.2 *Buoyant and dense gas cases*

Only the RANS-RLZ and LES-DS cases, which show the best results for the neutral gas case for each modeling approach, are compared. Time-averaged concentration in the buoyant gas case is illustrated in Figure 6. The experimental results show that the concentration for the buoyant gas case is very low windward of the exit in comparison with that for the

neutral gas case. The concentration at the lower part of the wake region is especially low. These results are clearly affected by the positive buoyancy of the tracer gas. Although both CFD results reproduce this tendency due to buoyancy, the predicted upward spreads of the concentrations are smaller than those of the experiment. The vertical distribution of the time-averaged concentration along the line between the exit and the building is also shown in Figure 6. LES-DS succeeds in reproducing the tendency of the concentration to decrease near the floor as in the experiment, while the concentration increases as the position approaches the floor in the RANS-RLZ case. However, the concentration is underestimated by both models in the upper part.

The time-averaged concentration for the dense gas case is shown in Figure 7. The experimental results show very high concentrations in the lower part of the wake region. An extraordinarily high concentration region occurred near the floor windward of the source exit. This tendency is well reproduced in both CFD results. The vertical distribution of the time-averaged concentration is also indicated in Figure 7. The difference between the two models is small, and they both reproduce the tendency for the concentration to increase rapidly as the position approaches the floor. The difference between the prediction accuracies for the buoyant and dense gases can be explained as follows: For the buoyant gas, the flow field is more diffusive than for the neutral gas, because the density gradient is positive (unstable) in most of the wake region. Therefore, the previously-mentioned underestimation of turbulent diffusion behind the building in RANS acts more significantly than for the neutral gas. On the other hand, since the flow field is stable due to negative buoyancy and turbulent diffusion is suppressed for the dense gas, no such discrepancy occurs for RANS. Therefore, the difference between the two models is relatively small compared with the neutral and buoyant gas cases.

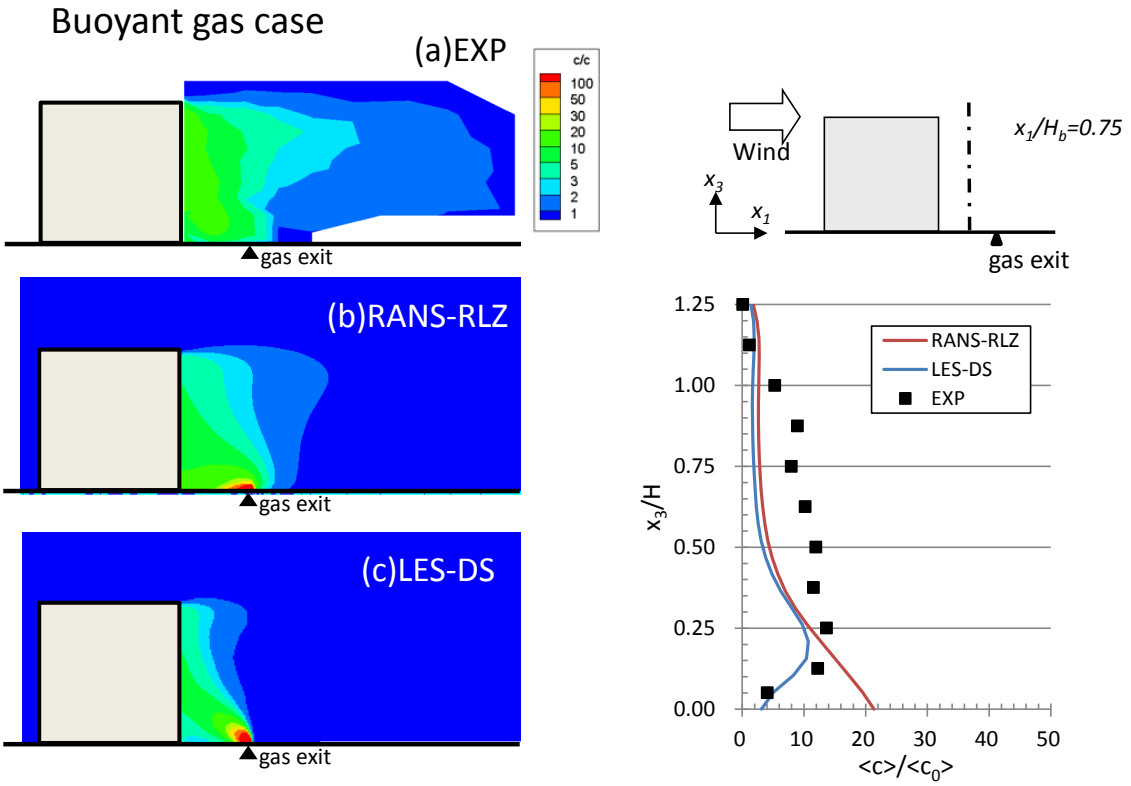

Figure 6 Time-averaged concentration <c>/<c_0> with buoyant gas. Left: Contour at center section obtained from (a) Experiment; (b) RANS-RLZ; and (c) LES-DS. Right: Comparison of vertical distributions at indicated line behind a building.

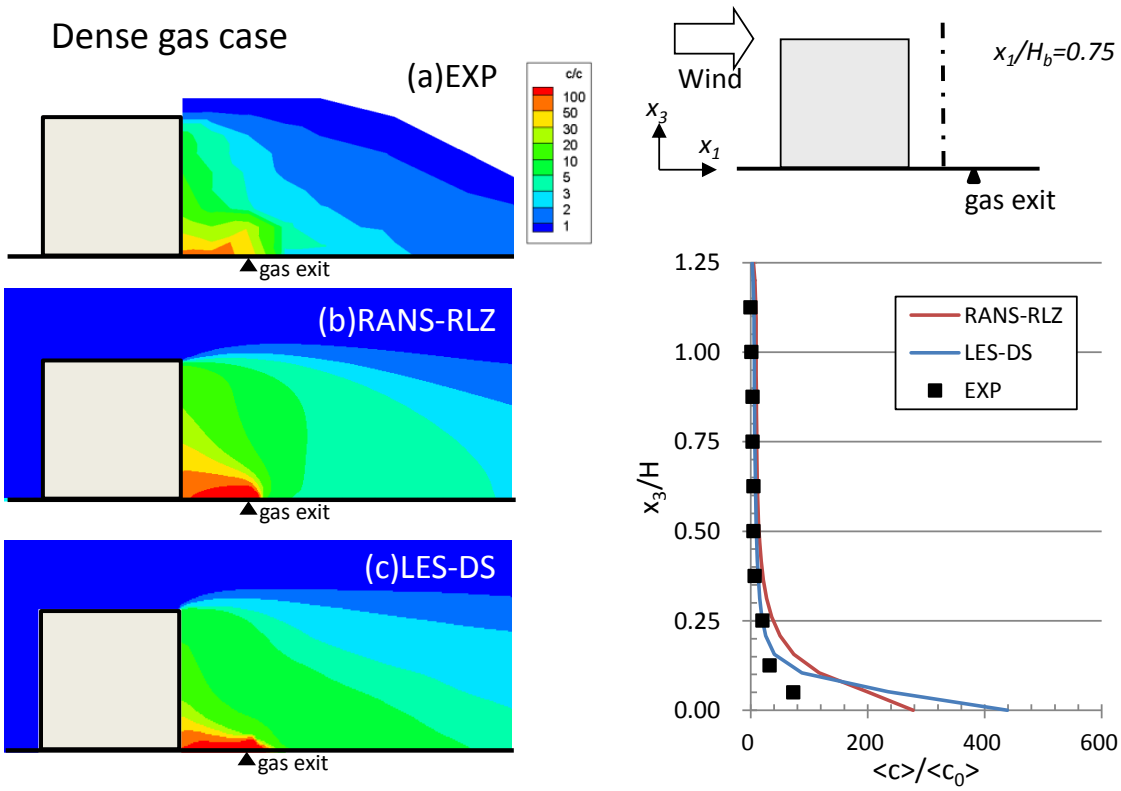

Figure 7. Time-averaged concentration <c>/<c_0> with dense gas. Left: Contour at center section obtained from (a) Experiment; (b) RANS-RLZ; and (c) LES-DS. Right: Comparison of vertical distributions at indicated line behind a building.

5 CONCLUSIONS

CFD simulations were performed for flow and dispersion fields around a cubic building model, in which the tracer gases were exhausted behind the building. The tracer gases were of three different densities, behaving as neutral, buoyant or dense gases. Two modeling approaches, steady RANS and LES, were used and compared. For the neutral gas, all RANS computations showed very large concentrations near the floor, which did not appear in the experimental and LES results. The same tendency was observed in the results for the buoyant gas. These high concentrations appearing in steady-RANS computations were mainly caused by underestimation of turbulent diffusion behind the building. On the other hand, since the density gradient was negative (stable) and turbulent diffusion was suppressed in the dense gas case, there was no noticeable discrepancy for steady-RANS. Therefore, the differences between the two models were relatively small in comparison with those for the neutral and buoyant gases. Detailed explanation on the influence of buoyancy effects on prediction accuracy will be presented in the final presentation.

NOMENCLATURE

c : concentration
<c_0>: standard gas concentration (=$q/(\langle u_b \rangle H^2)$)
<f> : ensemble average value of f
Fr_d :densimetric Froude Number (=$g\Delta\rho H/\rho_a \langle u_b \rangle^2$)
g : gravitational acceleration
H : building height
k : turbulent kinetic energy
q : gas emission rate

t^* : non-dimensional time unit ($=t<u_b>/H$)
u_i : three components of wind velocity
u_b : inflow velocity at building height H
w_s : exit velocity
x_i : three components of spatial coordinates (i=1,2,3: streamwise, lateral, vertical)
ρ_a : ambient air density
ρ_s : gas density

ABSTRACT: Large-Eddy Simulation is used to simulate wind-induced pollutant dispersion from a vent on the roof of a cubical building. The profiles of the computed mean value and standard deviation of the concentration in the wake of the building are compared to wind-tunnel measurements and good agreement is found. The velocity and concentration values at two monitoring points located in the shear layer developing above the roof have been sampled at each time step of the simulation. The statistics are presented and analyzed to provide insight into the dispersion process. In particular, the fact that the turbulent mass flux in the streamwise direction is directed from the low to high levels of mean concentration (counter-gradient mechanism) is explained.

KEYWORDS: Urban wind flow; scalar transport; turbulent mass flux; counter-gradient diffusion; turbulent Schmidt number.

1 INTRODUCTION

Computational Fluid Dynamics (CFD) is increasingly used to predict pollutant dispersion around buildings and in cities (e.g. Tominaga et al., 1997; Blocken et al., 2008; Gromke et al., 2008; Tominaga and Stathopoulos, 2010; Gousseau et al., 2011a; Gousseau et al., 2011b; Tominaga and Stathopoulos, 2011). Overall, it has been confirmed that Large Eddy Simulation (LES) is inherently more accurate than the Reynolds-Averaged Navier-Stokes (RANS) turbulence modeling approach for modeling wind flow and dispersion in urban environments (e.g. Tominaga and Stathopoulos, 2010; Gousseau et al., 2011a; Gousseau et al., 2011b; Tominaga and Stathopoulos, 2011).

Most of the two-equation RANS turbulence models like the standard or realizable k-ε models compute the turbulence-induced transport of concentration – and more generally, of scalars – based on the gradient of the mean value, with the so-called gradient-diffusion (GD) hypothesis, also called first-order closure:

$$\overrightarrow{Q_{a,t}} = -D_{a,t}\nabla A \tag{1}$$

where $\overrightarrow{Q_{a,t}}$ is the turbulent flux of a, $D_{a,t}$ is the turbulent diffusivity and $A=\langle a \rangle$ is the mean value of a. However, some recent studies (Rossi et al., 2010; Gousseau et al., 2011b) have shown that this hypothesis is not valid in the streamwise direction for dispersion around an isolated building. In this case, above roof level, the turbulent mass flux is directed backwards, i.e. from the low to high levels of mean concentration, in contradiction with Equation 1. This so-called counter-gradient (CG) mechanism of turbulent transport has also been reported in the literature for various cases such as a ground-level line source in a street canyon (Simoëns and Wallace,

2008), a line source in a turbulent boundary layer (Raupach and Legg, 1983; Lavertu and Mydlarski, 2005), or a stratified shear flow (Meroney, 1976).

The CG mechanism cannot be reproduced by RANS models which use Equation 1 to model the turbulent mass transport. Therefore, more elaborate models are needed. To support the choice of the existing appropriate model or to develop a new one, a more complete understanding of the physical mechanism of dispersion around bluff bodies is needed. The present study aims at exploring this mechanism with LES. Since the turbulent mass flux in a given direction is equal to the covariance of velocity and concentration, the observation of the statistics of these variables allows providing insight into the dispersion process and in particular to aid in explaning the CG mechanism in the streamwise direction.

The case under study corresponds to a wind-tunnel experiment which is briefly described in the next section together with the numerical model used. The experimental results are used to validate the CFD results in section 3. Next, the CFD simulations are used to monitor velocity and concentration statistics in two points located in the shear layer developing above the roof of the building, and the results are analyzed in the framework of turbulent mass transport.

2 NUMERICAL MODEL

2.1 Domain, grid and boundary conditions

The wind-tunnel experiment by Li and Meroney (Li and Meroney, 1983a; Li and Meroney, 1983b) has been reproduced with the Ansys 12.1 CFD code. It involves a cubical building model (height H=0.05m) immersed in a turbulent atmospheric boundary layer (ABL) with a mean velocity profile corresponding to a power law with an exponent equal to 0.19 and an aerodynamic roughness length z_0=7.5×10^{-5}m. Wind direction is perpendicular to the windward façade. At the center of the roof, helium is emitted by a 5mm diameter circular exhaust with a low velocity ratio M=0.19 (M=W_e/U_H where W_e is the vertical exhaust velocity and U_H is the mean velocity in the approaching ABL at building height). The Reynolds number based on H and U_H is equal to 1.1×10^4.

The computational domain is shown in Figure 1a. Its dimensions are 26H×11H×6H in the streamwise (x), lateral (y) and vertical (z) direction, respectively, following the COST Action 732 (Franke et al., 2007) and AIJ (Tominaga et al., 2008) guidelines. The ground and building walls are defined as no-slip walls. At the top and sides of the domain, symmetry boundary conditions are set. Zero static pressure is imposed at the outlet face of the domain. At the inlet, unsteady perturbations are super-imposed on the prescribed mean velocity profile by the vortex method (Mathey et al., 2006) with a number of vortices equal to 190. This technique also requires the vertical profiles of turbulent kinetic energy and dissipation rate, which are prescribed based on the experiments.

The computational grid has been created with the surface grid-extrusion technique (van Hooff and Blocken, 2010). It counts 1,480,754 cells in total and the building is discretized into 32 cells in the vertical direction and 25 cells in the lateral and streamwise directions (Fig. 1b). The monitoring points P1 and P2 are also shown in Figure 1b. P1 is located at x/H=1; y/H=0; z/H=1.24 and P2 at x/H=2; y/H=0.25; z/H=1.24.

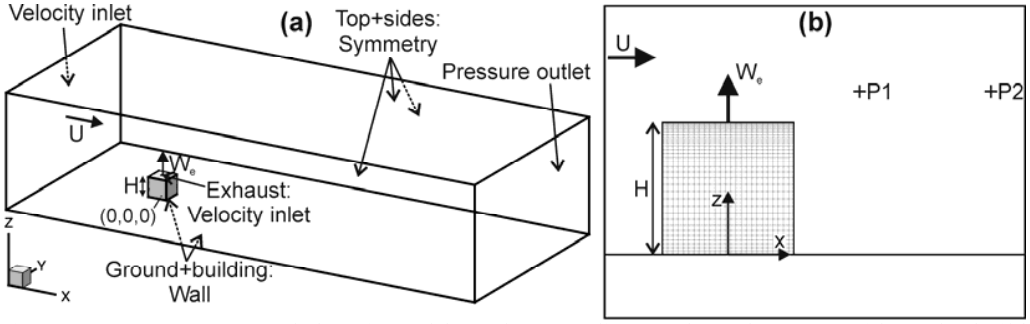

Figure 1. (a) Computational domain and boundary conditions. (b) Side view: grid on the building surface (total number of cells: 1,480,754) and location of the two monitoring points P1 and P2.

2.2 LES and dispersion modeling

In the remainder of the paper, the Reynolds decomposition is used for all variables; for example a is decomposed into its time-average component $A=\langle a \rangle$ and its fluctuation a' such that $a=A+a'$. Furthermore, in what follows, the overbar is used to symbolize the spatial-filtering operator. Note that it will be used only in this section and will be omitted in the remaining of the paper.

LES has been used with the dynamic Smagorinsky subgrid-scale (SGS) model (Smagorinsky, 1963; Germano et al., 1991; Lilly, 1992): the Smagorinsky coefficient C_s which allows computing the SGS turbulent viscosity is evaluated at each time step, based on the smallest resolved scales of motion.

The Eulerian approach has been adopted to compute the transport of the tracer gas concentration (c). In the filtered dispersion equation, the SGS mass flux $\overrightarrow{q_{SGS}}$ stands for the effects of the smallest scales of motion on the dispersion process. It is assumed to be proportional to the gradient of resolved concentration:

$$q_{SGS,i} = \overline{u_i c} - \overline{u}_i \overline{c} = -D_{SGS} \frac{\partial \overline{c}}{\partial x_i} \tag{2}$$

where D_{SGS} is the SGS diffusivity, computed with a dynamic procedure in the similar way as C_s (Moin et al., 1991).

The turbulent mass flux $\overrightarrow{Q_t}$ is the combined effect of the concentration and velocity fluctuations, plus the mean SGS mass flux:

$$Q_{t,i} = \langle \overline{u}_i' \overline{c}' \rangle + \langle q_{SGS,i} \rangle \tag{3}$$

Reference concentration (C_0) and flux (Q_0) are used to make the variables non-dimensional. These quantities are defined by:

$$C_0 = \frac{Q_e}{H^2 U_H} \tag{4}$$

$$Q_0 = C_0 \times U_H \tag{5}$$

where Q_e is the pollutant exhaust rate.

Discretization of the filtered momentum equation is performed with a second-order accurate bounded central-differencing scheme. A second-order scheme is used for the spatial derivatives of the other equations (energy, concentration). Pressure interpolation is second order. The non-iterative time advancement scheme is used for the unsteady solver, with the fractional step meth-

od for pressure-velocity coupling (Kim and Moin, 1985). One single outer iteration is performed per time step, allowing reduction of the computational time needed for the simulation. A fixed time step Δt^*=0.066 in non-dimensional time units ($\Delta t^* = \Delta t \times U_H/H$, where Δt is the physical time step) has been set. After an initialization period, which allows losing the dependence on the non-physical initial state, averaging is performed during t^*=1,584. The data at the monitoring points are stored at each of these 24,000 time steps.

3 MEAN CONCENTRATION AND TURBULENT MASS FLUX

The profiles of the non-dimensional concentration coefficient ($K=C/C_0$) and the non-dimensional standard deviation of concentration ($c_{rms}/C_{1G}=(<c'^2>)^{1/2}/C_{1G}$) obtained with LES along three vertical lines (x/H=1; 3; 5) in the vertical mid-plane are compared to the wind-tunnel measurements in Figure 2. The standard deviation of concentration is normalized by the mean ground concentration value at x/H=1 and y/H=0 (C_{1G}). Along these three lines, a good agreement is obtained for K (Fig. 2a). Close to the building, at x/H=1, the LES results over-estimate the concentration fluctuations (Fig. 2b). Along the two other lines, there is a very close agreement.

Contours of the different turbulent mass flux components are depicted in Figure 3. In this figure, the isolines $\partial C/\partial x_i$=0 in the corresponding directions are also shown (dashed lines) and, in circles, the sign of $\partial C/\partial x_i$ for each zone delimited by the dashed line. As far as the vertical and lateral components of the turbulent flux ($Q_{t,z}$ and $Q_{t,y}$) are concerned, the contours in Figures 3c and 3d show that turbulent mass transport operates as a diffusion mechanism directed from the high towards the low concentration values, i.e. from the centerline of the plume to its outer edges. In the streamwise direction, however, the mechanism is different. In the horizontal plane z/H=1.25 for example, and more generally in the large region above the roof level colored in light gray in Figure 3a, the streamwise turbulent mass flux is negative, i.e. directed towards the high levels of K. In this region where the turbulent mass flux and the mean concentration gradient are of the same sign, the CG mechanism of turbulent mass transport is present. Another CG zone is present in the near-wake of the building where both $Q_{t,x}$ and $\partial C/\partial x$ are positive.

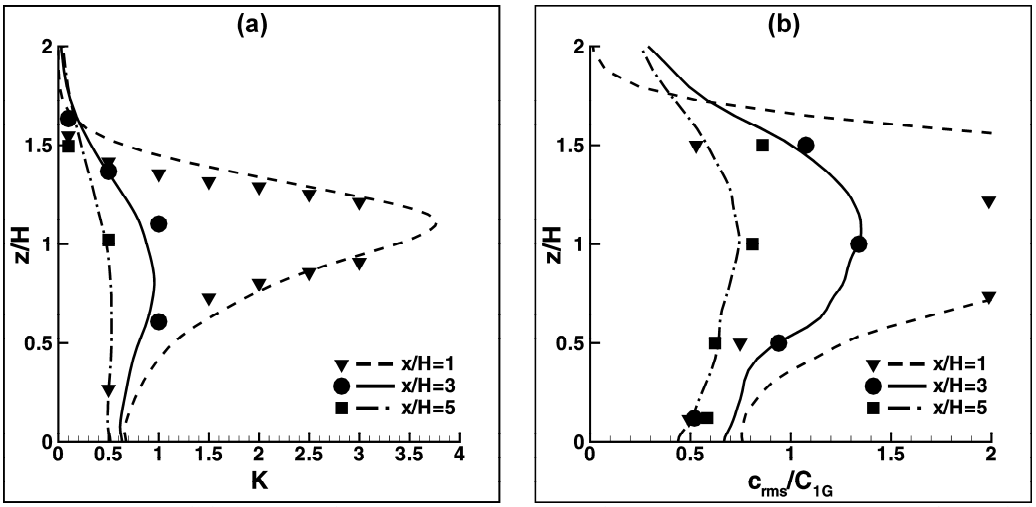

Figure 2. CFD validation: profiles of (a) non-dimensional concentration coefficient $K=C/C_0$ and (b) standard deviation of concentration normalized by C_{1G} along three vertical lines in the plane y/H=0. Symbols: wind-tunnel measurements (Li and Meroney, 1983a; Li and Meroney, 1983b); lines: LES of this study.

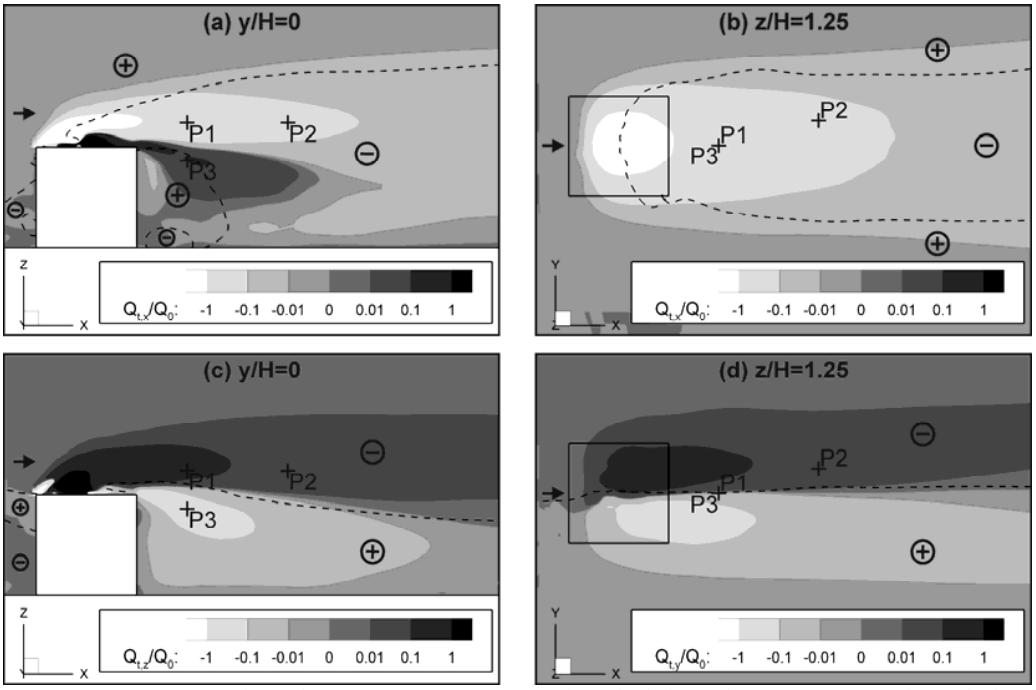

Figure 3. Contours of the (a,b) streamwise, (c) vertical, and (d) lateral components of the turbulent mass flux vector. The dashed lines represent the isolines $\partial C/\partial x_i$=0 in the corresponding direction: (a,b) x_i=x, (c) x_i=z, (d) x_i=y. On each side of the isoline, the sign of $\partial C/\partial x_i$ is indicated in circles (+: positive; -: negative). The CG mechanism of turbulent mass transport is characterized by $Q_{t,i}$ and $\partial C/\partial x_i$ of the same sign for a given direction

4 CONCENTRATION AND VELOCITY STATISTICS AT THE TWO MONITORING POINTS

The resolved concentration (c) and velocity components (u, v, w) have been recorded at the two monitoring points at each of the 24,000 time steps of the simulation. For the four variables of interest, the range of the non-dimensional fluctuations (a'_k/a_{rms}, where k is the sample number and the subscript rms indicates the standard deviation,) has been divided into 50 equal intervals I_i (i=1,…,50) and the frequency f_i of occurrence of a'_k/a_{rms} belongs to I_i has been calculated to build the histogram of frequency distribution:

$$f_i = \frac{n_i}{N} \quad (i = 1,...,50) \tag{6}$$

where n_i is the number of samples such as a'_k/a_{rms} belongs to I_i and N is the total number of samples.

The histograms for point P1 are shown in Figure 4. The histogram of concentration fluctuations (Fig. 4a) has an exponential-like shape, which indicates that P1 is most of the time characterized by a low background concentration level and the occurrence of rare but extremely high peaks of concentration (the kurtosis of the frequency distribution is high). Approximately 60% of the samples are of negative fluctuation and the average is raised by peaks of c' reaching up to 13 times the standard deviation. This asymmetry around the mean is quantified by the high skewness value. This shape of frequency distribution corresponds to measurements by Fackrell and Robins (Fackrell and Robins, 1982) far from the ground in the case of an elevated point source and was attributed to the meandering motion of the plume caused by large turbulent eddies.

Here, the largest turbulence scales are of the order of the cube size, larger than the size of the plume at P1, and tend to move the plume as a block, resulting in the high intermittency observed at this monitoring point.

The frequency distribution of u'/u_{rms} shows negative skewness (Fig. 4b): among the samples, the majority is of positive fluctuation but some of them are characterized by a large negative u'. The opposite holds for the vertical velocity fluctuations, whose frequency distribution is right-tailed (Fig. 4d). Considering that P1 lies in the vertical symmetry plane of the computational domain, it is logical that the frequency distribution of v'/v_{rms} is symmetric with respect to its zero mean (Fig. 4c).

A similar approach can be used to analyze the statistics of the variables two by two. The bivariate histograms have been built for the three couples of variables (c'/c_{rms}; $u_i'/u_{i,rms}$). For example, for two variables a and b, the range of the non-dimensional fluctuations has been divided into an arbitrary number of intervals (here: 20), say I_i for a'_k/a_{rms} and J_j for b'_k/b_{rms}. For given i and j, the frequency $f_{i,j}=f(I_i,J_j)$ is the ratio of the number of samples $n_{i,j}$ for which a'_k/a_{rms} belongs to I_i and simultaneously b'_k/b_{rms} belongs to J_j to the total number of samples N:

$$f_{i,j} = \frac{n_{i,j}}{N} \quad (i, j = 1,...,20) \tag{7}$$

Each of the four combinations of signs of (c'/c_{rms}; $u_i'/u_{i,rms}$) is associated with a specific event of pollutant transport. Observing the bivariate histograms gives therefore an indication of which events are the most frequent among the samples and/or contribute most to the turbulent flux. This so-called quadrant analysis was first introduced for momentum transfer (Shaw et al., 1983) but is also widely used in the case of scalar dispersion (Chen, 1990; Cheng and Liu, 2011). The definitions of the quadrants are shown in Table 1, together with the name given to the corresponding event in the vertical direction, for which quadrant analysis is often used. Note that this nomenclature can also be used here for the lateral direction, considering the symmetry of our problem. The frequency of occurrence of a given quadrant Q_m is equal to the sum of the frequencies of the intervals which compose Q_m. This frequency multiplied by the average of $u_i'c'$ on Q_m ($<u_i'c'>_{|Qm}$) gives the contribution of the quadrant Q_m to the turbulent flux in the direction i.

Table 1. Numbering and definitions of the quadrants. The names of the corresponding events hold for the vertical direction, following (Chen, 1990).

Quadrant	u_i'	c'	Name (z-direction)
Q1	>0	>0	Ejection
Q2	<0	>0	Inward interaction
Q3	<0	<0	Sweep
Q4	>0	<0	Outward interaction

The contours of $f_{i,j}$ in the planes (c'/c_{rms}; $u_i'/u_{i,rms}$) for P1 are shown in Figure 5. In the streamwise direction (Fig. 5a), the most frequent situation among the samples is simultaneously $u'>0$ and $c'<0$ (Q4): 46% of the samples are in this zone. Nevertheless, the most important contribution to the total turbulent flux is due to Q2, for which the frequency (27%) is lower than for Q4 but for which the individual contributions $u'c'$ are on average higher in magnitude. The contributions of Q1 and Q3 are minor in this case, both in terms of frequency and magnitude. The dominant contributions of Q2 and Q4, where u' and c' are of opposite signs, result on average in a negative turbulent flux $<u'c'>$. Concerning the lateral direction, the frequency distribution of (c'/c_{rms}; v'/v_{rms}) is approximately symmetrical with respect to the axis $v'=0$, leading to a zero turbulent mass flux in the lateral direction (Fig. 5b). Concerning the vertical direction, sweeps (Q3)

are the most frequent events of vertical mass transfer at P1 (Fig. 5c); they correspond to downward motions of fresh air. However, the calculation of the contribution of each quadrant to $Q_{t,z}$ shows that the dominant contribution is made by ejections (Q1), which occur less often but are more intense.

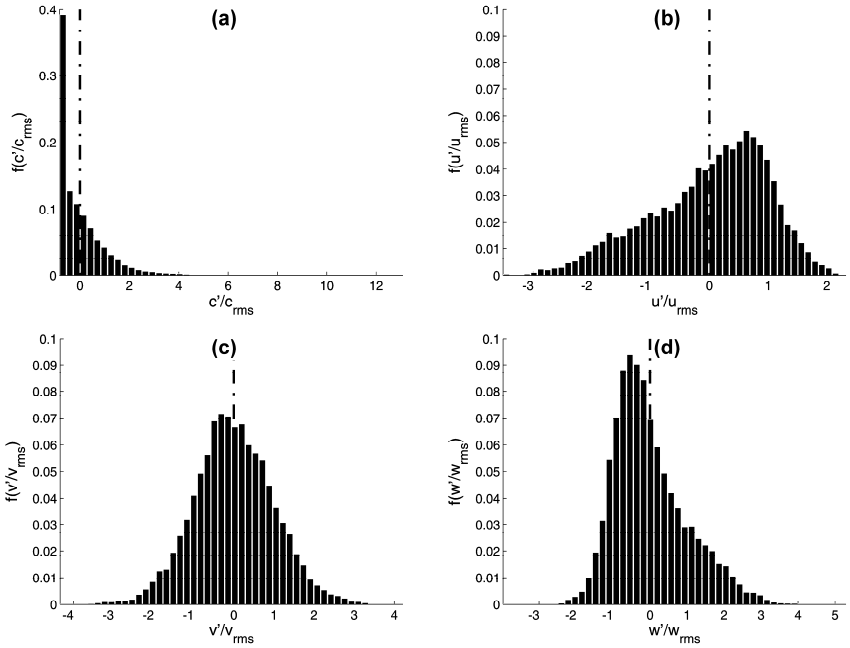

Figure 4. Point P1: frequency distribution histograms of (a) c'/c_{rms}, (b) u'/u_{rms}, (c) v'/v_{rms}, and (d) w'/w_{rms}. For each variable, the x-axis limits correspond to the minimum and maximum sample values. The dashed line indicates the mean (zero) values of the fluctuations. Mean values: K=3.00; U/U_H=0.84; V/U_H=0.01; W/U_H=-0.11.

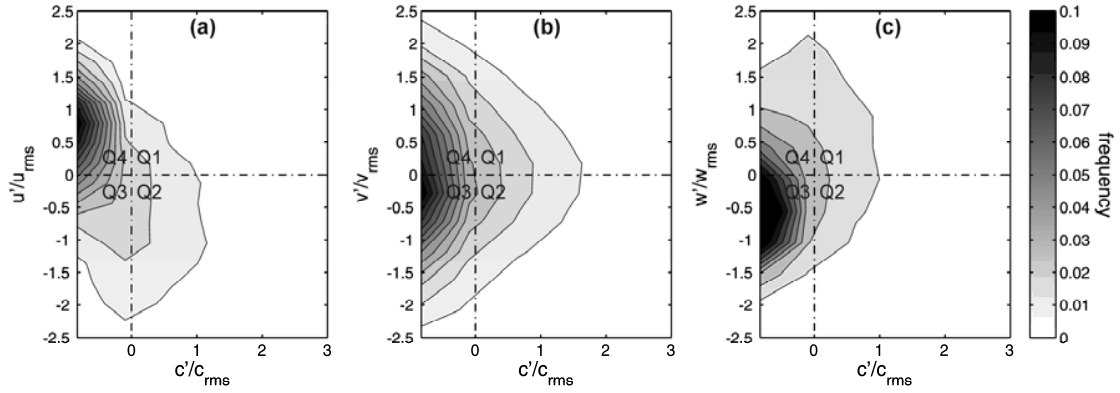

Figure 5. Point P1: bivariate histogram of frequency distribution for (a) (c'/c_{rms}; u'/u_{rms}), (b) (c'/c_{rms}; v'/v_{rms}), and (c) (c'/c_{rms}; w'/w_{rms}).

Figure 6a shows the frequency distribution of c'/c_{rms} for P2. The trend is similar as for P1, with even higher values of skewness and kurtosis, because of the off-center position of the sampling point at which the plume intermittency is higher (Fackrell and Robins, 1982). Approximately 65% of the samples have concentration values between zero and one third of the mean concentration value at this point. The velocity fluctuations in the x- and z-directions also have similar frequency distributions as those at P1, with a negative and positive skewness, respective-

ly. The main difference with point P1 is the asymmetry of the histogram of v'/v_{rms}, quantified by the non-zero skewness. This feature is due to the position of P2 out of the symmetry plane of the geometry.

The bivariate histogram of (c'/c_{rms}; v'/v_{rms}) is similar in shape to the one of (c'/c_{rms}; w'/w_{rms}) (Figs. 7b,c): a large majority of the samples belongs to Q3 and the main contribution to the mass flux is due to intense ejections corresponding to quadrant Q1. Hence, both $Q_{t,y}$ and $Q_{t,z}$ are positive at P2. Concerning the streamwise direction, the bivariate histogram (Fig. 7a) is similar in shape to the one at P1. Note that the intense Q2 events in the x-direction coincide with Q1 events in the y- and z-directions (not shown here).

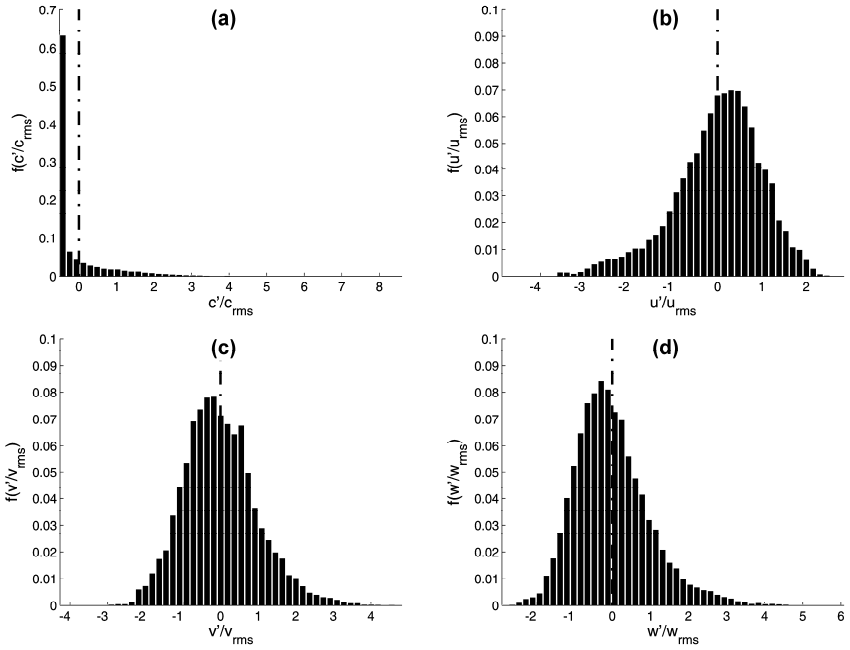

Figure 6. Point P2: frequency distribution histograms of (a) c'/c_{rms}, (b) u'/u_{rms}, (c) v'/v_{rms}, and (d) w'/w_{rms}. For each variable, the x-axis limits correspond to the minimum and maximum sample values. The dashed line indicates the mean (zero) values of the fluctuations. Mean values: K=0.50; U/U_H=0.94; V/U_H=-0.04; W/U_H=-0.08.

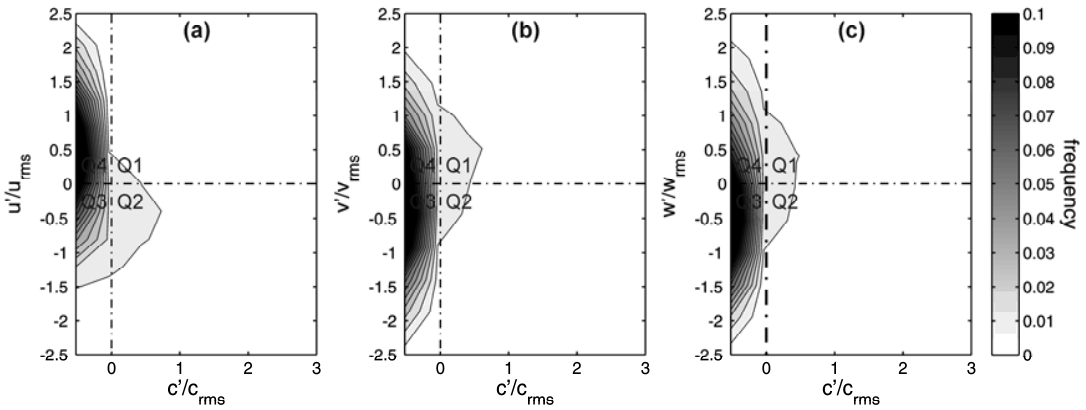

Figure 7. Point P2: bivariate histogram of frequency distribution for (a) (c'/c_{rms}; u'/u_{rms}), (b) (c'/c_{rms}; v'/v_{rms}), and (c) (c'/c_{rms}; w'/w_{rms}).

5 DISCUSSION AND CONCLUSIONS

Large-Eddy Simulation of pollutant dispersion around an isolated cubical building has been performed. The results have been compared with wind-tunnel measurements in terms of mean and standard deviation of concentration in the wake of the building and a fairly good agreement has been found between numerical and experimental values.

The velocity and concentration statistics have been reported for two points located in the shear layer developing above roof level. At this location, vortical structures generated at the front corner of the building and which are transported downstream are responsible for the meandering motion of the plume (see (Gousseau et al., 2012) for a further analysis of the flowfield). This could be observed in the histogram of frequency distribution of the concentration fluctuations at these two points: the exponential shape traduces the low background concentration and the occurrence of rare but intense peaks of concentration. The vortical structures also affect the frequency distributions of the velocity components by creating non-zero skewness. This holds also in the shear layers developing on the sides of the building (point P2). The bivariate analysis showed that for a given sign of c' there is a preferred sign of u_i' which is more likely to occur. In the streamwise direction, it was shown at P1 and P2 that c' and u' most of the time have opposite signs, leading on average to a negative turbulent mass flux $Q_{t,x}$ and explaining the CG mechanism in this zone.

It has been shown that specific unsteady events govern turbulent mass transport, which explains the failure of the first-order closure model (Eq. 1). If used, this model should be adapted to reproduce the CG mechanism of turbulent mass transport – for example by taking out the minus sign from the right-hand side of Equation 1 – and to take into account the flow anisotropy, by use of a diffusivity vector.

A review of cases of vortex shedding excitation in bridges: Sectional models testing

J. Á. Jurado[a], R. Sánchez[b], S. Hernández[c], F. Nieto[d], I. Kusano[e]

[a,b,c,d,e] *School of Civil Engineering. University of La Coruña, Campus Elviña 15071 La Coruña, Spain*

ABSTRACT: Vortex shedding excitation frequently occurs in cable supported bridges. Even other types of bridges such as beam or arch bridges suffer this phenomenon during or after construction. It is well-known that a bluff body sheds alternating vortices with frequency *n*, which mainly depends on the Reynolds number and body geometry. Vortices induce transverse forces on the body with the same frequency. In many cases of flexible and slender structures with a small damping, these forces may produce unacceptable vibrations. This paper reviews several bridges where this phenomenon was important and explains the approaches used to study the instability and the solutions to improve the behavior of the structures. Then several sectional models of long span bridges have been tested in the wind tunnel of the School of Civil Engineering at the University of La Coruña for the vortex shedding excitation.

KEYWORDS: Vortex shedding, Bridges, Deck Sectional Models, Wind Tunnel

1 VORTEX SHEDDING FUNDAMENTALS

Vortex shedding is perhaps one of the most studied phenomena of fluid mechanics, especially its interaction with circular cylinders; see for example Goswami *et al*. [1]. When a vortex is formed on one side of a body, it immediately increases flow velocity on the opposite side, which results, according to Bernouilli theory, in a pressure reduction. Under certain conditions such as a case of a cylinder, the vorticity in the shear layers of the body becomes periodic forming alternating vortices downstream. The periodic vortex street causes a fluctuating force on the body. If it is flexible or supported flexibly, an interaction takes place between downstream flow and body displacements. These periodic vortices are called Von Karman Vortex Street, named after Von Karman who studies the phenomenon around 1910. The fundamentals of this phenomenon can be found in classical literature such as Simiu & Scanlan [2] and Dyrbye & Hansen [3].

Vortex shedding can not be explained without taking into account of air viscosity. Air particles in contact with the body surface adhere to it, which produces the boundary layer; however, due to its mass, air undergoes inertial effect according to Newton's law and Navier-Stokes equations. The relationship between inertial and viscous effects is defined by Reynolds number, $Re = \rho UL/\mu$ (ρ, air density, μ, air viscosity, L, main dimension, U, velocity). The separation point of the boundary layer is the key to explain the body behavior immersed in a flow. When there is a surface body with high curvature, such as circular cylinder, the separation point changes with regard to *Re*, which produces very

different effects. The structures in civil engineering generally use bluff body sections that have separation points always at sharp corners, and therefore vortex shedding does not vary with *Re*. Although some bridge decks consisted of aerodynamic boxes with curved edges have different behavior when *Re* changes. This is a problem for carrying out wind tunnel testing, and it obliges us to use large scale models.

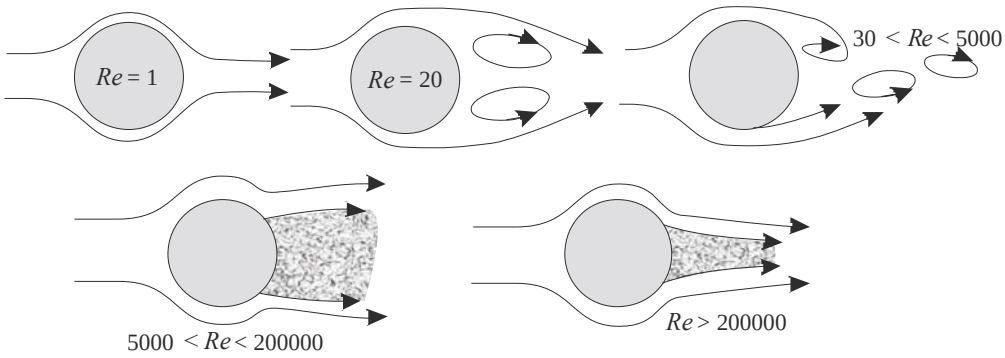

Figure 1. Reynolds dependency of the cylinder wake

Another determining parameter in order to study vortex shedding phenomenon is the Strouhal number $St=nD/U$ (n, vortex frequency). It is of a particular interest to establish a relationship between flow velocity and the frequency of the fluctuating forces on the body, which will permit the definition of a critical velocity at which vortex shedding frequency is close to a natural frequency of the structure. The Strouhal number is approximately constant. It has been evaluated for a great number of cross sections, and it takes values from 0.2 and 0.1 depending on the geometry. The value is greater if the section is rounded like a circular cylinder and lower if it is square like a flat plate. In the cases of flexible structures with a small damping, these forces can produce large vibrations. The greatest displacement occurs when the vortex frequency is close to the structural natural frequency. When this coupling takes place, the vortex shedding frequency does not change with the wind velocity in a significant range, which is called lock-in.

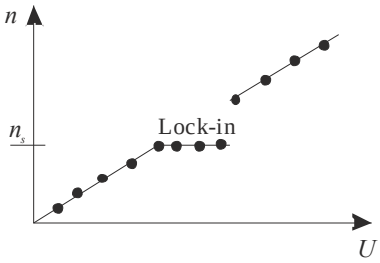

Figure 2. Lock-in effect when vortex frequency n is close to natural frequency of the body n_s.

Relating structural damping and mass with vibrations due to vortex shedding and air displaced, the Scrouton number can be established as $Sc=2\delta m/(\rho L^2)$. (δ, logarithm decrement damping, m, vibrating structural mass). This parameter is used to determine whenever structures are prone to suffer vibrations due to vortex shedding. Whenever Sc is high, structural damping and mass prevail over displaced air, so the structure should not have problems of vibrations. As soon as Sc reduces, the displaced air may induce negative

damping that nullifies the structural damping and induces stationary vibrations with high amplitude.

Other factors such as the turbulent scale of wind or the number and the shape of near bodies play an important role on wake behavior and structural excitation by vortex shedding. Long-scale turbulence means that wind velocity varies with a slow fluctuation, not allowing the vibrations to grow. When bodies are placed in a way that one follows the other such as the case of twin box decks (see Figure 3), or set of cables, the possibilities of vortex shedding increase, which also depends on the separation between bodies. The bodies may behave as a single body if the separation is small, while they behave as different bodies if the separation is sufficiently large. There are intermediate cases depending on the turbulence.

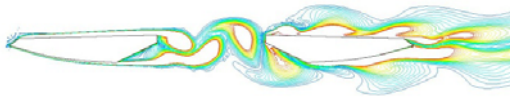

Figure 3. Vortex shedding of a twin box

2 VORTEX SHEDDING EXCITATION IN BRIDGES

Historically, many bridges have had vortex shedding vibration problems (Jurado et al. [4]). The first example was the clear vertical oscillations that the old Tacoma Narrows Bridge showed days before the collapse caused by flutter instability. Another veteran bridge like the Golden Gate Bridge suffered also this effect previously to its deck reinforcement. More modern bridge like Kessock Bridge, a cable stayed bridge in Scotland or Great Belt suspension bridge in Denmark showed this behavior. Not only cable supported bridges but also, continuous truss bridges like the one over Niterói River in Brasil showed this interaction with the wind. Moreover, the arch of Alconétar Bridge in Spain had big oscillations during the construction. A review of these cases helps us to explain the details of the phenomenon showing the best solutions to mitigate the vibrations.

Figure 4. From left to right: Kessock Brige, Great Belt Bridge, Niterói Bridge, Alconétar Bridge

Kessok Bridge has two planes of cable stayed and a 240 m of main span with an open cross section deck shown in figure 5. Since vibrations of large amplitude appeared during its construction, tuned mass dumpers (TMD) were installed. At the beginning of 90's monitoring measurements were registered and several events with large peak dynamic displacements were observed. For a wind velocity of about 21 m/s, the first mode of 0.51

Hz frequency were excited with large amplitude. Also in another occasion, the first torsional mode of 0.74 Hz frequency was excited. The Owen at al. [5] investigation concluded that TMDs did not succeed in limiting the response of the bridge to the desired level.

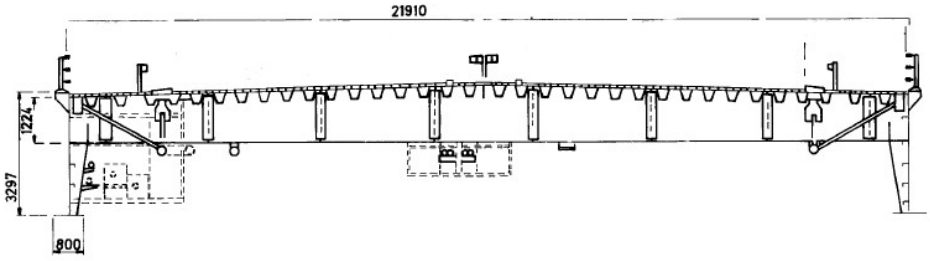

Figure 5. Open cross section of the Kessock Bridge

The Great Belt Suspension Bridge in Denmark also suffered vortex-shedding oscillations during last construction phases of the girder, before the application of the roadway surfacing. In January of 1998 a monitoring structural system of several accelerometers was installed (Larsen at al. [6]). At the same time the wind conditions at the bridge site were measured. The registered events of vortex shedding were for a mean velocity of $5 < U < 13$ m/s. The excited vertical modes were the third (0.13 Hz), the fifth (0.209 Hz), and the sixth (0.242 Hz). All the events had a reduce velocity $1 < U/nB < 1.5$. Its deck width measured $B = 31$m. These results were in agreement with the 1/80 sectional model. The structural analysis indicated that the vibrations were insignificant for structural safety, although they could cause bad sensations for the users. Thus a system of guide vanes was designed for mitigating the oscillations (see Figure 6). The rms of the vertical displacements of a 1/60 sectional model with guide vanes resulted almost null.

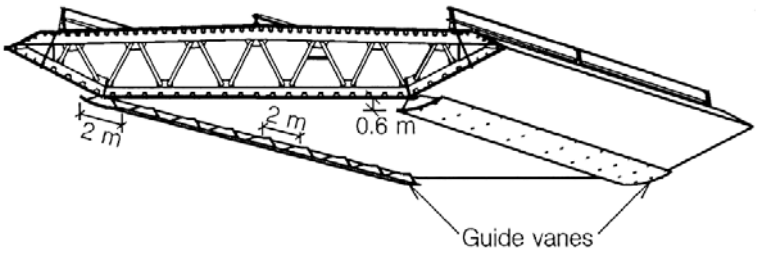

Figure 6. Bridge deck of Great Belt Bridge with guide vanes

The Rio Niterói Bridge has three continuous spans (200/300/200 m) of steel twin-box-girder. Since its opening to traffic in 1973, this non-cable-supported bridge also suffered several vortex shedding oscillation events for mean wind velocities close to 60 km/h. The figure 7 shows the bluff body cross section of the bridge deck which causes lock-in instability with big amplitudes. Considering that the natural frequency of the first excited bending mode is 0.32Hz, the Strouhal number results in around 0.14. An interested study for reducing the oscillation by active and passive control devices using TMDs was conducted by Battista & Pfeil [7]. They used structural optimization to design the TMD properties, achieving to avoid the coupling between the vortices and the structural motions.

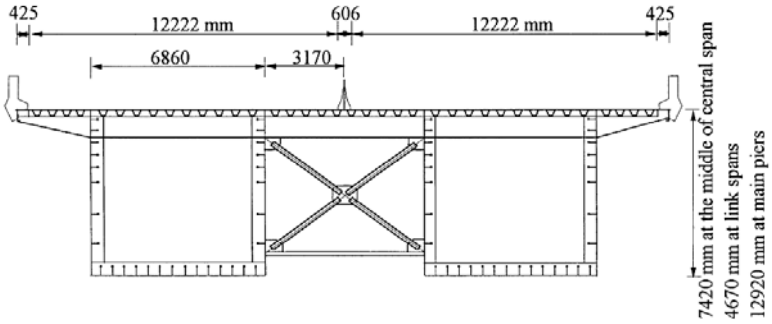

Figure 7. Steel twin-box-girder of Rio Niterói Bridge

The vortex shedding excitation also took place during the construction of the Alconétar Arch. As can be observed in figure 8, the bridge has two arches supporting two superior decks with 220 m of span length. The oscillations occurred when the first arch was closed, before the columns and deck where built. The mean wind velocity was estimated around 30 Km/h and the excited vibration mode was non-symmetrical with a frequency of 0.70 Hz. A 1/20 fixed sectional model, and 1/15 elastic model were tested in an aerodynamic wind tunnel; see Barrero et al. [8]. These experiments showed that the Strouhal number for the twin box section was 0.15. The solution to avoid the vibrations was to install guide vanes, which are small plates welded to the steel boxes. This type of aerodynamic appendages resulted easy to build and it reduced the oscillation amplitudes to an acceptable level. The complete arch bridge has no problems of wind structure interaction because its stiffness and damping of the complete structure is much greater than the isolate arches.

Figure 8. Arches of Alconétar Bridge.

The observation of these examples shows that non-aerodynamic sections of the Kessock Bridge, Niterói Bridge and Alconétar Arch, with twin boxes sections in the Niterói and Alconétar cases have tendency to vortex shedding excitation. Also the more aerodynamic

deck of the Great Belt Bridge generates the effect, but not a dangerous amplitude for the structure. TMDs installation is a suitable solution for bridges with bluff body sections in spite of maintenance problems; however, it is generally recommendable to use aerodynamic appendages. It is the case of the guide vanes of the Great Belt Bridge, or the welded plates of Alconétar arch section.

3 WIND TUNNEL TESTING

There are several ways to determine the wind speed for vortex shedding excitation and to evaluate if the oscillation amplitude is dangerous for the structure. Numerical methods based on CFD analysis have nowadays great expectation and give rapid results, but wind tunnel testing has been the most reliable way of studying the phenomenon. There are researches using complete models, taut-strip models and sectional models. Full models have to maintain the Froud number $Fr = U^2/Dg$ (g is the gravity), resulting that the velocity scale is the root of scale length; thus the velocity is very low in the wind tunnel. This generates low Reynolds numbers and inaccurate results for vortex shedding simulation. Taut-strip models are complicated compared to sectional models that are the most common way of studying vortex excitation. Larsen et al. [5] shows results for the Great Belt Bridge vortex shedding using three types of testing.

The sectional model validity is based on the dynamic similarity. The results in the wind tunnel can be apply to the real bridge if there is a geometric similarity and Reynolds number related to the air flow around the real obstacle is the same. The differential equation of the body displacement oscillating laterally respect to the air flow can be written:

$$m\left(\frac{d^2y}{dt^2} + 2\pi n\xi\frac{dy}{dt} + (2\pi n)^2 y\right) = F\left(\rho, \mu, U, D, n, y, \frac{dy}{dt}, \frac{d^2y}{dt^2}\right) \quad (1)$$

Where m is the mass per unit length, y is the lateral displacement, t the time, n the structural frequency, ξ the damping ratio, F the force per unit length which depends on the fluid properties. Using dimensionless parameters, it can be written:

$$\frac{d^2\eta}{d\tau^2} + 2\pi\xi\frac{d\eta}{d\tau} + (2\pi)^2\eta = \frac{\frac{1}{2}\rho U^2}{mn^2}F\left(Re, \frac{nD}{U}, \eta, \frac{d\eta}{d\tau}, \frac{d^2\eta}{d\tau}\right) \quad (2)$$

The Reynolds number dependency is small if the body has sharp corners, so the problem depends of the reduce frequency nD/U and of the parameter $\rho U^2/(mn^2)$. As ρ is the same value in model and real prototype, the velocity, mass and frequency scales must verify $(\lambda_U)^2=\lambda_m(\lambda_n)^2$ and keep nD/U, $\lambda_U=\lambda_n\lambda_L$. Both relations set up that mass scale must be the square of length scale $\lambda_m=(\lambda_L)^2$. For example, these similarity requirements were considered in the sectional model of the Alconétar Bridge arch [7] (see figure 9). When the length scale was fixed as λ_L = 1/15 because of the wind tunnel dimensions, the mass scale was defined as λ_m = 1/225. Then the stiffness of the suspension system determines that λ_n =3.31 and the velocity scale was calculated by $\lambda_U=\lambda_n\lambda_L$=1/4.5.

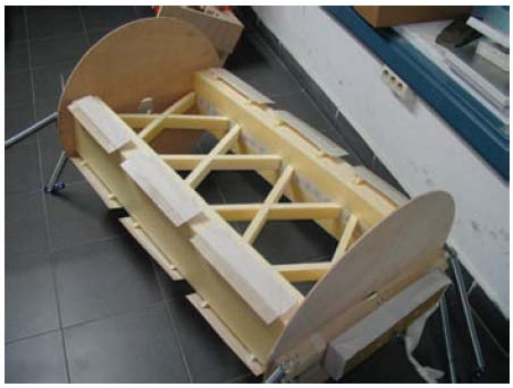

Figure 9. Sectional model of the arch with guide vanes

An interesting research about vortex shedding excitation for the twin box deck of the Stonecutters Bridge (Figure 10) in Hong Kong was done by Larose et al. [9]. In the study, a greater than usual sectional model scale of 1/20 was tested. The aim was to achieve a greater Reynolds number to compare the results with that of smaller scale. The results showed considerable differences with respect to a previous study using a 1/80 sectional model, mainly when the model is tested with aerodynamic appendages. If the wind velocity is the same, and the scale model is greater, the required frequency of the model at vortex shedding excitation decreases because the reduced frequency, *nB/U* should be constant during the phenomenon. The model weight was 215 Kg with the aspect ratio of 5:1, and the suspension system could vary the vertical frequency between 7 and 10 Hz. The damping was 1% log. dec. The tests were carried out in a smooth flow at 0º attack angle in a 9m x 9m wind tunnel of the National Research Council of Canada. The results showed clear vortex shedding peak at 0.35 of reduce velocity. The Strouhal number measured in the wake had two peaks for 0.20 and 0.14. The sectional model also was tested with guide vanes and it was checked that these aerodynamic appendages successfully mitigated the excitation.

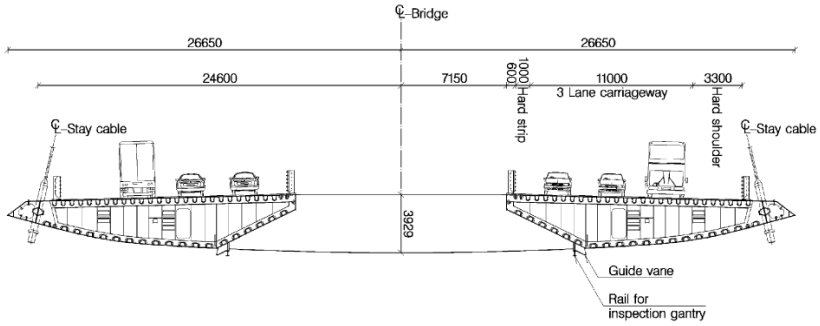

Figure 10. Stonecutters Bridge deck cross section.

4 SECTIONAL MODELS TESTED AT THE UNIVERSITY OF LA CORUÑA

Several experiments of vortex shedding on sectional models have been carried out in the wind tunnel of the School of Civil Engineering at the University of La Coruña. For determining the Strouhal number, it is useful to test the sectional model supported by a very

stiff system built by bars connected to load cells. A Fourier transform of the alternating forces measured by load cells permits to identify the force peak for vortex shedding and the greatest peak force at the natural frequency of the model. As figure 11 shows, both peaks values increase with the wind velocity. At lock-in both peaks overlap and the highest amplitude force appears.

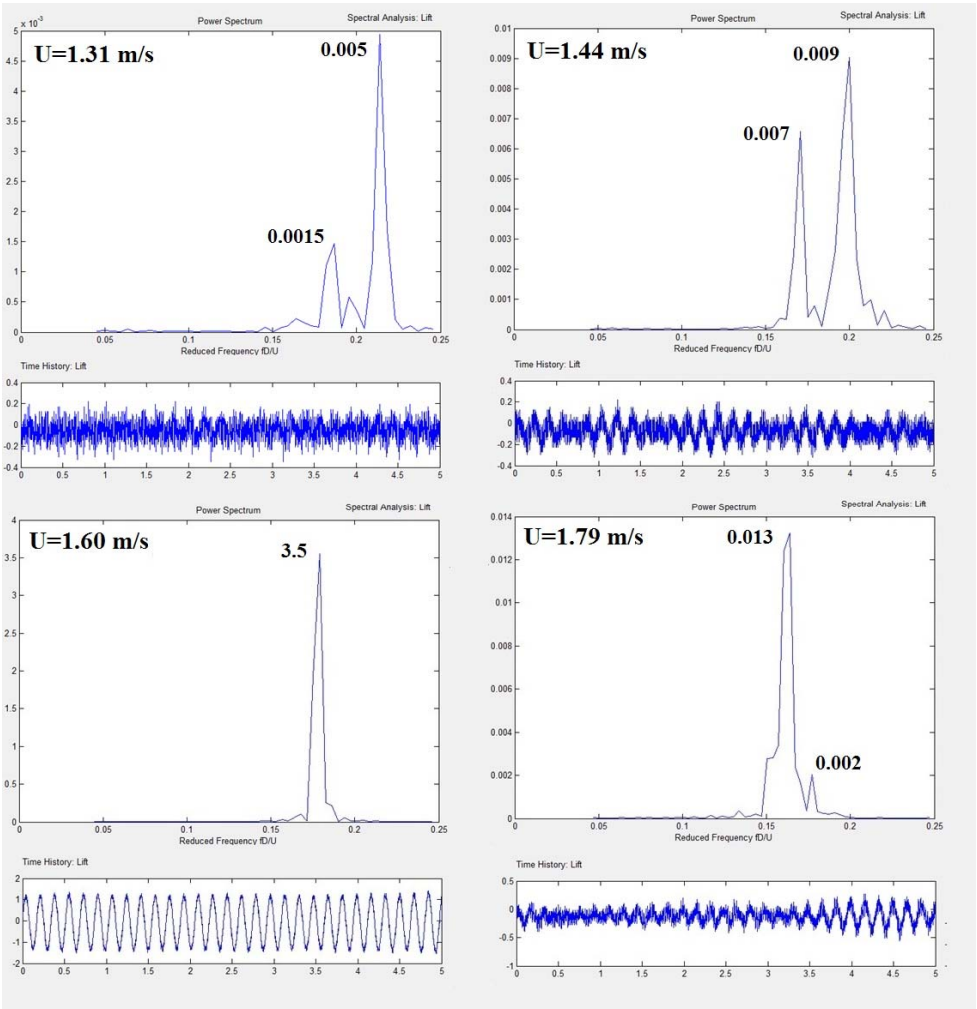

Figure 11. Vertical force Fourier transform on a sectional model with rigid support.

A graph that represents the vortex shedding frequency peaks as function of the value *U/D* permits the calculation of the Strouhal number value, which is the slop of the line. The figure 12 shows three sectional models: the twin-box deck of the Stonecutters Bridge (λ_L = 1/80), the single-box of the Miradoiros Project Bridge in La Coruña (Spain) (λ_L = 1/100) (Jurado et al. [10]), and the stress ribbon footbridge of Cuenca in Spain (λ_L = 1/10) (Jurado et al. [11]). For the case of the twin-box sectional model, the table 1 indicates a good agreement for the lift peaks at lock-in with regards to the results of Larose et al. [8]

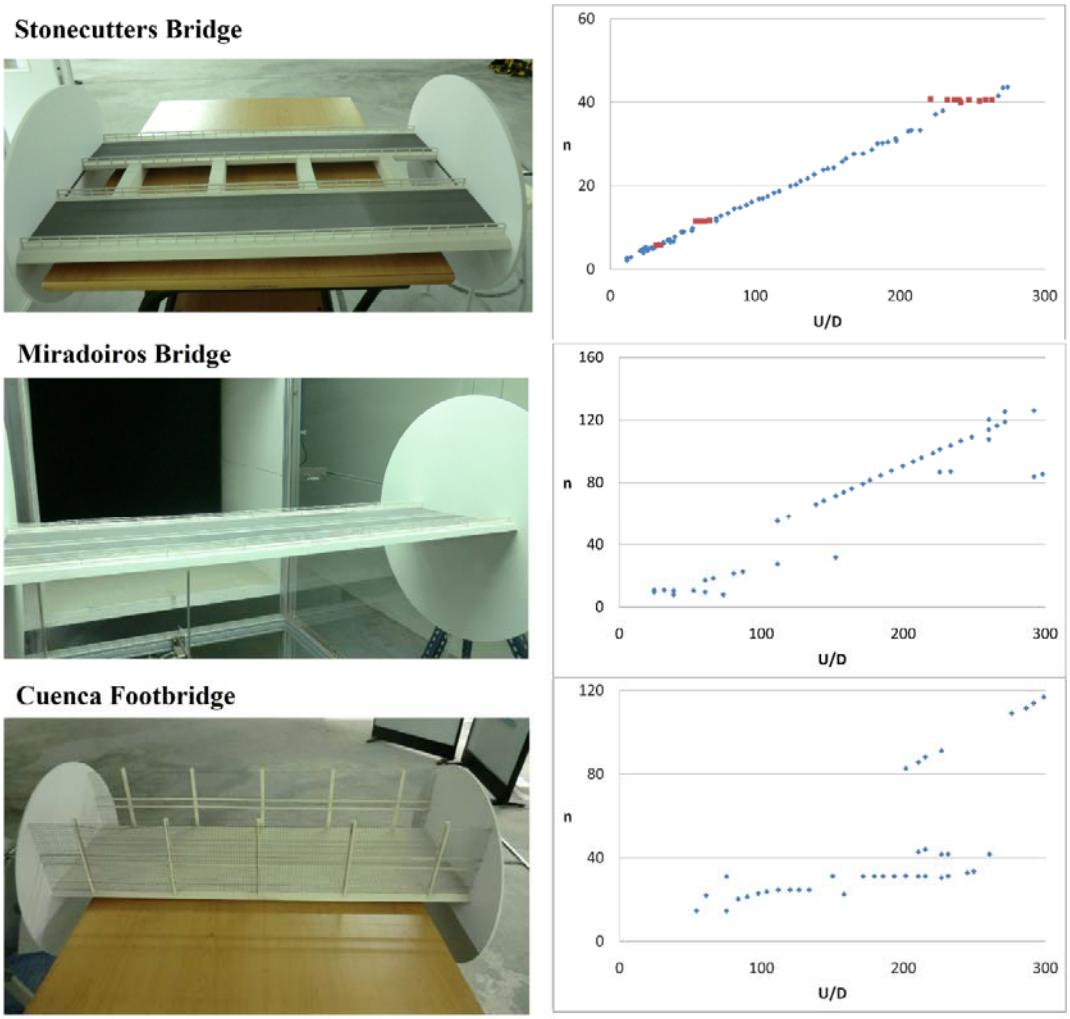

Figure 12. Frequency *n* of vortex shedding with regard to *U/D* for three sectional models.

Table 1. Strouhal number for the tween-box deck.

	U	*n*	*D*	*St*	(*St* Larose et al.[8])
	(m/s)	(Hz)	(m)		
First Lock-in	1.604	5.859	0.049	0.179	0.20
Second Lock-in	3.586	11.597	0.049	0.158	0.14

5 CONCLUSIONS

Vortex shedding fundamentals have been explained to understand several cases of bridges that suffered this effect.

The observation of these examples shows that non-aerodynamic sections, mainly with twin boxes have tendency for vortex shedding excitation. Also more aerodynamic sections could generate the phenomenon, as in the case of the Great Belt Bridge deck.

TMDs installation is a suitable solution for bridges, but it creates maintenance problems. It is generally recommendable to use aerodynamic appendages as guide vanes.

Testing sectional models is the most common way of studying vortex excitation. Several cases have been explained.

The Fourier transform of the lift force on a stiff sectional model is useful to determine the frequency of vortex shedding and the lock-in effect. The procedure has been used with several sectional models in the wind tunnel of the School of Civil Engineering at the University of La Coruña.

ABSTRACT: A new approach for extracting the aeroelastic parameters in semi-empirical nonlinear vortex induced force model is proposed based on the nonlinear least squares fitting. The approach consists of obtaining an approximate analytic solution to modified motion equation with homotopy analysis method and making use of genetic algorithms to conduct nonlinear fitting. Additionally, the concept of limit cycle for Van der Pol oscillator is employed to give the preliminary ranges of parameters to be extracted. Verification of the effectiveness and accuracy of the proposed methodology was conducted through numerical simulations in which both time histories with and without noise perturbation were adopted . Finally, wind tunnel tests of a streamlined bridge deck were carried out and the aeroelastic parameters in vortex induced force model were identified by the proposed method.

1. INTRODUCTION

Vortex-induced vibration(VIV) is a phenomenon that occurs when the vibration of a body immersed in a flow is governed by the action of the vortices periodically shedding from its own surface. As a self-excited system, one of the most prominent features of VIV is the existence of limit cycle in its phase space. Noticing this characteristic, Scruton[1], Simiu and Scanlan[2], and Larsen[3] et al proposed a set of single degree-of-freedom(SDOF) models based on the Van der Pol oscillator in which a single dynamic equation with aeroelastic forcing terms on the right hand side of the equation are used to describe this kind of vibration. These analytic vortex-induced force models commonly contain reduced frequency dependent areoelastic parameters which need to be extracted from wind tunnel tests. It is obvious that the accuracy of extracted aeroelastic parameters has a direct effect on the prediction of the prototype vortex-induced response. Consequently, an efficient method for identifying aeroelastic parameters in the SDOF vortex-induced force model is demanded. Work focusing on this aspect has already been reported in several literatures. Ehsan and Scanlan[4] proposed a method which consists of conducting a decay-to-resonance model test at wind speed in lock-in region after imposing the model a higher initial displacement. Gupta et al.[5] described a technique for this extraction based on the theory of invariant imbedding. It is essentially a kind of nonlinear least squares fitting method which inherently makes the fitting results dependent on a set of initial values. Unfortunately, the appropriate initial values corresponding to the global optimum aren't easy to be known preliminarily. By introducing the quasi-linear approximation to the Van der Pol equation, Marra et al.[6] suggested an alternative identification procedure based on the method of slowly varying parameters and verified its validness. Zhou[7] obtained the analytic formulation of vortex-induced response also based on the slowly varying parameters method. But it was found that the power spectral density of the extracted vortex-induced force contained an additional frequency component besides the

prominent mechanical frequency corresponding to the Strouhal frequency. In this paper, a new identification procedure is proposed for the extraction of the aeroelastic parameters in the semi-empirical nonlinear vortex-induced force model.

2. SDOF MODEL FOR BRIDGE DECK VOTEXT INDUCED VIBRATION

Among the proposed SDOF models, the so called semi-empirical nonlinear model proposed by Scanlan[8] is widely adopted to estimate of the response of VIV because of its accuracy and simplicity. This SDOF model has the general form as follows:

$$m(\ddot{x} + 2\xi\omega_n\dot{x} + \omega_n^2 x) = \frac{1}{2}\rho U^2(2D)\left[Y_1(K)\left(1 - \epsilon\frac{x^2}{D^2}\right)\frac{\dot{x}}{U} + Y_2(K)\frac{x}{D} + C_L(K)\sin(\omega_s t + \psi)\right] \quad (1)$$

In Equation(Eq.) (1), m=mass per unit span; ξ=mechanical damping ratio; ω_n=natural circle frequency in rad/sec; U=flow velocity in the lock-in region; $x, \dot{x}, \ddot{x}$ represent displacement, velocity and acceleration, respectively; D=a characteristic length of bridge deck section; ω_S=circular frequency of vortex shedding; ψ=initial phase angle of the harmonic force. $K = \omega_n D/U$ is the reduced frequency during vortex-induced vibration. The remaining notations $Y_1(K), \epsilon, Y_2(K), C_L(K)$ are aeroelastic parameters that need to be extracted from wind tunnel tests. In practical usage, the instantaneous fluctuating lift force term, namely $1/2\rho U^2(2D)C_L(K)\sin(\omega_s t + \psi)$, is often neglected since it is generally smaller than the aerodynamic lift caused by the motion of the body[4]. Thus at the lock-in region, Eq.(1) can be reduced to the flowing form:

$$m(\ddot{x} + 2\xi\omega_n\dot{x} + \omega_n^2 x) = \frac{1}{2}\rho U^2(2D)\left[Y_1(K)\left(1 - \epsilon\frac{x^2}{D^2}\right)\frac{\dot{x}}{U} + Y_2(K)\frac{x}{D}\right] \quad (2)$$

Obviously, Eq.(2) shows aspects of Van der Pol oscillator. Making some proper transformations to Eq.(2), a Van der Pol oscillator would be obtained. Initially, making the variables in Eq.(2) dimensionless by introducing follow definitions:

$$\eta = \frac{x}{D}, \qquad s = \frac{Ut}{D}, \qquad K_n = \frac{\omega_n D}{U}, \qquad m_r = \frac{\rho D^2}{m}, \qquad \dot{\eta} = \frac{d\eta}{ds} \quad (3)$$

Eq. (2) becomes:

$$\ddot{\eta} - \mu_1\left(1 - \frac{\mu_2}{\mu_1}\eta^2\right)\dot{\eta} + \mu_3\eta = 0 \quad (4)$$

where

$$\mu_1 = -\left(2\xi K_n - m_r Y_1(K)\right) \quad (5)$$

$$\mu_2 = m_r Y_1(K)\epsilon \quad (6)$$

$$\mu_3 = K_n^2 - m_r Y_2(K) \quad (7)$$

Eq.(4) conforms with the constitution of a Van der Pol oscillator. Analyzing the system described by Eq.(4), one could find the oscillating behavior depends on the parameters μ_1 and μ_2. When μ_1 and μ_2 have different signs, in other words one of the two is positive while the other is negative, the vibrational amplitude will either becomes zero or proceeds to a divergent level. Consequently, μ_1 and μ_2 have the same sign which means both of them are positive or negative. Reviewing the existing literatures on aeroelastic parameters of vortex-induced force model, the coefficients relating to the linear and nonlinear damping force terms $Y_1(K)$ and ϵ are mostly positive. It is subsequently acceptable assuming these two parameters are positive. Therefore, define a substitution:

$$y = \sqrt{\frac{\mu_2}{\mu_1}}\eta \quad (8)$$

We obtain a classical Van der Pol-type oscillator:

$$\ddot{y} - \mu_1(1 - y^2)\dot{y} + \mu_3 y = 0 \tag{9}$$

where $\dot{y} = dy/ds$.

3. APPROXIMATE ANALYTIC SOLUTION TO VAN DEL POL OSCILLATOR

Van der Pol oscillator is a subject that has been well studied in the field of science and engineering. It is a nonlinear self-excitation system while exhibiting a characteristic of self-sustained periodic oscillation. The accurately analytic solution to this system is still an unsolved problem. Methodologies documented in the literature on this subject include perturbation method, KBM method, the harmonic balance method and so on. Solutions from these schemes are essentially approximate, and the feasibility of these solutions require the precondition of small parameters. An alternatively analytic method, the so-called homotopy analysis method[9], has been recently proposed to obtain the analytically serial solution to free oscillations of self-excited system. As it is described about this method that the requirement of small parameters is unnecessary and it is convenient to get higher-order analytic approximation. In this work, we adopt this method to obtain the approximate analytic solution to Eq.(4).

Initially, define new notations to Eq.(9):

$$\tau = \omega s, \qquad y(s) = a u(\tau) \tag{10}$$

Under the definition of Eq.(10), Eq.(9) could be rewritten as follows:

$$\omega^2 u''(\tau) + \mu_3 u(\tau) = \mu_1 \omega [1 - a^2 u^2(\tau)] u'(\tau) \tag{11}$$

Following the basic ideas and approaches of homotopy analysis method[9], a second order approximation could be obtained:

$$u^{(2)}(\tau) = \mathrm{Cos}[\tau]\left(1 - \frac{13\mu_1^2}{192\mu_3}\right) + \mathrm{Sin}[\tau]\left(-\frac{3\mu_1^3}{128\mu_3^{3/2}} + \frac{3\mu_1}{8\sqrt{\mu_3}}\right)$$
$$+\mathrm{Sin}[3\tau]\left(\frac{\mu_1^3}{128\mu_3^{3/2}} - \frac{\mu_1}{8\sqrt{\mu_3}}\right) + \frac{3\mathrm{Cos}[3\tau]\mu_1^2}{32\mu_3} - \frac{5\mathrm{Cos}[5\tau]\mu_1^2}{192\mu_3} \tag{12}$$

$$a = 2 + \frac{\mu_1^2}{96\mu_3} \tag{13}$$

$$\omega = \sqrt{\mu_3} - \frac{\mu_1^2}{16\sqrt{\mu_3}} \tag{14}$$

Substituting the above three equations into Eq.(10), the second order approximation to Eq.(9) becomes:

$$y^{(2)}(s) = a\mathrm{Cos}[\omega s]\left(1 - \frac{13\mu_1^2}{192\mu_3}\right) + a\mathrm{Sin}[\omega s]\left(-\frac{3\mu_1^3}{128\mu_3^{3/2}} + \frac{3\mu_1}{8\sqrt{\mu_3}}\right)$$
$$+a\mathrm{Sin}[3\omega s]\left(\frac{\mu_1^3}{128\mu_3^{3/2}} - \frac{\mu_1}{8\sqrt{\mu_3}}\right) + a\frac{3\mathrm{Cos}[3\omega s]\mu_1^2}{32\mu_3} - a\frac{5\mathrm{Cos}[5\omega s]\mu_1^2}{192\mu_3} \tag{15}$$

Using the symbolic calculation software, higher-order approximations could be easily obtained. The fact that small damping in bridge deck VIV, equivalently the small magnitude of μ_1, makes the selection of second order approximation be reasonable. So we choose second order approximation in this work.

With the obtained analytic approximation, Eq.(15), as the estimated displacement, the objective function of this extraction problem could be expressed by following equation:

$$f(\mu_1, \mu_3) = \sum_{i=1}^{N} \left(y^m(s) - y^e(\mu_1, \mu_3, s) \right)^2 \tag{16}$$

in which $y^m(s)$ and $y^e(\mu_1, \mu_3, s)$ are the measured and the estimated displacement response, respectively. *N* denotes the total number of samples used for parameters identification, and *s* represents the dimensionless sampling time. It is easy to understand that the extraction of these two parameters is equivalent to obtain the minimum value of the function $f(\mu_1, \mu_3)$ within the ranges of μ_1 and μ_3. Thus, this identification problem is essentially an optimization problem under certain initial conditions.

4. GENETIC ALGORITHMS FOR AEROELASTIC PARAMETERS IDENTIFICATION

As it has been mentioned in the previous section, extraction of aeroelastic parameters, μ_1 and μ_3, in the semi-empirical SDOF model is a nonlinear optimization problem whose dependence on initial values has a direct effect on the results. As a general rule of thumb the objective functions of many nonlinear optimization problems possess a large number of local minima and maxima. For arbitrarily given initial values, the results extracted by classical gradient related methods may be just a local optimum but global optimum. Classical schemes include Newton's method, quasi-Newton method, gradient descend method and so on. Being aware of the difficulties of finding global optimum, some heuristic search strategies have been proposed to solve this problem in a more or less intelligent way.

A genetic algorithm[10] which will be adopted in this article is one of these heuristic search strategies that mimics the process of natural evolution. After deciding the genetic representation of the solution domain and the fitness function, a classical genetic algorithm consists of four parts, namely initialization, selection, reproduction and termination. Specifically, a set of individually initial solutions are randomly produced in the range of solution domain, and then the better solutions are selected as the parents to breed the next generation according to the value of fitness function, and in the reproduction step, a new generation representing averagely better solutions are produced through a series of genetic operations, namely crossover and mutation, and finally when the above evolutionary process reaches the termination conditions including a satisfactory fitness level or a maximum number of generations, the global optimum could be obtained in a great probability. Repeating this heuristic search certain times, the best individual among these times could be identified as the global optimum.

Following the previous introductions, a program was developed to search an optimal solution to Eq.(16).

5. NUMERICAL SIMULATIONS

The feasibility of making use of genetic algorithms combining with the approximately analytic formulation to identify the areoelastic parameters in SDOF model needs to be verified to evaluate its performance. Besides, it should be remarked that the measured data from wind tunnel tests or field observations are inevitably contaminated by noise. Therefore, both samples with and without noise perturbations should be adopted to justify the effectiveness of this methodology. In these numerical simulations, the values of parameters μ_1 and μ_3 were set as 0.70 and 1280, respectively[5]. Approximate solution to Eq.(9) at the tenth-order obtained by the homotopy analysis method was employed as the non-contaminated time history $y^{ms}(s)$.Additionally, a Gaussian white noise was added to simulate a noisy process $y^{mn}(s)$ maintaining a noise-to-signal ratio of 0.5%. The inherent parameters of a genetic algorithm were set as follows: the population size $M = 50$, the crossover probability $P_c = 0.7$, the

mutation probability $P_m = 0.05$, the maximum iteration times $N = 300$. Another necessity for genetic algorithms is having a preliminary information on the solution domain so as to capture the global optimum within the restricted ranges. In this numerical simulation, we set the lower and upper bounds of μ_1 as 0 and 1, respectively. Of course, a wider domain could also be adopted, but it should be remembered that the wider the provided domain is, the more rapidly the computing resources increase. Taking the fact of μ_3 approximating to squared oscillating circle frequency which enormously influences the sum of squared residuals into account, a wider range of $[30^2, 40^2]$ was selected for μ_3 with the purpose of detecting the performance of developed genetic algorithm program. In the selection operator, the linear ranking selection combining with elitist model was adopted to avoid the premature convergence. In this simulation, fitness function is defined as a reciprocal of the objective function.

$$F(\mu_1, \mu_3) = \frac{1}{f(\mu_1, \mu_3)} \tag{17}$$

where $f(\mu_1, \mu_3)$ is the sum of squared residuals defined in Eq.(16). To this definition, the greater the fitness function of an individual is, the greater its selection probability is. Taking account of the degree of nonlinearity of this optimization problem and the fact that heuristic search method may failure in achieving the global optimum with a certain possibility, conducting a certain times of simulation is necessary for obtaining the results as optimal as possible. This simulation was conducted both 30 times for two cases to determine and compare the extracted parameters.

For the simulation results of non-contaminated sample, it was found that the estimated values converged to the true value with a high accuracy and ratio. Both the two identified parameters varied a little in all 30 times simulations. And the finally determined values corresponding to minimum of the sum of squared residuals almost exactly equaled the true values, $\mu_1 = 0.7084$ and $\mu_3 = 35.7771^2 \approx 1279.994$. The accuracy of this simulation result demonstrated the effectiveness of this method adopted in smooth signal processing.

However, in analyzing the simulation results of noisy sample we found that the estimated value of μ_1 dispersed a lot, whereas μ_3 almost kept constant with maximum variation less than 0.3% with respect to its true value. Thus, an identification error for μ_1 is defined:

$$e_{\mu_1}(\%) = 100\frac{|\mu_1^t - \mu_1^e|}{\mu_1^t} \tag{18}$$

in which superscript "t" denotes the "true value" of μ_1 whereas the superscript "e" denotes the estimated value from the simulation.

Table 1. Identification results of noisy sample

Identification error	Times
$e_{\mu_1} \leq 10\%$	9
$10\% < e_{\mu_1} \leq 15\%$	7
$e_{\mu_1} > 15\%$	14

Based on the principle of minimizing the sum of squared residuals, equivently maximizing the fitness function, the best simulation results could be determined from these 30 times simulations. And the finally determined values for μ_1 and μ_3 were 0.6300 and 1279.96, respectively. An emphasis should be made at this point that the final determination of the estimated values from the repeated simulations is not based on the identification error defined in Eq.(18) but the sum of squared residuals. Comparing to the original values of $\mu_1 = 0.7$ and $\mu_3 = 1280$, one could find that the error in parameter μ_3 was almost negligible, yet the error in μ_1 was calculated as 10%. The reason for this enormous change of μ_1 due to the added noise with relatively small noise-to-signal ratio could be attributed to the sensitive dependence of amplitude on damping parameter μ_1. Hence, the consequence of the limit cycle which directly depends on the amplitude being destroyed by the added noise affects the extracted value of μ_1 to a high extent. Figure 1 shows the estimated displacement responses calculated with the extracted parameters $\mu_1 = 0.6300$, $\mu_3 = 1279.96$ and the originally noisy signal.

The consistence of the oscillatory behavior generated by the estimated formula and original data verifies the effectiveness of this identification method to some extent.

6. WIND TUNNEL TESTS

6.1 *Outline of wind tunnel tests*

To evaluate further the applicability of this method for the extraction of aeroelastic parameters in SDOF force model, wind tunnel tests of a streamlined bridge deck section(Figure 2) were conducted.

The tests were carried out in TJ-3 Boundary Layer Wind Tunnel of Tongji University. The facility is a closed-circuit wind tunnel, with a working section of 15m wide, 2m high, and 14m long and wind velocity ranging from 1.0m/s to 17.6m/s. In tests, an decomposable elastic suspension system was developed. In order to reduce aerodynamic end effects, two Plexiglas end plates were fixed to the both longitudinal ends of the section model. Restraining the lateral DOF, only the vertical and torsional DOFs were interested in the tests. The bridge section model was elastically suspended by 8 springs. Figure 3 shows the setup of this tests.

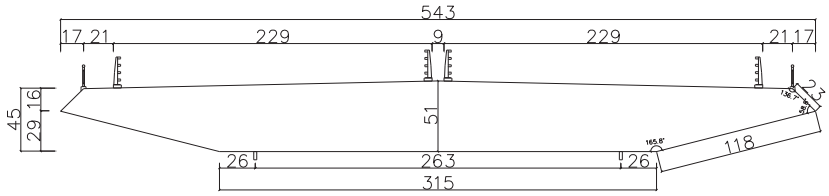

Figure 2. Streamlined box gird section model for wind tunnel tests

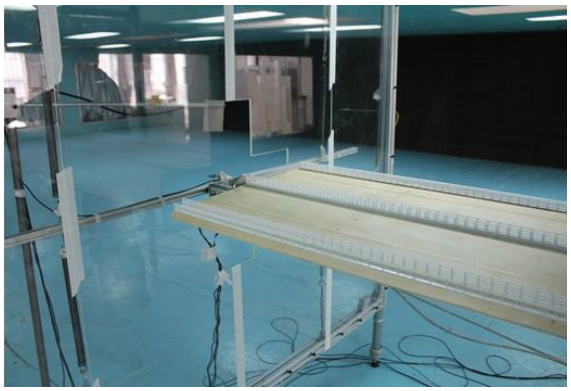

Figure 3. Setup of wind tunnel tests

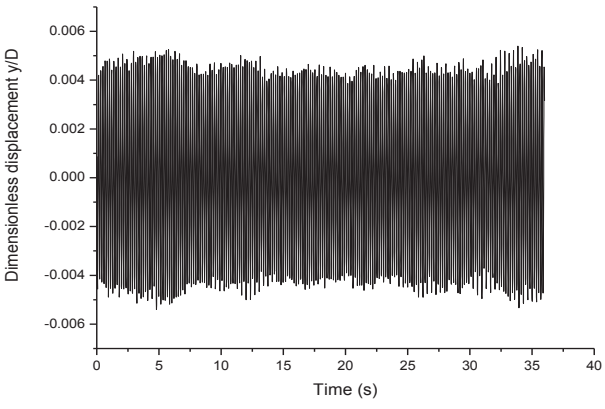

Figure 4. Vertical VIV displacement time history

The tests were conducted in smooth flow. The main parameters of the section model were as follows: the width $D = 0.543\text{m}$, the height $H = 0.051\text{m}$, the longitudinal length of the section model $L = 1.70\text{m}$, the total mass of the section model and the components of the suspension system vibrating in the vertical direction $m = 10.1\text{kg}$, the first vertical vibrational frequency $f = 5.664\text{Hz}$, the mechanical damping ratio $\xi = 1.25\%$. The phenomenon of synchronization was observed at the wind velocity of $U = 6.0\text{m/s}$. Under this condition, the reduced frequency corresponding to this wind velocity was $K_n = 3.221$.

Measurements of displacement time histories of the section model were accomplished with 2 laser displacement transducers. A sampling rate of 100Hz was used to acquire displacement data with 3,600 sample points in each time history.

6.2 *Test results and determination of the ranges of desired parameters*

Figure 4 shows a dimensionless vertical VIV displacement time history of this streamlined bridge deck section model at a wind velocity of $U = 6.0\text{m/s}$. It is this one that is used to extract the areoelastic parameters with the scheme proposed in the previous sections.

First of all, a transformation of the quantities from dimensional ones to their dimensionless counterparts was accomplished according to Eq.(3). With neglect of the second order of μ_1 in Eq.(13), a constant amplitude of 2 could be obtained from the dimensionless Van der Pol equation, namely Eq.(4). As it has been established in Eq.(8), the relationship of μ_1 and μ_2 in terms of amplitude could be approximated to:

$$\sqrt{\frac{\mu_2}{\mu_1}} = \frac{2}{A_t} \tag{19}$$

where A_t is the dimensionless amplitude of the test results. Considering the minor differences among every amplitude, mean value of all peaks and troughs could be used alternatively. Therefore, the estimated displacement responses corresponding to this actual situation is:

$$y^e(\mu_1, \mu_3, s) = \frac{y^{(2)}(s)}{\sqrt{\frac{\mu_2}{\mu_1}}} \tag{20}$$

For the parameters inherent to the genetic algorithms, most of them kept the same as that has been described in section 5, while the solution domains for the desired parameters μ_1 and μ_3 still need to be paid more attention.

Noticing the negligible frequency shift, linear aeroelastic stiffness in Eq.(7), $-m_r Y_2(K)$, could be asserted sufficiently small in most cases. Consequently, the lower and upper boundaries of μ_3 could be determined around the value of squared reduced frequency, namely K_n^2. In this work, we choose 3^2 and 4^2 as the lower and upper boundaries for μ_3, respectively.

Relatively, it is more difficult to obtain a preliminary information on the solution domain of parameter μ_1. Although difficulties exist, it is of importance that one should provide an appropriate range for μ_1 due to its direct effect on the final extraction of the original nonlinear aeroelastic damping parameters $\mathrm{Y}_1(K)$ and ϵ. In terms of Van der Pol equation (Eq.(9)), μ_1 is the parameter that indicates the nonlinearity and the strength of the damping. The fact that Van der Pol system satisfies the Liénard's theorem ensures that there is a limit cycle in the phase space. With the variation of parameter μ_1, the behavior of Van der Pol system runs from near-harmonic oscillations for μ_1 close to zero to relaxation oscillations when μ_1 tends to infinity[11]. Thus, the effect of different magnitudes of parameter μ_1 on the behavior of Van der Pol system could also be observed from the shape of limit cycle. Inversely, the rough ranges of parameter μ_1 may be determined by comparing the limit cycle of the measured data with the ones corresponding to different magnitudes of parameter μ_1.A methodology was proposed in Ref.(11) for approximately calculating the amplitude and form of limit cycles of weakly nonlinear Liénard's systems.

Following the procedures presented in the article[11], an alternative representation of Eq.(9) with time variable being implicit could be written as follows:

$$\delta\delta' + \mu_1(1-y^2)\delta + \mu_3 y = 0 \tag{21}$$

where $\delta(y) = \dot{y}(s)$, $\delta(y)\delta'(y) = \ddot{y}(s)$ and $\delta'(y) = d\delta/dy$. It is obvious that Eq.(21) is equivalent to Eq.(9). Being aware of the conservation of mechanical energy(Eq.(22)) in a half oscillation, a transformation to Eq.(21) could be derived in the form of Eq.(23).

$$E = \frac{\delta^2 + \mu_3 y^2}{2} \tag{22}$$

$$S(a) = \int_{-a}^{a} \frac{dE}{dy} dy = \int_{-a}^{a} -\mu_1(1-y^2)\delta dy = 0 \tag{23}$$

Based on the condition of Eq.(23), an approximation to the limit cycles and amplitude up to the Nth order in small parameter μ_1 could be assumed:

$$\delta(y) = \delta_0(y) + \sum_{n=1}^{N} \mu_1^n \delta(y) \tag{24}$$

As reported, the second order is accurate enough to describe the limit cycle of Van der Pol system with small parameter[11]. Therefore, In this work we choose the second order solution to form the limit cycle of Eq.(21), which will be listed below. Details of derivation and calculation could be retrieved to the Ref.(11).

$$\delta_0(y) = \sqrt{\mu_3(4-y^2)} \tag{25a}$$

$$\delta_1(y) = \frac{1}{4} y(4-y^2) \tag{25b}$$

$$\delta_2(y) = \frac{2+y^2}{96\sqrt{\mu_3}}(4-y^2)^{\frac{3}{2}} \tag{25c}$$

Assemble Eq.(25) to generate the second approximation of limit cycles:

$$\delta^{(2)}(y) = \delta_0(y) + \mu_1\delta_1(y) + \mu_1^2\delta_2(y) \tag{26}$$

With the approximation of $\mu_3 \approx K_n^2$, plotting the limit cycles of different μ_1 within the weakly nonlinear regimes is realizable, as showed in Figure 5. Thanks to the smoothness of the acquired displacement time histories, the limit cycle for the test results is also plotted with the velocity derived by central difference method.

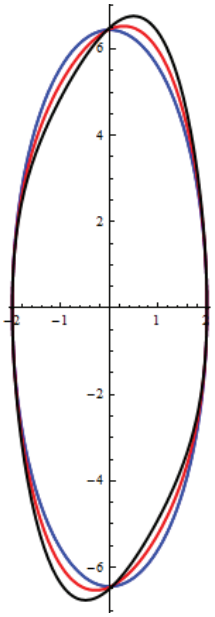

Figure 5. Limit cycles for Eq.(18) with: $\mu_1 = 0$(blue), $\mu_1 = 0.5$(red), and $\mu_1 = 1$(black)

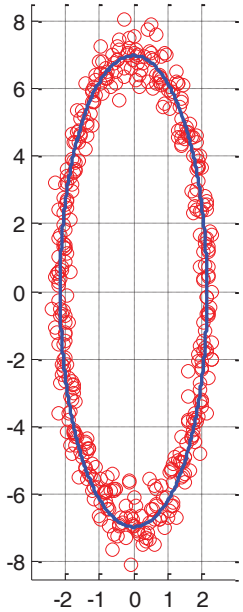

Figure 6. Limit cycle for measured data: test results(red circle), fitted cycle(blue line)

Figure 6 shows the limit cycle roughly fitted with the test results. It is obviously that the major axis of the ellipse approximately coincides with vertical axis of the coordinate system. Combining the displayed limit cycles for different values of μ_1, a choice of the range [0, 0.5] for μ_1 is made with some certainty.

So far all the demanded parameters for genetic algorithms have yet been decided.

6.3 *Simulation results and determination of the aeroelastic parameters*

With the displacement signal presented in Figure.4 as original data, simulation were carried out 50 times with the purpose of verifying the stability of estimated results. Most of these 50 times simulations converged to the same result of $\mu_1 = 0.394$ and $\mu_3 = 3.24^2$. Figure 7 shows good consistence between the estimated time histories of displacement and the measured one, which demonstrates the precision and effectiveness of the identification method.

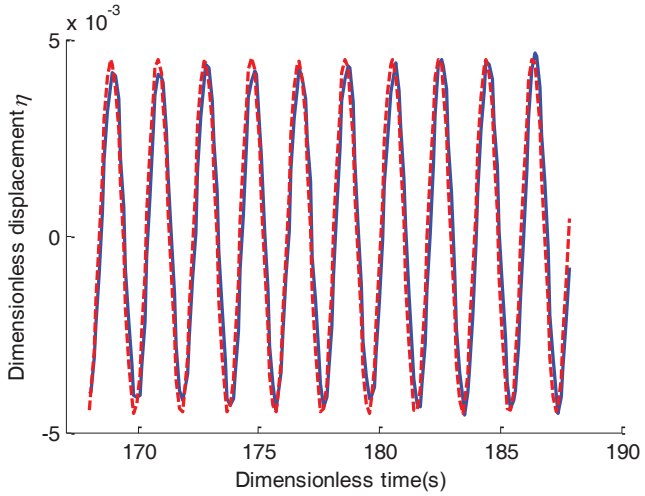

Figure 7. A section of estimated(red) and measured(blue) displacement time histories

As $\mu_1$has been extracted, μ_2 could be successively calculated according to Eq.(19) with dimensionless amplitude A_t being 4.5031×10^{-3}.

$$\mu_2 = \mu_1 \left(\frac{2}{A_t}\right)^2 = 77720.96 \tag{27}$$

Combining the definitions of μ_1, μ_2, μ_3 in Eqs5, 6 and 7, determinations of aeroelastic parameters of the SDOF vortex induced force model are realizable. With dimensionless structural parameters listed in previous sub-section, table 2 summarizes the identified and calculated results for this bridge deck section model.

Table 2. Identified and calculated parameters of SDOF vortex induced force model

μ_1	μ_2	μ_3
0.394	77720.96	3.24^2
$Y_1(K)$	ϵ	$Y_2(K)$
7.65	163772	-1.98

7. CONCLUSTIONS

A transformation of the semi-empirical nonlinear vortex induced force model to classical Van der Pol oscillator was made at the first step of this work, with subsequently replacing the original aeroelastic parameters with a new set of three characteristic parameters inherent to Van der Pol oscillator. An operation of substitutions of variables further simplified the equation with parameter μ_2 being implicit. Based on the obtained equation, homotopy analyses method

was adopted to estimate the displacement response.

The objective function on the basis of minimizing the sum of squared residuals was constructed to perform a nonlinear fitting. Taking account of the initial value dependence nature and the difficulties of providing appropriate initial boundaries of the nonlinear fitting method, a heuristic search method, namely a genetic algorithm, was selected and developed. The results of a numerical simulation with given values of parameters verified the effectiveness of the suggested procedure to some extent.

Wind tunnel tests of a streamlined bridge deck section model were then conducted in the TJ-3 boundary wind tunnel in Tongji University. A limit cycle in phase space for the measured displacement response was obtained to make a comparison with the limit cycles for given values of μ_1. Following the previous process, a determination of a range of μ_1 is accomplished. The consistence between estimated displacement response and measured counterpart shows the effectiveness of the proposed methodology in the usage of practical wind tunnel tests. The extracted parameters μ_1, μ_2 and μ_3 give a direct way to finally identify the desired aeroelastic parameters in semi-empirical nonlinear vortex induced force model.

Vortex-induced vibration prediction of long-span bridges considering imperfect correlation of aerodynamic forces

Li Mingshui [a], Sun Yanguo [a], Liao Haili [a]

[a] *Research Centre for Wind Engineering, Southwest Jiaotong University, Chengdu, China*

ABSTRACT: Periodical wake vortices may cause vortex induced vibration (VIV) of a long span bridge, the vortex-induced aerodynamic forces produced by vortices are partial correlation along the span. Based on Scanlan's semi-empirical linear and nonlinear models, the correlation of vortex-induced aerodynamic forces along span is studied respectively in frequency domain, and reduced factor of vortex-induced response between two-dimensional model to three-dimensional prototype structure is defined, and the methodology for extending the test results of section model into prototype structure by considering partial correlation of vortex-induced aerodynamic force along span is discussed. Validity of proposed theory is proved by sectional model tests and observed results in field.

KEYWORDS: Vortex-induced vibration; long span bridge; linear and nonlinear force models; partial correlation; wind tunnel testing.

1 INTRODUCTION

Vortex-induced vibration (VIV) of line-like structures, such as flexible long-span bridge, is one of the most common aeroelastic phenomena due to wind-structure interaction at relative low wind speeds. In the recent decades, obvious vortex-induced vibration has been observed in many long-span bridges (Kumarasena 1991, Larsen 2000, Fujino 2002). Various mathematical models that reflect the main aspects of the vortex-induced response of bluff bodies have been proposed (Hartlen & Currie, 1970, Iwan & Blevins, 1974, Scanlan, 1981, Larsen 1995), and most of these models were developed for the 2-D model. Elastically-mounted, rigid, section model (2-D) wind tunnel testing technique becomes a general methodology to investigate VIV of long-span bridges. However, the vortex-induced aerodynamic force produced by vortices is imperfect correlation along the span (Williamson 1988, Miller 1994). Consistence between the observation of prototype bridge and predictions based on 2-D model testing is still uncertain due to contribution of spatial spanwise correlation of vortex-induced aerodynamic forces (Wilkinson 1981). There is still lack of comprehensive theory to extend the test results of section into prototype bridge vibration because of the fact that the existence of mode shapes and the nonlinear vortex-induced forces are not fully correlated along the span, although several researchers tried to study it (Ehsan and Scanlan 1990, Zhu 2005, Xian 2008).

Two methods for considering the effect of imperfect span-wise correlation of aerodynamic forces on the vortex-induced response of long-span flexible bridges are described in this paper. These methods are based on semi-empirical linear and nonlinear mathematical model respectively. Validity of proposed theory is proved by sectional model tests and observed results in field.

2 LINEAR METHOD

2.1 *Linear model description*

By considering the existence of phase-difference along the span, the across-flow vortex-induced vibration of a rigid bluff body based on Scanlan's semi-empirical linear force model (1981) should take the form (here take the lift as an example):

$$m(\ddot{y} + 2\zeta\omega_0\dot{y} + \omega_0^2 y) = \frac{1}{2}\rho U^2 D[Y_1(K)\frac{\dot{y}}{U} + Y_2(K)\frac{y}{D} + \frac{1}{2}C_L(K)\sin(\omega t + \psi(x))] \quad (1)$$

Where, m=mass of per unit span length; ζ=damping ratio-to-critical; $\omega 0$=mechanical circular frequency; ρ=air density; U=the velocity of wind flow; D=across-flow dimension of section; $y(x,t)$=the vortex-induced vibration of the body, x=along-span degree-of-freedom; $K=\omega D/U$, ω is vortex shedding frequency that satisfies the Strouhal relation $2\pi S=\omega D/U$ (S is Strouhal number) ; $Y_1(K)$, $Y_2(K)$, $C_L(K)$ and $\psi(x)$ are unknown parameters to be identified by experiments. The vertical motion y at the location x along the deck can be expressed as:

$$y(x,t) = \phi(x)\xi(t)D \quad (2)$$

In which, $\phi(x)$=mode shape; ξ=generalized coordinate. The dimensionless form of the mathematical model can be written as the following equation by inserting Eq.2 into Eq.1, multiplying both sides by $\phi(x)$ and integrating over the span length L,

$$\ddot{\xi}(s) + (2\zeta K_0 - \frac{\rho D^2}{2m_{eq}}Y_1)\dot{\xi}(s) + (K_0^2 - \frac{\rho D^2}{2m_{eq}}Y_2)\xi(s) = \frac{\Gamma F(s)}{\vartheta} \quad (3)$$

Here,

$$s = \frac{Ut}{D};\ \Gamma = \frac{\rho D^2 C_L}{4m_{eq}};\ \vartheta = \frac{1}{L}\int_{-L/2}^{L/2}\phi^2(x)dx;\ m_{eq} = \frac{M}{L\vartheta};\ M = \int_{-L/2}^{L/2} m(x)\phi(x)^2 \mathrm{d}x;$$

$$F(s) = \frac{1}{L}\int_{-L/2}^{L/2}|\phi(x)|\sin[Ks + \psi(x)]\mathrm{d}x$$

The correlation of $F(s)$ along the span is studied in following. $F(s)$ can be written in the form:

$$F(s) = \frac{1}{L}\int_{-L/2}^{L/2}|\phi(x)|f(s,x)\mathrm{d}x \quad (4)$$

Where, $f(s,x)=\sin[Ks+\psi(x)]$, the correlation of $F(s)$ can be expressed as:

$$R_{F(\tau)} = \frac{1}{L^2}\int_{-L/2}^{L/2}\int_{-L/2}^{L/2}|\phi(x_1)|\cdot|\phi(x_2)|R_{f(\tau)}dx_1dx_2 \quad (5)$$

Fourier transform is applied in both sides of above equation：

$$S_F(\omega) = \frac{1}{L^2}\int_{-L/2}^{L/2}\int_{-L/2}^{L/2}|\phi(x_1)|\cdot|\phi(x_2)|\cdot S_f(\omega,|x_2 - x_1|)dx_1dx_2 \quad (6)$$

Correlation function of three-dimensional spectrum can be written as (Houblt 1958):

$$R(M,M',\omega) = S_F(M,M',\omega)/S(\omega) \quad (7)$$

Here, M and M' represent any two points in 3-D space, Eq.6 can be rewritten as follow by using Eq.7,

$$S_F(\omega) = \frac{1}{L^2}\int_{-L/2}^{L/2}\int_{-L/2}^{L/2}\left|\phi(x_1)\right|\cdot\left|\phi(x_2)\right|\cdot R(\omega,\left|x_2 - x_1\right|)\mathrm{S}(\omega)dx_1 dx_2 \tag{8}$$

Where $S(\omega)$=power spectrum of vortex induced force at any cross section of span; correlation function R is independent with frequency ω, as vortex induced vibration is always one participation mode at lock-in. Eq.8can be written as follow:

$$S_F(\omega) = R_F \mathrm{S}(\omega) \tag{9}$$

$$R_F = \frac{1}{L^2}\int_{-L/2}^{L/2}\int_{-L/2}^{L/2}\left|\phi(x_1)\right|\cdot\left|\phi(x_2)\right|R(\left|x_2 - x_1\right|)dx_1 dx_2 \tag{10}$$

Auto-convolution Integral of mode shape is pre-defined as following form (Li and Tanaka 1996):

$$\theta(\Delta x) = 2\int_{-L/2}^{L/2-\Delta x}\left|\phi(x)\right|\cdot\left|\phi(x+\Delta x)\right|dx \tag{11}$$

The reduced relation of vortex induced forces between two-dimensional and three-dimensional is $F=\Phi\cdot f$. After inserting Eq.11 into Eq.10, and extracting square root of Eq.9. Reduced factor Φ, representing the transformation of vortex induced response between two-dimensional and three-dimensional, is defined as,

$$\Phi = 1/L\sqrt{\int_0^L \theta(\Delta x)R(\Delta x)d\Delta x} \tag{12}$$

Where $R(\Delta x)$ is correlation function of vortex-induced aerodynamic force along span, Δx is spacing along span. It is obvious that reduce factor belongs to the range of (0,1].

The Eq.3 can be written in the following form,

$$\ddot{\xi}(s) + (2\zeta K_0 - \frac{\rho D^2}{2m_{eq}}Y_1)\dot{\xi}(s) + (K_0^2 - \frac{\rho D^2}{2m_{eq}}Y_2)\xi(s) = \frac{\Gamma\Phi\sin[Ks+\psi_0]}{\vartheta} \tag{13}$$

The simplified form of Eq.13 can be rewritten as,

$$\ddot{\xi}(s) + 2\gamma\hat{K}_0\dot{\xi}(s) + \hat{K}_0^{\,2}\xi(s) = \frac{\Gamma\Phi}{\vartheta}\sin[Ks+\psi_0] \tag{14}$$

In which,

$$2\gamma\hat{K}_0 = 2\zeta K_0 - \frac{\rho D^2}{2m_{eq}}Y_1;\quad \hat{K}_0^{\,2} = K_0^2 - \frac{\rho D^2}{2m_{eq}}Y_2 .$$

The amplitude of the generalized coordinate can be calculated by:

$$\xi(s) = \frac{\Gamma\Phi}{\vartheta\hat{K}_0^2}\frac{\sin[Ks-\theta]}{\sqrt{(1-\beta_v^2)^2 + (2\gamma\beta_v)^2}} \qquad \theta = \arctan\frac{2\gamma\beta_v}{1-\beta_v^2} \quad (\beta_v = K/\hat{K}_0) \tag{15}$$

2.2 *Application of linear method*

As there is no correlation function available for the concerned bridge, the correlation function proposed by Wilkinson (1981) based on pressure measurement on square cylinder is used in present analysis (Fig. 1):

$$R(\Delta x) = \exp[-f_1(\eta)(\frac{\Delta x}{D})^{f_2(\eta)}] \tag{16}$$

Here, η is non-dimensional amplitude, $f_1(\eta)$ and $f_2(\eta)$ are fitted as the following functions (Ehsan 1990):

$$f_1(\eta) = \frac{0.052}{0.298+\eta^{0.25}} \qquad f_2(\eta) = \frac{0.065}{0.042+\eta} \tag{17}$$

For section model case, the reduced factor varies with length of model and amplitude. The mode shape function is $\phi(x)=1$, $\theta(\Delta x)$ and $R(\cdot)$ can be calculated by Eqs.11 and 16 respectively. The reduced factor Φ is then obtained fromEq.12. Fig. 2 shows the reduced factors of section model varying with length of model and amplitude. For prototype or full bridge model of long span suspension bridge, the mode shape function of first symmetric vertical (V-S-1) mode can be simplified as $\phi(x)=\cos(\pi \cdot x/L)$. The reduced factor can also be obtained from above mentioned equations. Fig. 3 shows the reduced factors for prototype bridge or full bridge model varying with length and amplitude (V-S-1).

The amplitude derived from section model testing can be interpreted into prototype bridge by the following iteration equation:

$$A_{pi+1} = nA_m \cdot \frac{\Phi_{pi}\vartheta_m}{\Phi_m\vartheta_p} \tag{18}$$

In above, n is model scale, A is amplitude, m and p represent model and prototype.

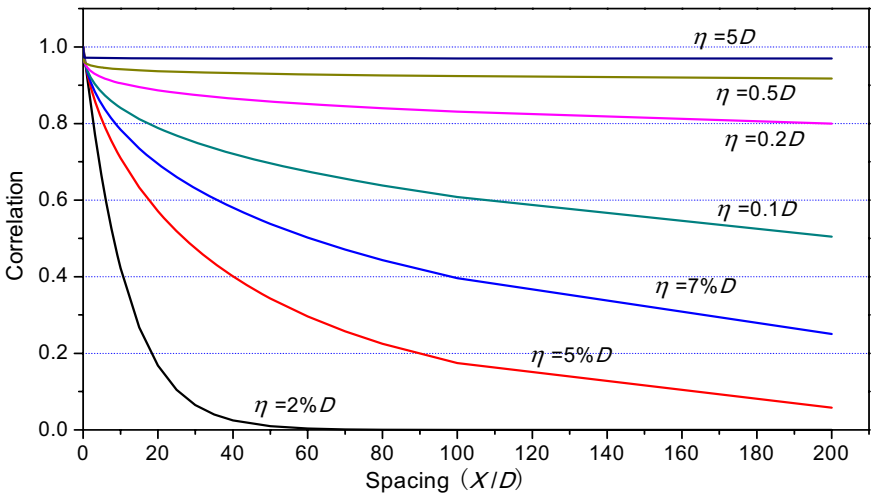

Fig. 1 Examples of correlation curves (Wilkinson, 1981)

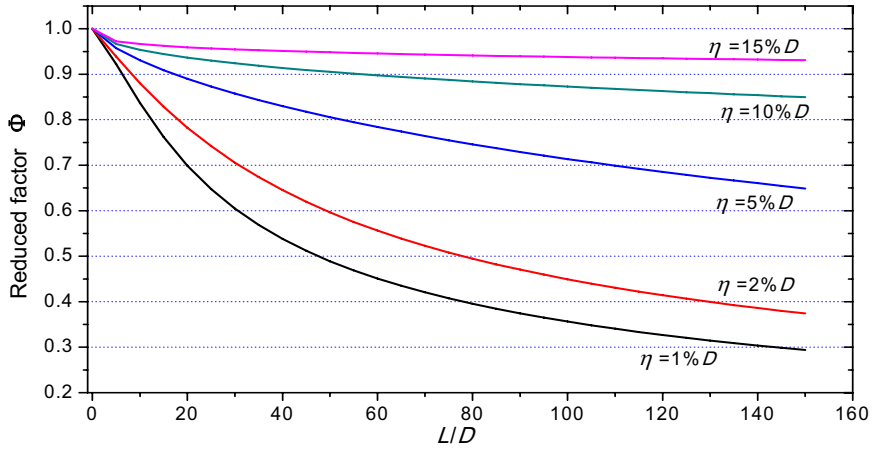

Fig. 2 Reduced factors for section model, $\phi(x)=1$

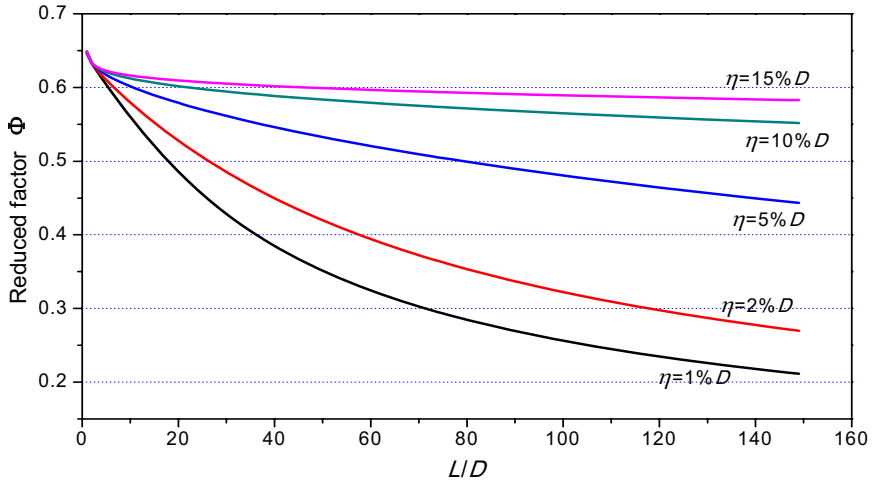

Fig. 3 Reduced factors for suspension bridge (V-S-1)

The maximum amplitude of prototype bridge can be found by Eq.16 after several iteration. Special attention is required that the amending for mode shape has been finished in the first iterative process, and it shouldn't be included in the rest iterative processes. It means that the iterative equation of the rest processes can be written as

$$A_{pi+1} = nA_m \Phi_{pi} / \Phi_m$$

3 NONLINEAR METHOD

3.1 *Nonlinear model description*

Scanlan (1981) proposed a semi-empirical nonlinear model. In this model, a linear mechanical oscillator is subjected to a forcing function which is assumed to be the sum of a motion-induced component and a direct vortex shedding component:

$$m(\ddot{y}+2\zeta\omega_0\dot{y}+\omega_0^2 y)=\frac{1}{2}\rho U^2(2D)\left[Y_1(K)\left(1-\varepsilon(K)\frac{y^2}{D^2}\right)\frac{\dot{y}}{U}+Y_2(K)\frac{y}{D}+\frac{1}{2}C_L\sin(\omega t+\theta)\right] \tag{19}$$

The parameters Y_1, ε, Y_2, C_L and θ in this model should be estimated by section model wind tunnel testing. Several methods for estimating the parameters were outlined by Scanlan (1981) Ehsan (1990) and Li (1995) etc. The other notations in Eq.19 denote the same means as Eq.1.

At lock-in, it is assumed that the parameters of aerodynamic stiffness term Y_2 and instantaneous lift coefficient C_L are very small compared to aerodynamic damping term Y_1. It means Y_2= C_L =0. Although an elastic suspended section model is assumed to behave in a two dimensional manner, it is actually a three-dimensional object so that the aerodynamic force are not perfectly correlated along its length. In the case of an actual bridge, the vortex-induced aerodynamic force introduced by vortices is imperfect correlation along the span. Thus Y_1 and ε estimated from section model testing actually represent these forces in an average sense only, they may be varied with the location x along the span. Thus, the modified model can be expressed as:

$$m(\ddot{y}+2\zeta\omega_0\dot{y}+\omega_0^2 y)=\rho UD\left[Y_1(K,x)\left(1-\varepsilon(K,x)\frac{y^2}{D^2}\right)\frac{\dot{y}}{U}\right] \tag{20}$$

The non-dimensional form of the model should be written in the following form by non-dimensional process and introducing generalized coordination ξ(*t*):

$$m\phi(x)\left(\ddot{\xi}(t)+2\zeta\omega_0\dot{\xi}(t)+\omega_0^2\xi(t)\right)=\rho UD\left[Y_1(K,x)\left(1-\varepsilon(K,x)\phi^2(x)\xi^2\right)\phi(x)\dot{\xi}\right] \tag{21}$$

Multiplying both sides by ϕ(*x*) and integrating over the span *L* of the deck:

$$M\left(\ddot{\xi}(t)+2\zeta\omega_0\dot{\xi}(t)+\omega_0^2\xi(t)\right)=\rho UD\int_0^L\left[Y_1(K,x)\left(1-\varepsilon(K,x)\phi^2(x)\xi^2(t)\right)\phi^2(x)\dot{\xi}(t)\right]dx \tag{22}$$

Where *M* is the generalized mass, $M=\int_{-L/2}^{L/2}m(x)\phi(\mathrm{x})^2\mathrm{dx}$.

3.2 *Section model case*

For section model case, the mode shape function is ϕ(*x*)=1, the reduced factor varies with length of model and amplitude. The mathematic model can be written as following by inserting ϕ(*x*)=1 into Eq.22.

$$M\left[\ddot{\xi}(t)+2\zeta\omega_0\dot{\xi}(t)+\omega_0^2\xi(t)\right]=\rho UDLF(t) \tag{23}$$

Here, $F(t)=\frac{1}{L}\int_{-L/2}^{L/2}f(\mathrm{t,x})\mathrm{dx}$, $f(t,x)=Y_1(K,x)\left[1-\varepsilon(K,x)\xi^2(t)\right]\dot{\xi}(t)$.

The correlation of *F*(*s*) is studied by using the similar method as last chapter (Eqs.5-9). The reduced relation of vortex induced aerodynamic forces between two-dimensional and three-dimensional is still F=Φ·f. Reduced factor Φ of vortex induced response between two-dimensional and three-dimensional is defined as follow:

$$\Phi=\sqrt{\frac{1}{L^2}\int_{-L/2}^{L/2}\int_{-L/2}^{L/2}R(\Delta x)dx_1dx_2} \tag{24}$$

Eq.23 can be rewritten as the following form by using correlation function proposed by Wilkinson,

$$M\left[\ddot{\xi}(t)+2\zeta\omega_0\dot{\xi}(t)+\omega_0^2\xi(t)\right]=\Phi\rho UDLY_1'\left[1-\varepsilon'\xi^2(t)\right]\dot{\xi}(t) \tag{25}$$

It is worth mentioned that the parameters of $Y_1'$and ε' in this equation are based on absolute two-dimensional estimation. It may be quiet different with the one estimated from section model wind tunnel testing. After analyzing the right side of Eq.22, it is clearly that the parameter ε is constant and retains its two-dimensional value and parameter Y_1 has the same reduced factor with vortex induced force. It means that,

$$Y_1'=Y_1/\Phi \qquad \varepsilon'=\varepsilon \tag{26}$$

If the net energy loss or gain per cycle is zero at lock-in,

$$\int_0^T\left[2M\zeta\omega_0-\Phi\rho UDLY_1\left(1-\varepsilon\xi^2(t)\right)\right]\cdot\dot{\xi}^2(t)dt=0 \tag{27}$$

Assuming that the generalized coordinate is sinusoidal, i.e. $\xi(t)=\xi_0\cos(\omega t)$, then,

$$\xi(t)=\xi_0\cos(\omega t);\quad \int_0^T\dot{\xi}^2(t)dt=\pi\omega\xi_0^2;\quad \int_0^T\dot{\xi}^2(t)\xi^2(t)dt=\frac{\pi}{4}\omega\xi_0^4$$

The energy condition leads to the following expression for the amplitude of the generalized coordinate ξ_0,

$$\xi_0=2\sqrt{\frac{\Phi Y_1'-\dfrac{2M\zeta\omega}{\rho UDL}}{\Phi Y_1'\varepsilon'}} \tag{28}$$

In which, $M=mL$. Lets $m_r=\rho D^2/m$, Eq.28 can be rewritten as:

$$\xi_0=2\sqrt{\frac{1}{\varepsilon'}}\left(1-\frac{2\zeta K}{m_r\Phi Y_1'}\right)^{1/2} \tag{29}$$

3.3 *Prototype bridge*

In the case of an actual bridge, it has an infinite set of modes. The mode shape function $\phi(x)$ of the bridge should be gained by mode analysis. For arbitrary $\phi(x)$, the vertical displacement at lock-in can be calculated using the condition that net energy loss or gain per cycle is zero. The energy condition leads to the following expression for the amplitude of the generalized coordinate ξ_0:

$$\xi_0=2\sqrt{\frac{\displaystyle\int_0^L Y_1\phi^2(x)\frac{dx}{L}-\frac{2M\zeta K}{\rho D^2L}}{\displaystyle\int_0^L Y_1\varepsilon\phi^4(x)\frac{dx}{L}}} \tag{30}$$

Ehsan (1990) proposed a roughly method to account for the imperfect correlation of aerodynamic forces along the span. The similar method with linear theory (Chapter 2) and Duhamel Integral theory are applied in this study. Eq.22 can be rewritten as follow:

$$M\left(\ddot{\xi}(t)+2\zeta\omega_0\dot{\xi}(t)+\omega_0^2\xi(t)\right)=\rho UD\left(\int_0^L Y_1\phi^2(x)dx-\int_0^L Y_1\varepsilon\phi^4(x)dx\xi^2(t)\right)\dot{\xi}(t) \tag{31}$$

According to Duhamel Integral theory, mode shape function ϕ(x) can be seen as input function, and correlation function R(Δx) can be treated as response functions. The mathematic model can be written as following form:

$$M\left(\ddot{\xi}(t)+2\zeta\omega_0\dot{\xi}(t)+\omega_0^2\xi(t)\right)=\rho UDL\left(Y_1'\Phi_2-Y_1'\varepsilon'\Phi_4\xi^2(t)\right)\dot{\xi}(t) \tag{32}$$

Where

$$\Phi_2=\sqrt{\frac{1}{L^2}\int_{-L/2}^{L/2}\int_{-L/2}^{L/2}\phi^2(x_1)\phi^2(x_2)R(\Delta x)dx_1dx_2}$$

$$\Phi_4=\sqrt{\frac{1}{L^2}\int_{-L/2}^{L/2}\int_{-L/2}^{L/2}\phi^4(x_1)\phi^4(x_2)R(\Delta x)dx_1dx_2} \tag{33}$$

The energy condition leads to the following expression for the amplitude of the generalized coordinate ξ_0:

$$\xi_0=2\sqrt{\frac{\Phi_2Y_1'-\dfrac{2M\zeta\omega}{\rho UDL}}{\Phi_4Y_1'\varepsilon'}} \tag{34}$$

Eq.34 can be re written as,

$$\xi_0=2\sqrt{\frac{\Phi_2}{\varepsilon'\Phi_4}}\left(1-\frac{2\zeta K}{m_r\Phi_2Y_1'}\int_0^L\phi^2(x)dx\right)^{1/2} \tag{35}$$

If the parameters of the model indentified from sectional model testing are available, the vortex induced response of bridge can be estimated by using Eq.35 and taking into account the imperfect spanwise correlation of aerodynamic forces.

3.4 *Application of nonlinear method*

For section model, $\phi(x)=1$, $\theta(\Delta x)=2(L-\Delta x)$, and the reduced factor can be obtain by inserting it into Eq.24:

$$\Phi=\sqrt{\frac{1}{L^2}\int_0^L 2(L-x)R(\Delta x)d\Delta x} \tag{36}$$

Lets $z=\Delta x/L$ and $\hat{L}=L/D$, the non-dimensional form of Eq.36 can be expressed as follow：

$$\Phi(\hat{L})=\sqrt{\int_0^1 2(1-z)\exp[-f_1(\eta)\cdot(\hat{L}z)^{f_2(\eta)}]dz} \tag{37}$$

For prototype or full bridge model of long span suspension bridge, the mode shape function of first symmetric vertical can be assuming as the form $\phi(x)=\cos(\pi\cdot x/L)$. The reduced factor can be obtained by inserting it into Eq.33:

$$\Phi_2 = \sqrt{\frac{1}{L^2}\int_0^l 2\int_{-L/2}^{L/2-\Delta x} \cos^2(\frac{\pi \cdot x}{L}) \cdot \cos^2(\frac{\pi \cdot (x+\Delta x)}{L}) dx \cdot \exp[-f_1(\eta) \cdot (\Delta x / D)^{f_2(\eta)}] d\Delta x}$$

$$\Phi_4 = \sqrt{\frac{1}{L^2}\int_0^l 2\int_{-L/2}^{L/2-\Delta x} \cos^4(\frac{\pi \cdot x}{L}) \cdot \cos^4(\frac{\pi \cdot (x+\Delta x)}{L}) dx \cdot \exp[-f_1(\eta) \cdot (\Delta x / D)^{f_2(\eta)}] d\Delta x} \quad (38)$$

Lets $\hat{x} = x / L$, the non-dimensional form of Eq.38 can be written as：

$$\Phi_2 = \sqrt{2\int_0^1 \int_{-1/2}^{1/2-z} \cos^2(\pi \hat{x}) \cdot \cos^2(\pi(\hat{x}+z)) d\hat{x} \cdot \exp[-f_1(\eta) \cdot (\hat{L}z)^{f_2(\eta)}] dz}$$

$$\Phi_4 = \sqrt{2\int_0^1 \int_{-1/2}^{1/2-z} \cos^4(\pi \hat{x}) \cdot \cos^4(\pi(\hat{x}+z)) d\hat{x} \cdot \exp[-f_1(\eta) \cdot (\hat{L}z)^{f_2(\eta)}] dz} \quad (39)$$

4 CASE STUDY

Obvious vortex induced vibration (VIV) was observed during sectional model testing and prototype for the Deer Isle-Sedgwick bridge in the third vertical mode. Details of the testing are given by Ehsan (1988) and Kumarasena (1989). The estimated parameter values at K=0.929 and ζ=0.00625 were Y_1=10.54 and ε=228.7. The main span of the bridge is 329.2m long; the deck is 1.98m deep. The mass ratio was computed to be m_r=0.001348. The peak-to-peak amplitude derived from section model testing is interpreted into prototype bridge with linear VIV theory and nonlinear VIV theory are 0.076m and 0.101m respectively by considering imperfect correlation of vortex-induced aerodynamic force along span. The amplitude observed in the field is 0.096m. It's obvious that the proposed response estimation method yields very reasonable results.

Experimental study of vortex-induced vibrations on H-shaped sections

Abraham S. Corriols [a], Miguel A. Astiz [a], Antonio Barrero [a]
[a] *Technical University of Madrid, Prof. Aranguren s/n, Spain*

ABSTRACT: Experimental results of aeroelastic tests carried out with H-section models, aiming to study in detail the aeroelastic phenomena associated with vortex shedding, are presented through this paper. Such phenomena led to the oscillations of Alconétar arch bridge during its construction in 2006. The facility used is a small, simple wind tunnel built at the Ignacio Da Riva Institute, School of Aeronautics, Technical University of Madrid. Also a comparison with data from rectangular tandem section tests that conform to the geometry of the bow section of the Alconétar Bridge and some conclusions are outlined.

KEYWORDS: Aerodynamics, Vortex shedding, Vibration, Tandem section, H-shaped section

1 INTRODUCTION

The oscillations observed in the Alconétar steel arch bridge during its construction in January 2006 before placing the superstructure [1], led to the initiation of a research aimed at studying in detail the aeroelastic phenomena related to the vortex shedding that resulted in such an event [2].

Figure 1. Alconétar bridge during erection (left) and cross-section with main dimensions (right)

The maximum amplitude reached was 80 cm on the vertical axis [1]. The box depth corresponding to the maximum amplitude value is D=2.41 m, the box width is B=1.2m and the total width is W=7.74 m, giving a side ratio of W/D = 3.21. Measured wind speeds during the Alconétar Bridge vibration episode did not exceed 30 km/h, so the corresponding reduced frequency was close to 0.21, typical from a H-shaped section with the same side ratio. [3]. The modal mass is 1,133 kg/m and the damping ratio of critical, 0.003.

It is well known that bluff bodies behave very differently than streamlined bodies with the passage of air flow. In high curvature surfaces, an adverse pressure gradient is added to the retardant action of friction surface, which can cause the flow to be interrupted and retreat to a region adjacent to the surface. This results in the emergence of a back flow region, and a detached boundary layer appears below. For sufficiently high Reynolds numbers (say, above 10^3), the region due to the separation flow becomes unstable and an oscillating wave composed of large-scale eddies, known as Von Karman vortex street, is formed downstream of the body.

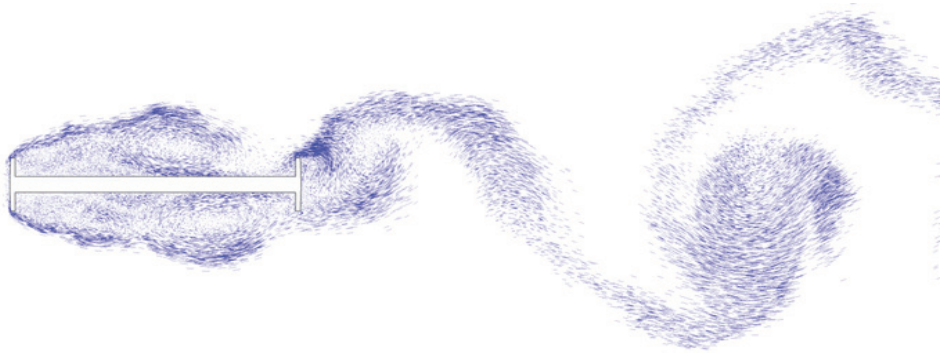

Figure 2. Visualization of the vortex shedding phenomenon through a numerical simulation code

The vortex shedding typically develops with great regularity showing a dominant frequency, which is characterized by the Strouhal number, according to the following expression:

$$St = \frac{fD}{U_\infty} \tag{1}$$

where D is the section depth, and U_∞, the speed of the current incident. The Strouhal number (St) mainly depends on the geometry of the object.

When the natural frequency of the structure is close to the value of the vortex shedding frequency, the periodic forces caused by the alternate shedding can give rise to resonance oscillations, resulting in a complex coupling between the motion of the structure and the wake pattern (e.g., the spacing between the vortices can change). Usually these type of oscillations are classified as instability induced excitations (IIE) [3]

When analysing the effect of vortex-induced oscillations, it is important to note that the amplitude of the structure is self-limited [3]. There is an upper threshold with a maximum equal to the vertical dimension of the body. Nevertheless, these types of oscillations can be considered as problematic for the serviceability of the structure. Thus, it is necessary to limit the level of vibrations in structures to ensure an appropriate standard of comfort for the users and avoid fatigue damage over time.

2 EXPERIMENTAL SET-UP

Tests were conducted in a small, simple wind tunnel built at the Ignacio Da Riva Institute, School of Aeronautics, Technical University of Madrid (see fig. 2). The installation has a rotor capable of generating an air flow that can reach a maximum speed of 1.40 m/s, driven by an AC motor. The regulation of the flow speed is achieved through a variable transformer capable to get speed increments of 0.01 m/s (the same as the tolerance of the hot wire anemometer used for

measuring the flow speed values). A laser device to measure the oscillation amplitudes of the models is employed. An oscilloscope has been connected in order to allow a better visualization of periodic movements.

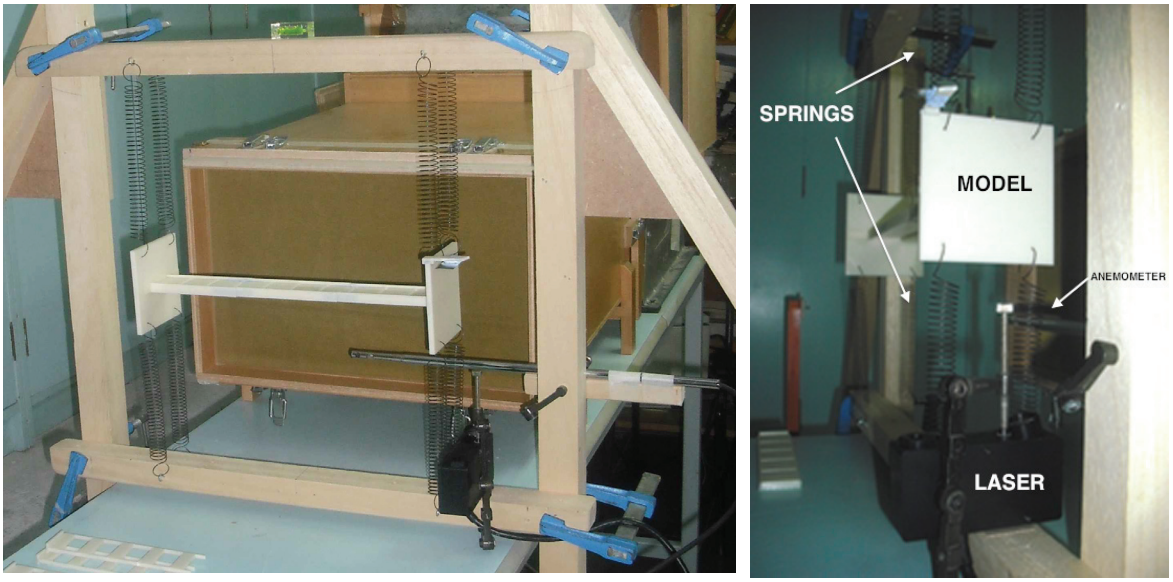

Figure 3. General view of the installation (left). Detail of springs, laser and hot wire anemometer (right)

Eight springs support the model elastically normal to the air flow. Linearity of the mechanical properties for every model was checked. These properties ready for testing are listed in Table 1.

Compared to the real section of Alconétar Bridge, it has a scale factor of 1/240. The Reynolds number range is between 67 and 930. Typical Reynolds numbers for real bridges are between 10^5 and 10^7, so it creates a turbulent wake behind the section. For Reynolds numbers less than 10^3 as the case is, viscous forces are still important, so it will be necessary to consider this fact to draw the appropriate conclusions and compare the results with other tests performed.

3 MODELS TESTED

Table 1 summarizes the geometry properties of the models used, being W/D the width/depth ratio corresponding to each model.

Table 1. Geometry of models tested

Model	Length (L) mm	Width (W) mm	Depth (D) mm	W/D
H-SHAPED 2.0	300	20	10	2.0
H-SHAPED 2.5	300	25	10	2.5
H-SHAPED 3.0	300	30	10	3.0
H-SHAPED 4.0	300	40	10	4.0
H-SHAPED 5.0	300	50	10	5.0
H-SHAPED 6.0	300	60	10	6.0
H-SHAPED 7.5	300	75	10	7.5

Dynamic properties to characterize frequency and damping for each W/D ratio are presented below.

Table 2 summarizes dynamic parameters of models tested

MODEL	W/D -	D m	f Hz	m Kg/m	.ξ %	m* -	m*ξ -
H-SHAPED 2.0	2.0	0.01	4.73	0.1017	0.110	813.5	0.8957
H-SHAPED 2.5	2.5	0.01	4.69	0.1031	0.107	825.1	0.8830
H-SHAPED 3.0	3.0	0.01	4.80	0.0982	0.131	785.4	1.0296
H-SHAPED 4.0	4.0	0.01	4.76	0.1011	0.131	809.1	1.0568
H-SHAPED 5.0	5.0	0.01	4.76	0.1046	0.101	837.2	0.8456
H-SHAPED 6.0	6.0	0.01	4.75	0.1038	0.141	830.5	1.1705
H-SHAPED 7.5	7.5	0.01	4.80	0.1042	0.133	833.3	1.1091
H-SHAPED 4.0 POROSITY 0%	4.0	0.01	4.33	0.0994	0.076	794.8	0.6065
H-SHAPED 4.0 POROSITY 10%	4.0	0.01	4.60	0.0867	0.129	693.5	0.8397
ALCONÉTAR BRIDGE	3.21	2.41	0.70	1131	0.300	153.9	0.4616

where W/D=width/depth ratio; f=the vibration frequency of the model; m=linear mass associated to the model; ξ=damping ratio; m*=mass ratio (=m/ρD^2); m*ξ=reduced damping. In order to achieve a realistic comparison, not only depending on the W/D ratio, similar values of damping ratio in all models have been sought. In this case, the values are all close to unity.

A model with a porosity ratio of 10% (related to overall surface and distributed in hollow strips parallels to the air flow direction) has also been tested, in order to compare the amplitude of oscillations with solid models. Also another model with a lower reduced damping (m*ξ) have been considered to check the dependency of the amplitude of oscillations as a function of reduced damping. Lastly, real data from Alconétar Bridge are also included.

Figure 4. Model with of W/D=4.0 and porosity ratio of 10% ready to be tested

4 RESULTS

Figure 5 shows a series of plots corresponding to the amplitude spectrum of lift coefficient oscillations (left) and temporal registration of vertical movements (right) that identify the process of vortex-induced vibration of the model with a W/D = 4.0, for a given range of air flow speeds. Frequency range of the spectrum is 20 Hz, and the time interval considered is one minute, always leaving two minutes at each speed interval prior to the start of data recording to ensure that the steady state is reached.

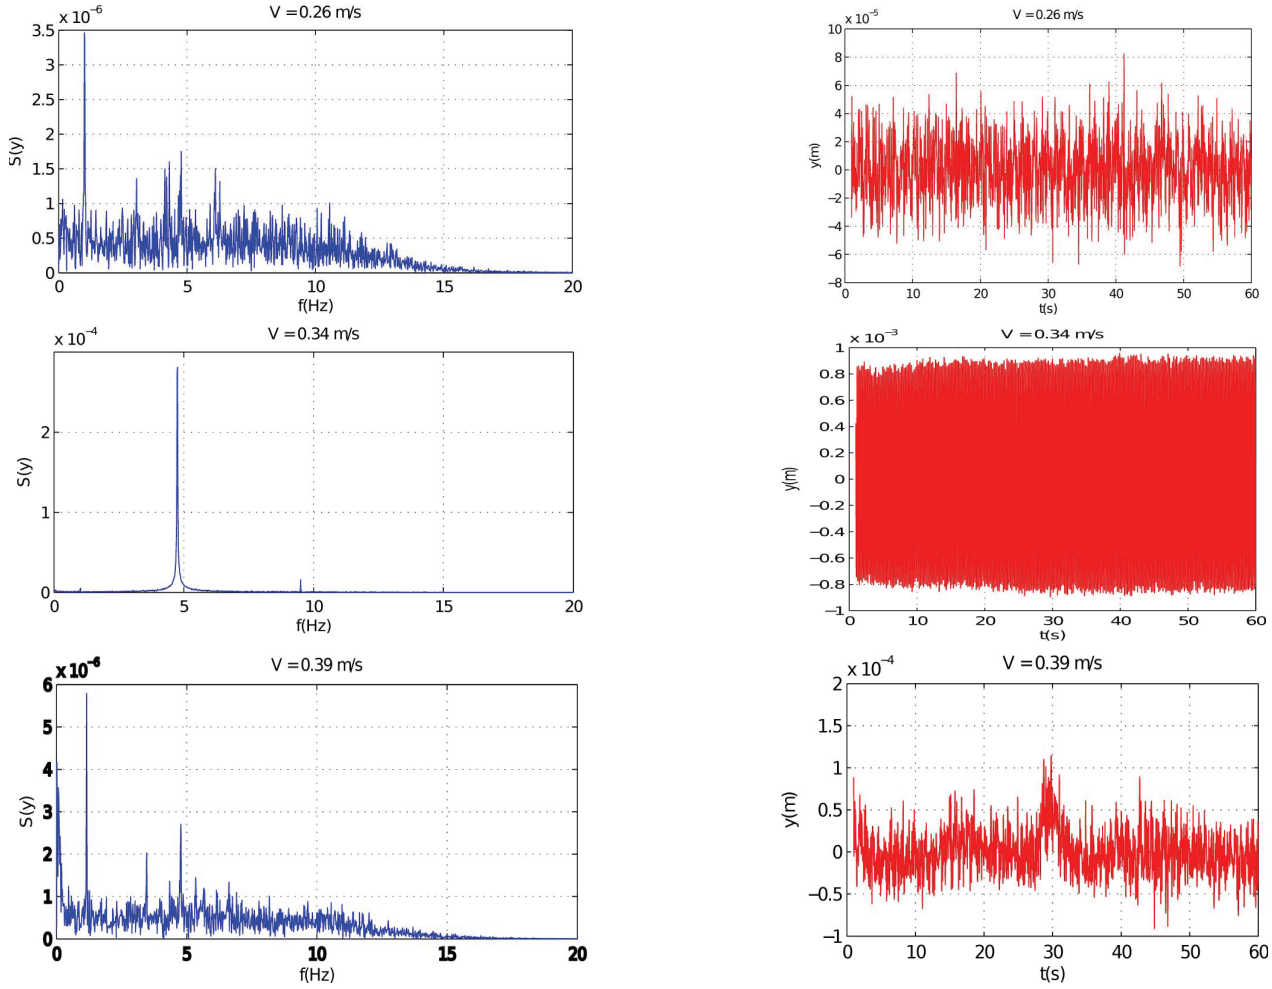

Figure 5. Amplitude spectrum of lift coefficient oscillations (left) and temporal register of vertical displacements within the wind speed range of VIV (right). Model with side ratio of W/D=4.0

Figure 5 (v = 0.26 m/s) shows that the excited frequency range is quite broad, which indicates that the model is vibrating slightly. However, there is no coupling between the natural vibration frequency and the vortex shedding frequency. The oscillations are small, not exceeding the threshold of $6 \cdot 10^{-5}$ m of amplitude (y/D<0.6%). As the wind speed increases, the vortex shedding frequency approaches the natural frequency. Oscillations become more regular and their amplitude increases, reaching a value close to 10^{-4} m (y/D = 1.0%) for an air flow speed value of 0.28 m/s. This value can precisely be considered as the starting speed of vortex-induced vibration phenomenon (v_0), which occurs within an air flow speed range between 0.28 m/s and 0.37 m/s. Critical air flow speed (v_{crit}) is 0.34 m/s, associated to the peak value of vertical oscillations, around $9 \cdot 10^{-4}$m (y/D = 9%). From 0.37 m/s, air flow speed considered as the end of the coupling phenomenon (v_e), small peaks in the spectrum different to the natural oscillation frequency begin to appear, decreasing the amplitude of the oscillation gradually and losing the regularity simultaneously, turning back to the prior oscillation state.

Figure 6 shows the root mean square (RMS) of the amplitude of oscillation as a function of the reduced speed for each model. The range of reduced speeds in which the phenomenon of vortex-induced vibration (VIV) occurs when the W/D ratio varies from 2.0 to 7.5, is between 3.0 and 15.5. For the comparison to be effective and not depend only on the W/D ratio, similar low values of damping ratio (or Scruton number, which is an equivalent parameter) in all models has been sought to achieve.

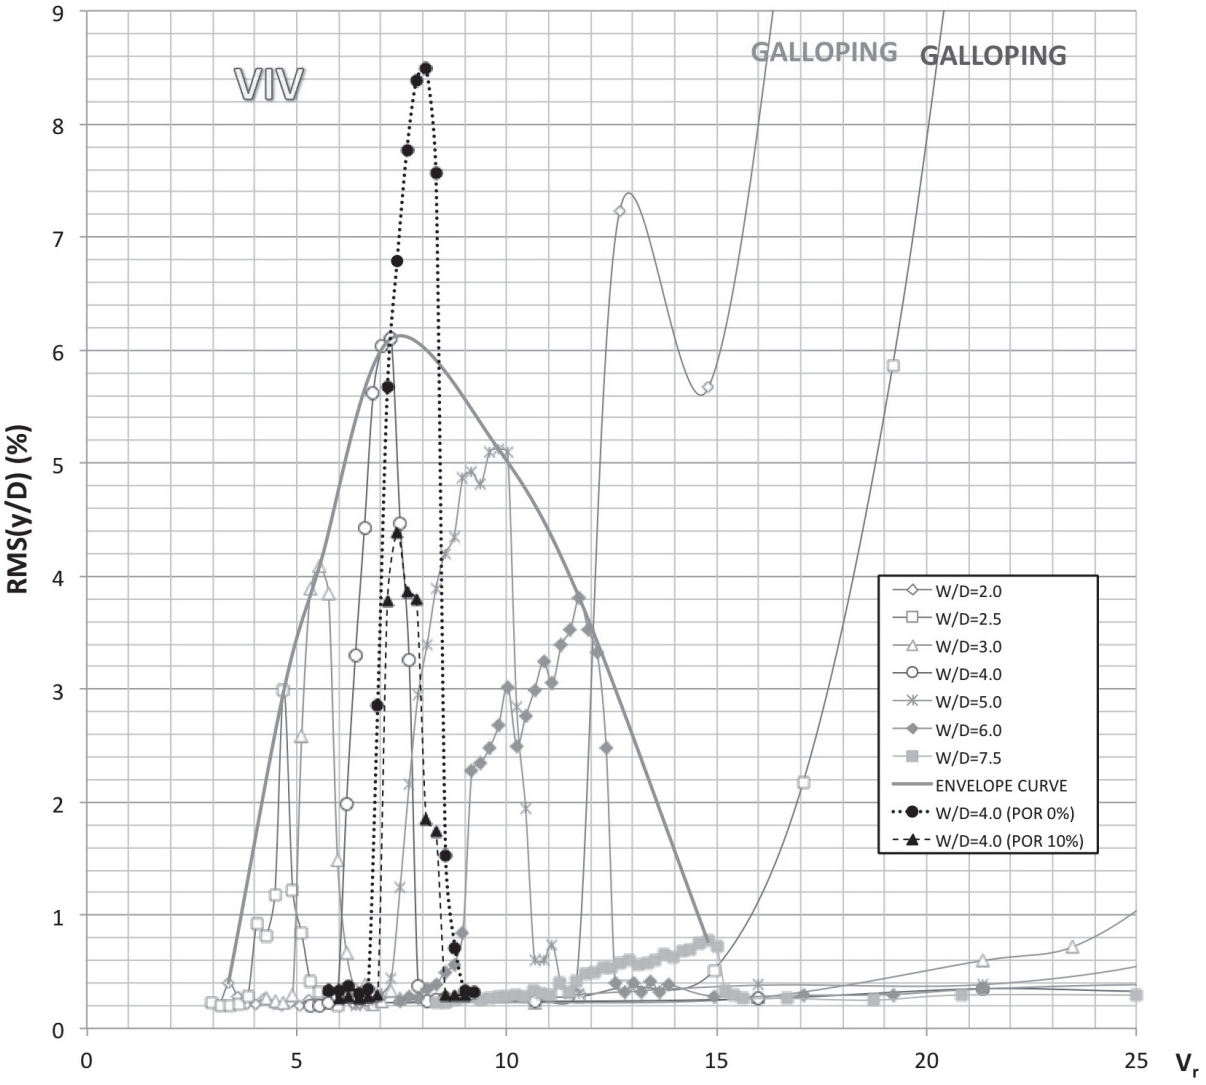

Figure 6. RMS non-dimensional amplitude (RMS(y/D)%) as a function of the reduced speed, v_{red} of models tested

Table 3 collects the most important data represented in figure 6.

Table 3 summarizes main results extracted from the tests

MODEL	$v_{red,crit}$ -	$v_{red,0}$ -	$v_{red,e}$ -	Band-width	$RMS(y)_{max}$(%) -	Sc -
H-SHAPED 2.0	3.38		3.81	0.64	0.40	11.26
H-SHAPED 2.5	4.69	3.17	5.50	1.70	2.99	11.10
H-SHAPED 3.0	5.54	3.80	6.40	1.50	4.09	12.94
H-SHAPED 4.0	7.25	4.90	7.89	1.92	6.10	13.28
H-SHAPED 5.0	9.81	5.97	10.66	3.41	5.12	10.63
H-SHAPED 6.0	11.73	7.25	12.58	3.63	3.81	14.71
H-SHAPED 7.5	14.79	8.95	15.20	3.74	0.08	13.94
H-SHAPED POROSITY 0%	8.08	6.93	8.61	1.68	8.49	7.62
H-SHAPED POROSITY 10%	6.96	6.82	9.02	2.20	4.39	11.23
ALCONÉTAR BRIDGE	≈5.0	-	-	-	≈16.60	5.80

where $v_{red,crit}$=critical reduced wind speed ($v_{red,crit}$=U/fD, being U=air flow speed corresponding to the maximum amplitude of oscillation); $RMS(y)_{max}$=root mean square of the maximum amplitude of oscillation; $RMS(y/D)_{max}$ (%)=root mean square of non dimensional maximum amplitude; Sc=Scruton number ($Sc = 4\pi m^*\xi$)

The most important fact to note is the variation of the maximum response as a function of W/D ratio. As shown in figure 6, the response increases as the W/D relationship increases, up to a maximum, which reaches a non dimensional amplitude of 6.10%for a given side ratio of W/D=4.0. From this value, the response amplitude decreases while W/D increases, so that, with a side ratio of 7.5, the effects of vortex-induced vibrations on the H-shaped section are not significant. The evolution of the response and its dependence on W/D can be explained by the coalescence phenomena of vortices that occur when the air flow interacts with the model [4]. It has been shown that models with W/D=2.0 and W/D=2.5 experience vibrations associated with the phenomenon of transverse galloping at excessively high reduced speeds. It would be interesting to test other models at higher speeds, and thus verify if they might undergo transverse galloping as well at certain air flow speeds.

Figure 7 shows the critical reduced speed, $v_{red,crit}$, the onset reduced speed, $v_{r,0}$, and the ending reduced speed, $v_{red,e}$, as a function of the W/D ratio. All these parameters keep a linear dependence on the W/D ratio. Expressions obtained by least squares adjustment are also given by the following expressions:

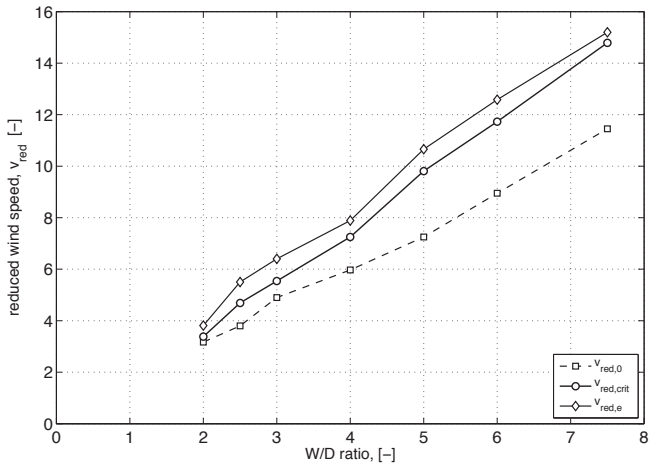

Figure 7. Reduced speeds as a function of W/D ratio for H-shaped section models

$$v_{red,crit} = 2.06 \cdot \frac{W}{D} - 0.67 \quad (2)$$

$$v_{red,o} = 1.47 \cdot \frac{W}{D} - 0.18 \quad (3)$$

$$v_{red,e} = 2.05 \cdot \frac{W}{D} - 0.08 \quad (4)$$

H-shaped section models represent a transition between rectangular sections and two prisms in tandem arrangement. In this case, the vortex shedding pattern presents a peculiar behaviour as described below and depicted in figure 8 with the aid of a CFD code, a very useful tool for understanding the vortex shedding mechanism. For small side ratios the central spacing between section borders do not have any influence and behaves as an equivalent rectangular section. For side ratios greater than 2.0, vortex shedding mechanism responds to the ILEV type [3] That is due to the appearance of convection cells in the upper and lower gap, which maintains the detached boundary layer and favours the formation of impinging leading edge vortices along the surface (ILEVcc). This effect is less important as the side ratio increases. Furthermore, according to figure 8, with side ratios between 2.0 and 4.0, a transition zone between normal ILEV pattern and that caused by convection cells (ILEVcc) gives rise to a dual vortex shedding frequencies, thus we conclude that the resonant effect may occur for two different horizontal wind speeds.

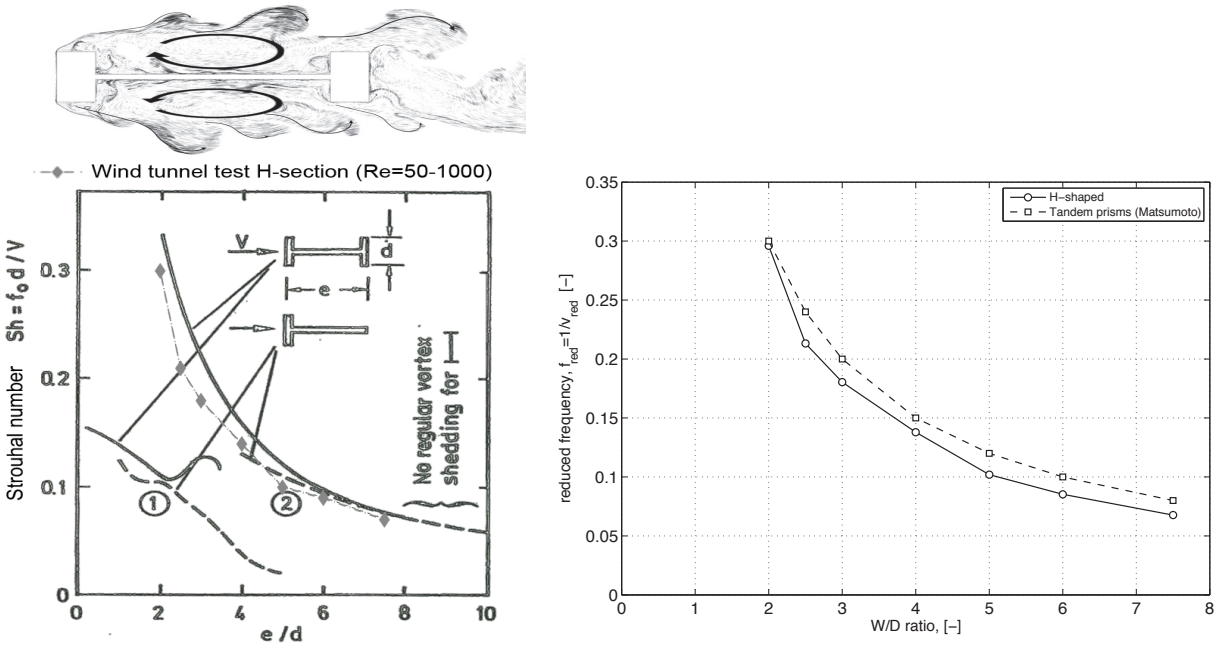

Figure 8. CFD flow visualization and Strouhal number for different H-section side ratios (After [5], p. 129), with present results added (left). Reduced frequency of VIV p as a function of W/D ratio (right)

5 COMPARISON WITH OTHER EXPERIMENTAL RESULTS

Experimental wind tests similar to that described in this paper were carried out by Matsumoto and other researchers with rectangular sections in tandem configuration [4] are shown in figure 9. The model tested consist in two prisms in tandem arrangement with W/D=4.0, B/D=1.0 and a splitter plate behind the prism downstream. Two vortex shedding patterns are identified: the movement induced excitation (MIE) and Karman Vortex (KV). MIE pattern can be associated to the ILEV mechanism, as described previously.

The upper curve on the right (see figure 8) corresponds to the onset reduced frequency ($f_{red,o}=1/v_{red,o}$) of MIE vibrations type, characterized by Matsumoto and experienced by rectangular tandem sections. Their values are very close to the lower curve, which relates the reduced

frequency with the W/D ratio for H-shaped section models. Results for H-shaped section correlate well with those obtained by the Japanese researcher.

Figure 9 shows the value of non dimensional amplitude, η/D, based on the reduced speed obtained by Matsumoto [4]. Peaks amplitudes are located close to 15%. In the case of H-shaped sections, the maximum peak amplitude registered was 9.0% for 'H-SHAPED W/D=4.0' and 12.1% for 'H-SHAPED W/D=4.0 POROSITY=0%'. The maximum RMS value was 6.1% and 8.5%, respectively. Both models have the same geometry but different values of reduced damping: m*ξ=1.06 for 'H-SHAPED W/D=4.0' and m*ξ=0.61 for 'H-SHAPED W/D=4.0 POROSITY=0%'. Matsumoto's model has a total value (two prisms) of m*ξ=1.66 (m*δ=5.2 per prism, being δ=2πξ). The larger reduced damping is, the smaller the smaller amplitudes of oscillation are. However, H-shaped section and two prisms in tandem cannot be compared, since their force coefficients are not equivalent and the amplitude of oscillation significantly depends on the lift coefficient as well.

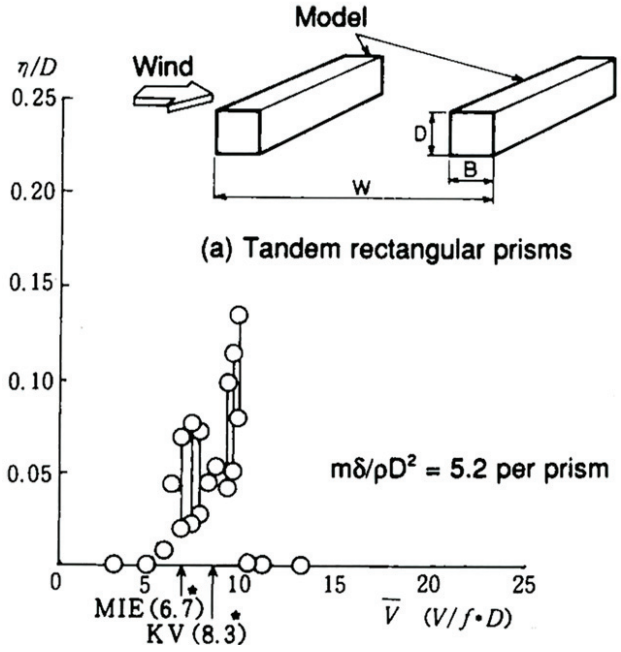

Figure 9. Non dimensional amplitude of oscillation as a function of reduced speed for prisms in tandem arrangement (from [4])

6 CONCLUSIONS

Vortex-induced vibrations identified in the H-shaped section models are not due to alternating shedding of vortices, or Von Karman vortices (KV, according to the description made by Matsumoto in [4]) as it might be initially thought, but an excitation induced by the movement of the structure itself. The vortices originated from the interaction between the air flow and the studied section also come into play different from alternating shedding of vortices. As in the rectangular tandem sections, the aerodynamic forces acting on the H-shaped section models seem to be largely conditioned by the section oscillations.

This issue highlights the importance to understand the mechanism that causes the aerodynamic phenomenon and thus take the required measurements to eliminate or minimize vibrations as they can endanger the integrity of certain structures such as bridges, if the circumstances occur. The vibration episode of Alconétar Bridge might be explained through two possible vortex shedding patterns analyzed herein.

7 ACKOWLEDGEMENTS

The authors would like to thank Ignacio Da Riva Institute staff for their kindness and availability to perform the wind tests.

ABSTRACT: The vortex shedding response of a bluff bridge girder deck with and without balusters has been investigated by numerical simulation and wind tunnel experiments with the objective of identifying the mode of vortex excitation and effects of balusters on vortex-induced vibration of bridge deck. Tests on 2 spring suspended models revealed different vortex response. This process is likely to render the blunt bridge girder deck with balusters more susceptible to vortex shedding excitation than the bare section. Measurement of the fluctuating pressure around the deck surface indicates that vortices shed from the downstream section with balusters have greatly contributed to the vertical vortex-induced vibration, while the bare section (i.e. without balusters) pressure fluctuations over the entire upper and lower surface have little contribution to the vortex response.

1 INTRODUCTION

Vortex-induced vibration which is prone to occur is one of the wind-induced vibration phenomenon. For many years, lots of researchers have fully proved that the vortex response has a strong dependence on the shape of structures. Kubo et al. [1] had investigated the air flow characteristics of the torsional vortex-induced vibration of a π section with C/D = 0.5 and C/D = 2, where C is the length of the cantilever and D is the π section height. The results show that the flow separation in the C/D = 0.5 is more obvious than C/D = 2, that is, the more blunt π section is, the more serious separation. Nagao and co-workers [2] studied effects of handrails on the vortex-induced oscillations, the conclusion is that the handrails can amplify the vertical vortex-induced vibration, and in torsional vortex-induced vibration, the interaction of the separated flow and handrails can not only weaken the formation of vortices shedding, but also reduce the self-excited forces.

In order to analyze influences of balusters on vortex response of the bridge deck, this present paper makes a research on vortex-induced vibration response of a bluff bridge girder deck with and without balusters, and explains the differences of both vortex response through an analysis of surface pressure distribution.

2 VORTEX EXCITATION OF BRIDGE DECKS

The test section is based on a bluff bridge deck section with flanges (Fig. 1). As a trapezoidal box shape, Von Karman type vortices are expected to form and to be shed at regular time intervals in the downstream box as illustrated in the snapshots taken from a detached eddy simulation of the air flow, Fig. 2.

Fig. 2 indicates that the flow separation of two kinds of section is fairly different. The balusters have a great impact on the vortex shedding. Vortices of bare section are much less than vortices of section with balusters. The vortex shedding process of section with balusters may, if could allow to occur, lock-in with a vertical eigenmode, and thus excite vertical vortex-induced oscillations.

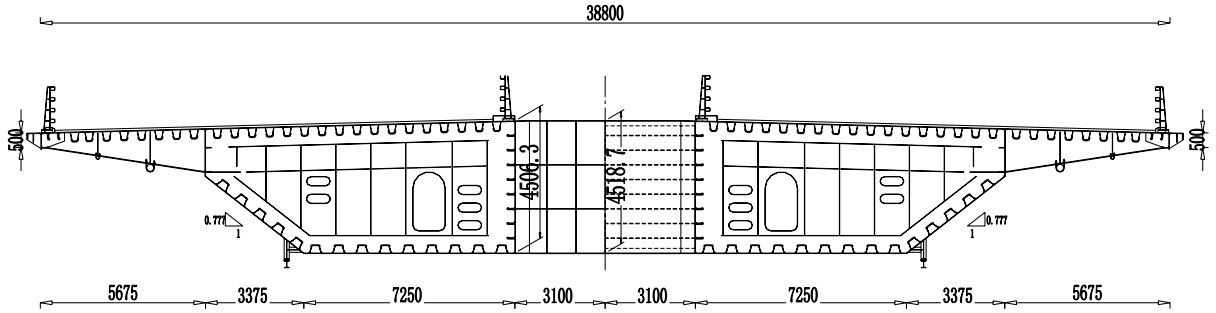

Fig. 1. Section of a box bridge girder. 38.8 meters wide (B), 4.5 meters high (H), the aspect ratio H/B = 1: 8.62. There are four balusters with the height of 1.5m along the bridge cross section.

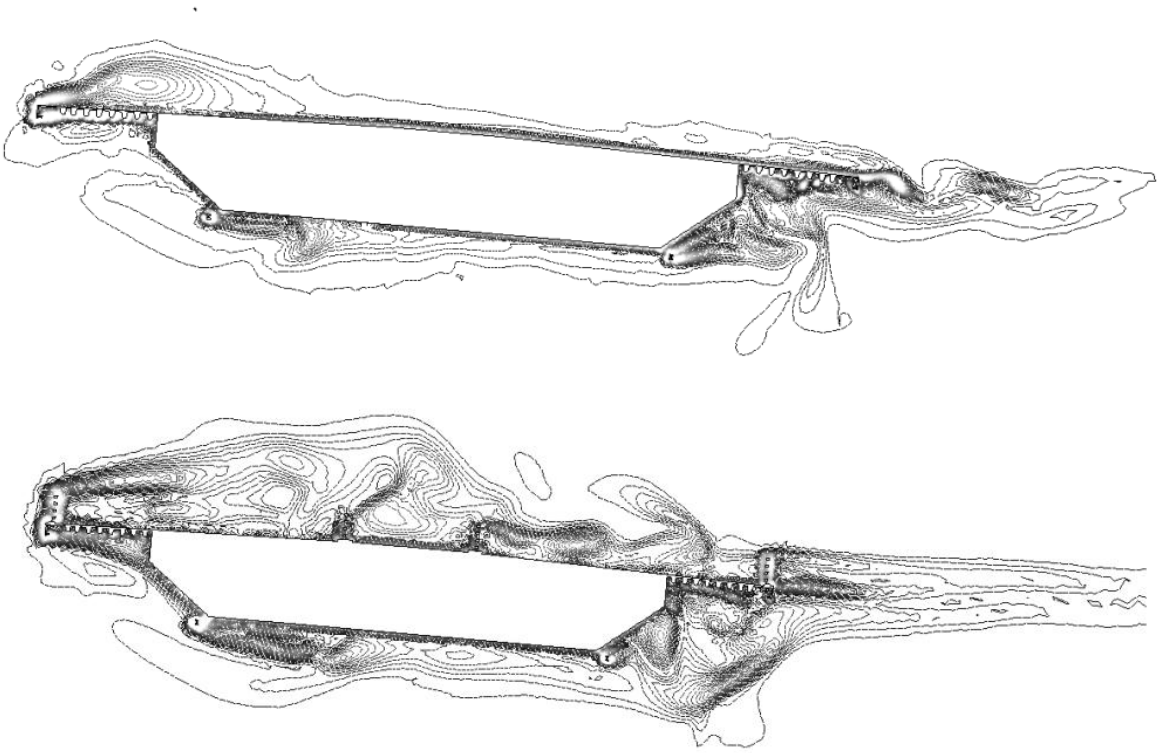

Fig. 2. Detached eddy simulation of the air flow about the bridge deck cross section with and without balusters. Angle of attack α = +5deg, wind speed is 15 m/s. Bare section, i.e. without balusters (top), section with balusters (bottom).

3 VERTEX SHEDDING TESTS

The vortex response of two sections, as shown in Fig. 3, were test during standard 1:20 scale section model wind tunnel experiments conducted in CA-1 wind tunnel which is a closed circuit wind tunnel with test section of 3.0m × 2.5m. Tests on the section with balusters under the uniform flow revealed a vertical response peak of 5% root mean square (rms) amplitude of the section depth H at a non-dimensional wind speed U/fB ≈ 1.88, while no vertex-reduced vibration happened in the bare section. Experimental studies had shown that the section with balusters excited two lock-in districts of vertical vortex-induced vibration. Larsen and his co-workers [3] also obtained the similar results in a 1 : 80 scale wind tunnel tests of a twin box bridge deck section.

The present paper focuses on the latter vortex-reduced vibration because the latter amplitude is fairly larger than the former. In order to understand the vortex response difference of the two sections, surface pressure measurements should be conducted.

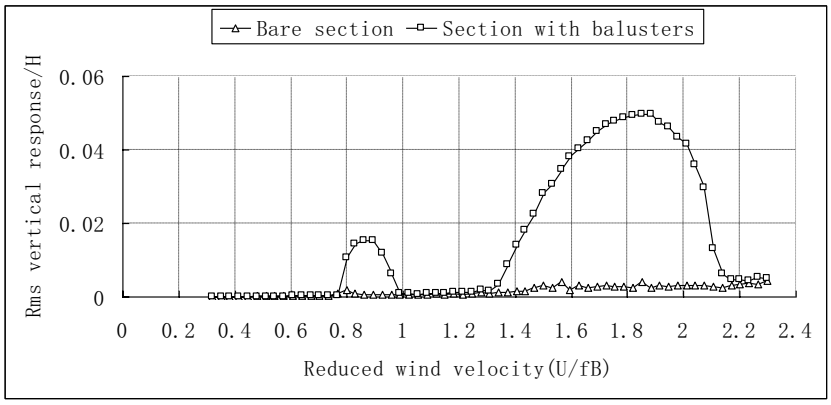

Fig. 3. Vortex response of the two kinds of section. 1:20 scale section model is supported by a 4.04 Hz spring suspension having a nominal structural damping ζ = 0.3% relative-to-critical. Angle of attack α = +5deg, U is wind speed, f is vertical frequency and B is the overall deck width.

4 SURFACE PRESSURE MEASUREMENTS

The surface fluctuating pressure status gave an opportunity to look further into the vortex dynamics through high frequency pressure measurements made at 120 taps (Fig. 4) mounted with the box section circumference. Two electronic pressure scanning valves manufactured by the PSI company in U.S were used to measure the fluctuating pressure around the two kinds of section. The range of each electronic pressure scanning valve is ±10 inch water column. There are 64 channels on a single valve and the measurement time delay is not greater than 3.2×10^{-3}s, it is considered that every channel is measured simultaneously.

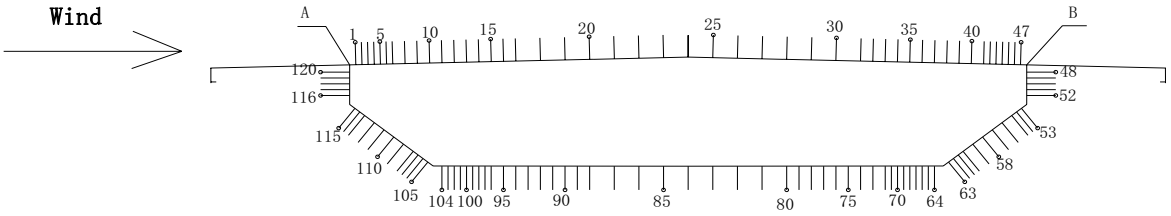

Fig. 4. Arrangement of pressure taps.

4.1 *Mean pressure coefficient*

Fig. 5 compares the mean pressure coefficient between the bare section and section with balusters at the non-dimensional wind speed U/fB ≈ 1.88. The presence of balusters does not change the mean pressure distribution of soffit plate (Fig. 5 bottom), but significantly change the pressure distribution on the upper surface (Fig. 5 top). When introducing the balusters it is noted that the adverse pressure gradient on the upper surface (x/D ≈ 0.25 ~ 0.76) of bare section vanish. In other words, the air flow separation on the upper surface come earlier owing to effects of balusters. Boundary layer separation would lead to vortex shedding, and vortex-induced forces from periodic vortex shedding would have contributed to the vortex-induced oscillations.

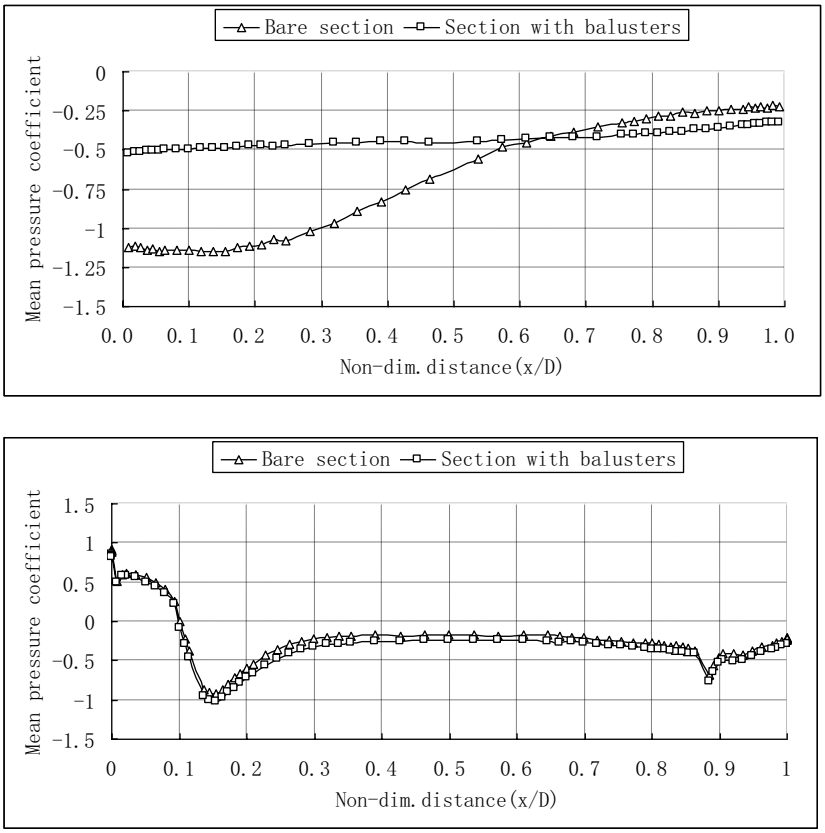

Fig. 5. Mean surface pressure coefficient of the two kinds of section at U/fB ≈ 1.88. Upper surface (top) and lower surface(bottom).

4.2 *Rms pressure coefficient*

With reference to the response diagram in Fig. 6, corresponding normalized rms pressure coefficient distributions obtained for the bare section and the section with balusters were obtained through the calculation of surface pressure time-history of every tap. Analysis of the rms pressure coefficient can find the critical region of vortex-induced vibration. In particular, fairly large rms pressures which result from the adverse pressure gradient are observed on the central upper surface of bare section(x/D = 0.32~0.68). Observing the difference between the bare section and section with balusters rms pressure coefficients, it is noted that the strong pressure fluctuation of bare section on the upper surface vanish due to the existence of the balusters, but the fluctuating pressures are significantly increased in the downstream zone of the upper surface, especially in the region x/D = 0.76~1.00. When introducing the balusters it is noted that the pressures on the entire lower surface are markedly increased. The Rms pressure coefficients of the entire lower surface have increased by 2 times when going from no balusters to having balusters. Comparing the downstream zone pressure distributions for the bare section and section with balusters, it is evident that the presence of balusters has strengthened the pressure fluctuation significantly, giving evidence that the downstream zone of deck have great contribution to the vertical vortex-induced response.

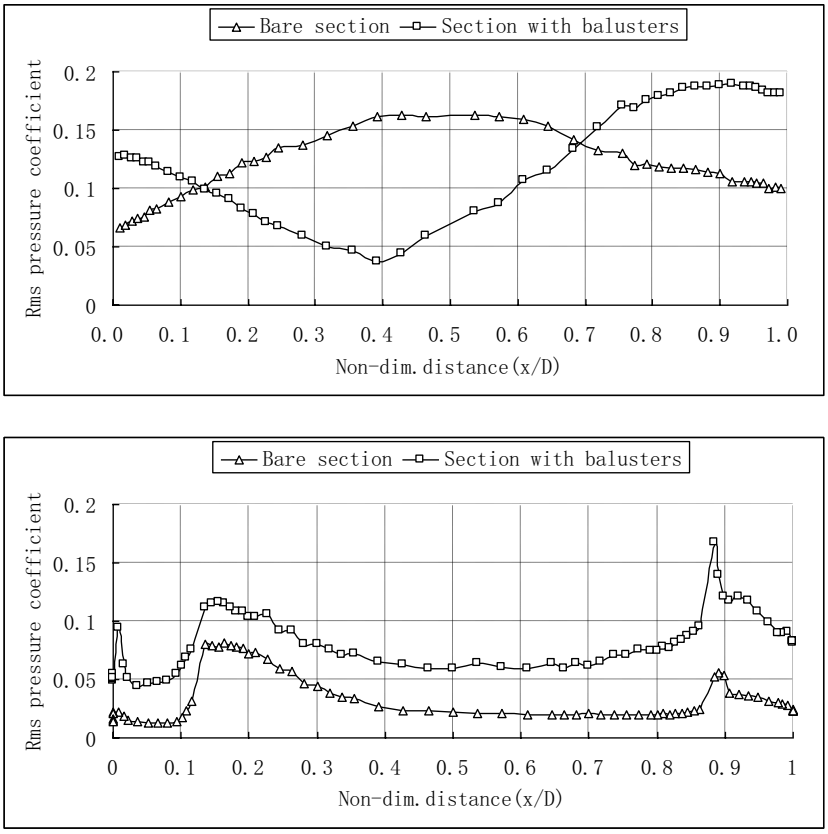

Fig. 6. Rms surface pressure coefficient of the two kinds of section at U/fB ≈ 1.88. Upper surface (top) and lower surface(bottom).

5 AERODYNAMIC FORCES

In this paper, aerodynamic forces in wind-axis coordinate system were obtained from the recorded pressure signals by using a method of surface pressures integration [4]. Aerodynamic force of a single pressure tap means aerodynamic force of the area which the tap represents, the total aerodynamic force is got by summarizing all the single taps.

Fig. 7 compares lift force time-history between bare section and section with balusters, and the curves of lift force power spectral density are shown in Fig. 8. For the section with balusters, a sinusoidal curve of lift force is shown in Fig. 7 (right) and a 4.04Hz harmonically lift force is noted in Fig. 8 (right). When the balusters are removed, Fig.7 (left) and Fig. 8 (left), the sinusoidal lift force and the distinct harmonic lift force altogether disappear, bearing evidence that the aerodynamic force of exciting vertical vortex-induced vibration is lift force. Vertical vertex-reduced vibration can be study through analysis of the changing of lift force because the vibration is caused by lift force.

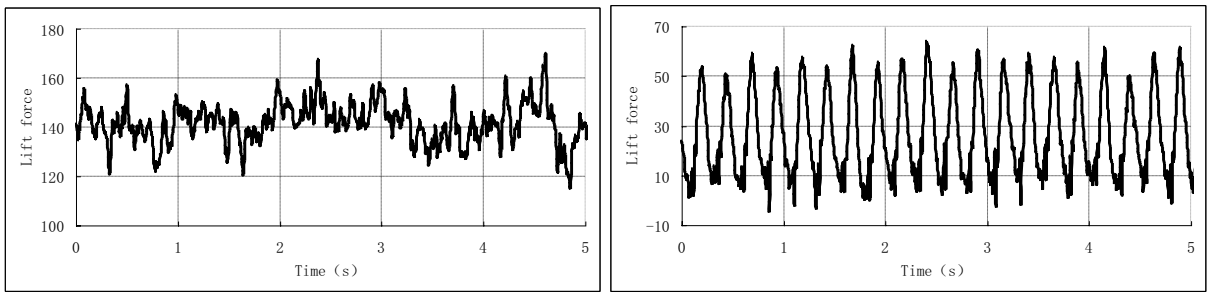

Fig. 7. Lift force time-history of the two kinds of section at U/fB ≈ 1.88. Bare section (left) and section with balusters (right).

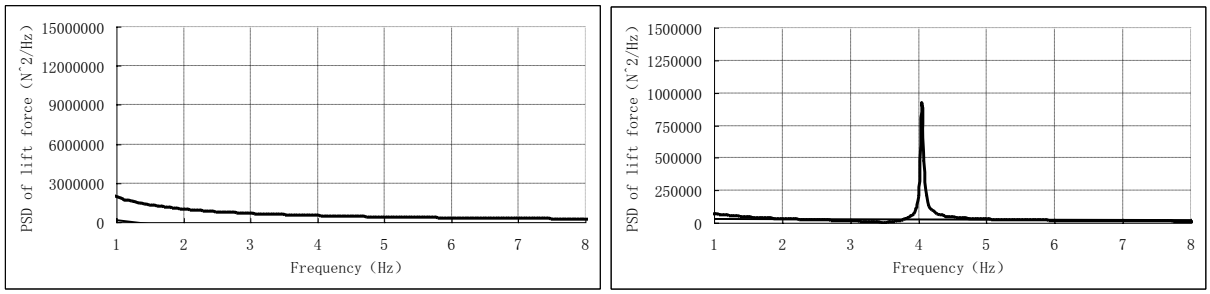

Fig. 8. Lift force power spectral density of the two kinds of section at U/fB ≈ 1.88. Bare section (left) and section with balusters (right).

Fig. 9 shows Karl Pearson correlation coefficient between local lift force and total lift force. The contribution of the local lift force to vortex-reduced vibration, as shown in fig.10, can be obtained through the multiplication of local rms lift force and the correlation coefficient between local lift force and total lift force.

From Fig 9 it is noted that the correlation between local lift force and total lift force in the downstream zone have markedly increased due to the role of balusters. For the section with balusters, as shown in Fig. 10, the upper surface of the region x / D = 0.68 ~ 0.99 and the lower surface of the region x / D = 0.35~0.98 have a greater contribution to vertical vertex-reduced vibration, and the contribution of upper surface is significantly larger than the lower surface.

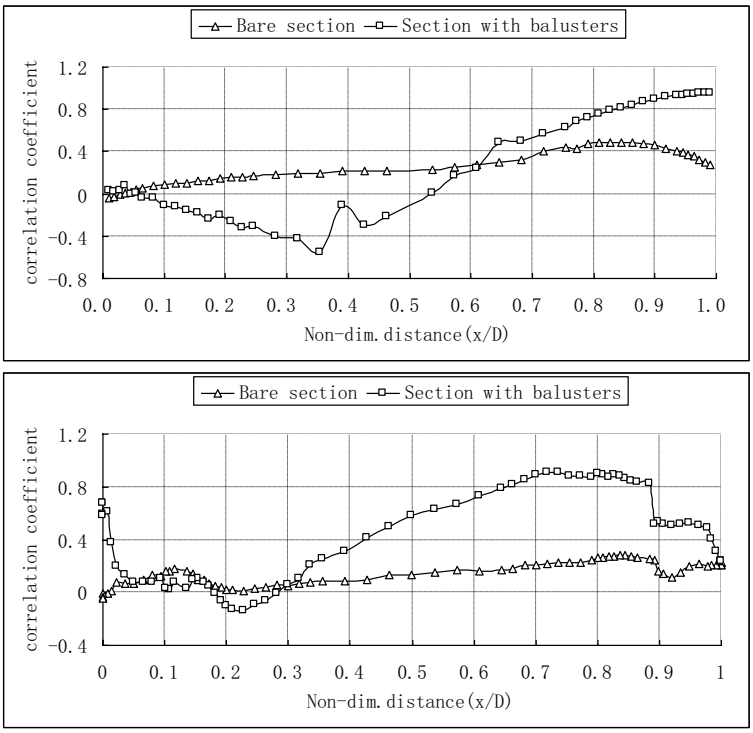

Fig. 9. Karl Pearson correlation coefficient of local lift force and total lift force at U/fB ≈ 1.88. Upper surface (top) and lower surface (bottom).

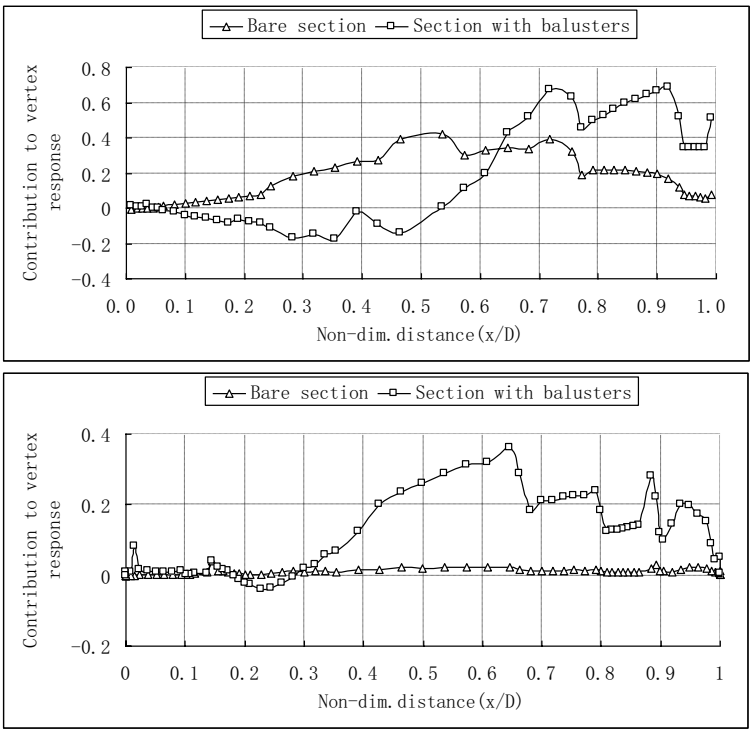

Fig. 10. Contribution of the local lift force to vortex-reduced vibration at U/fB ≈ 1.88. Upper surface (top) and lower surface(bottom).

6 CONCLUSIONS

The present paper has examined vertical vortex response of a bluff bridge deck with a view to unveil the excitation mechanism of balusters on vortex-induced vibration of bridge deck. The following is concluding remarks about vortex response of the bridge deck section with and without balusters.

1) The balusters of bridge deck significantly affect the mean pressure distribution of the upper surface, but the lower surface mean pressure distribution will not be change by balusters. The balusters of bridge deck will not only dramaticlly affect the upper surface pressure fluctuation but also the lower surface pressure fluctuation.

2) It is concluded that vortex excitation of deck with balusters is likely to be stronger than vortex excitation of bare deck, as the deck with balusters fluctuating pressures originating from the vortex impinging on the downstream box are larger than the fluctuating pressures of bare deck.

3) The balusters of bridge deck stimulate the vertical vortex-reduced vibration. It may achieve the purpose of suppression of vortex-induced vibration through partially sealing the balusters. In order to verify the suppression effect of partially sealing the balusters, it is necessary to carry out wind tunnel tests.

ABSTRACT: Dynamic wind tunnel tests of twin box girders with a space ratio of L/D=1.70 have been performed in this study. The results show that although the strength of the vortex is very weak under stationary conditions, it gives rise to vortex-induced vibrations with a lock-in range of $0.570 \leq U_r \leq 0.668$ in dynamic testing. To further study the flow characteristics around the twin box girder when undergoing vortex-induced vibration, a hybrid method combining experiments with numerical simulations is employed. The energy transfer between the flow and motion of the body, and evolution of flow patterns over vortex-induced vibration process are analyzed based on the computational results. The results indicate that with an increase in oscillation amplitude, strong vortices form in the gap between the two box girders. These vortices impinge on the windward wall of the downstream box girder and cause the flow to separate and re-attach periodically around the windward corners of the downstream box girder.

1 INTRODUCTION

With increases in the spans of bridges, bridges become more flexible and have small damping. Therefore, the bridges more readily oscillate dramatically when subjected to wind. In order to improve the aerodynamic stability of long-span bridge, twin-separated box steel girder configuration may be a good choice. For the kind of bridge, the bridge deck is composed of two parallel longitudinal girders with an open space between them. The two parallel girders are connected by transverse cross-beams. Now some super-long span bridges have chose this section configuration, for instance, Xihoumen suspension Bridge (main span: 1650m, China), Hong Kong Stonecutters cable-stayed Bridge (main span: 1018m, China), Gwangyang suspension Bridge (main span: 1545m, Korea). Although it is proved that twin-separated box girder has higher critical flutter speed than single box girder (Ge and Xiang, 2009), the flow characteristics around the bridge deck become more complicated due to the effects of gap between two separated box girders.

It is well known that when the vortex shedding frequency is close to the natural frequency of the body, it can cause vortex-induced resonance. Although vortex-induced vibration is limited amplitude vibration and does not cause collapse for the bridge, it can result in large displacements and discomfort to the drivers. In addition, the vortex-induced oscillations commonly occur in the low wind speed region, so the occurrence probability of vortex-induced vibration is high, resulting in long-term fatigue damage. The main objective of the paper is to investigate the flow characteristics around twin box girders and deeply understand the mechanism of vortex-induced vibration of twin box girders.

2 EXPERIMENTAL INVESTIGATION OF VORTEX-INDUCED VIBRATIONS OF TWIN BOX GIRDERS

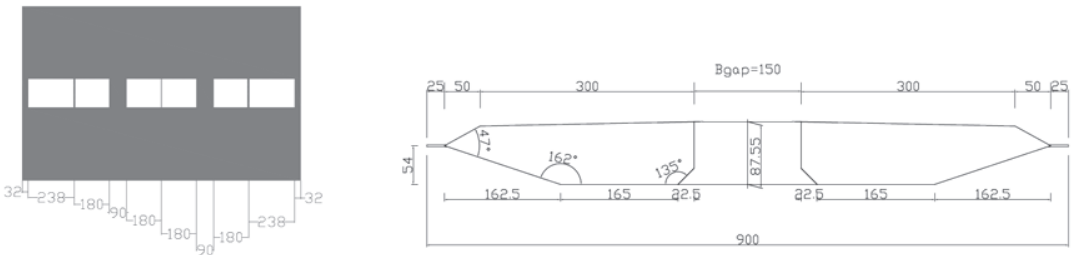
2.1 *Experiment set-up*

The experiments are conducted in a closed circuit wind tunnel, which has a small rectangle testing section of 4 m in width, 3 m in height and 25 m in length and a large rectangle testing section of 6 m in width, 3.5 m in height and 50 m in length (see Figure 1). In the small testing section, the maximum wind velocity can be 50 m/s, the turbulence intensity of the free stream can be no stronger than 0.46% and the non-uniformity of free-stream is less than 1%. In this study, all experiments are carried out in the small testing section.

The model is composed of two parallel box girders with an open space of L=150 mm. The two parallel girders are connected by transverse cross-beams every 360 mm. The length and height of the model are 1440 mm and 87.55 mm, respectively. Detailed geometry of the section model is shown in Figure 2. In the dynamic test, the modal is supported by 8 springs allowing a vertical degree of freedom with a natural frequency of 4.272 Hz and damping ratio of 0.21%. The lower surface of the section model is 1.20 m from the bottom of the wind tunnel. The geometric blockage ratio in the testing section is 2.9%; thus the blockage effects are negligible.

Two one-dimensional hotwire probes (Dantec 55P11) are used in the experiment. One is placed at 1.5 m upstream from the leading edge of the section to measure the oncoming free-stream velocity, while the other probe is moved to different locations near the section model to obtain the vortex-shedding information. The sampling frequencies of both hotwire probes were set at 1 kHz.

When carrying out the vortex-induced vibration test, the inflow velocity is increased stepwise, and the increment of each step is approximately 0.05 m/s over the range of 2.19≤U≤2.65 m/s (1.3e5≤Re≤1.59e5).



(a) Top view (b) Side view

Figure 1Geometry information of the section model

2.2 *Vortex-induced response*

Figure 2 presents the time history of vertical acceleration when the twin box girder is undergoing vortex-induced vibrations. The vertical displacement of oscillation is obtained by integrating the vertical acceleration twice. Figure 3 shows the relationship between the RMS of displacement response and reduced wind velocity ($U_r = U/f_{\text{vertical}}B$, in which U_r is the reduced wind velocity and f_{vertical} is the vertical nature frequency of the model). The response amplitude increases in two steps with an increase in the reduced inflow velocity up to U_r=0.650. Over the range of 0.57≤U_r≤0.603, the amplitude increases extremely slowly, whereas over the range of 0.616≤U_r≤0.650, the amplitude increases very rapidly. At U_r=0.668, the amplitude undergoes a small reduction. When the reduced inflow velocity increases to 0.689, the amplitude of vortex-induced vibration abruptly drops to zero, which suggests that the vortex exciting force suddenly

disappears. In the whole process of vortex-induced vibration, the largest RMS of non-dimensional displacement, RMS(y)/D, is 0.029 at U_r=0.650, which is much smaller than that of rigid cylinders, where the maximum is 0.11 at the same Skop-Griffin parameter of S_G=1.875 (Sarpkaya, 2004). In the range of 0.57≤U_r≤0.603, the vortex-shedding frequency is controlled by the oscillation frequency of the body, which is identical to the natural vertical frequency of the system. Beyond this range, the vortex-shedding frequency follows Strouhal's law. The variation of the dimensionless vortex-shedding frequency with the reduced wind velocity is shown in Figure 4.

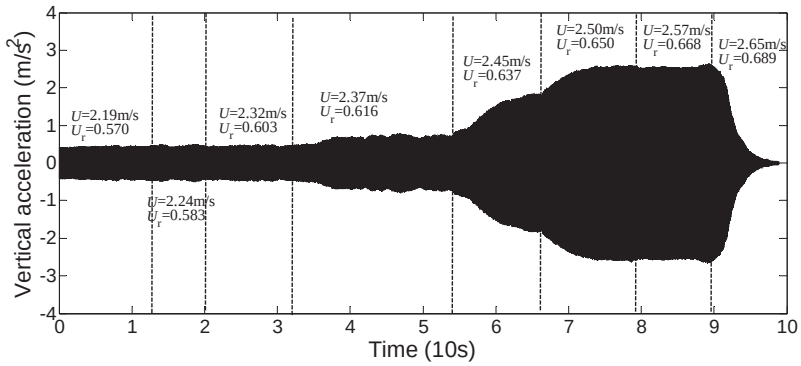


Figure 2. Time histories of vertical acceleration.

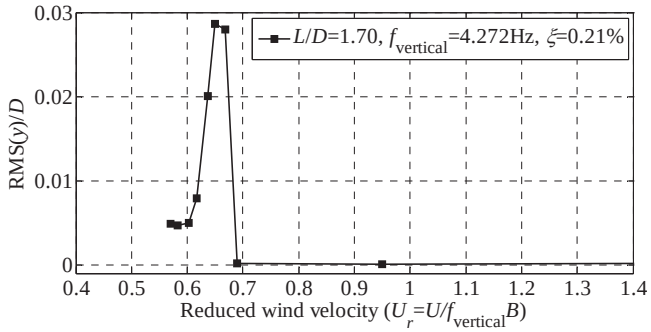

Figure 3. Vortex response of the twin separated box girders.

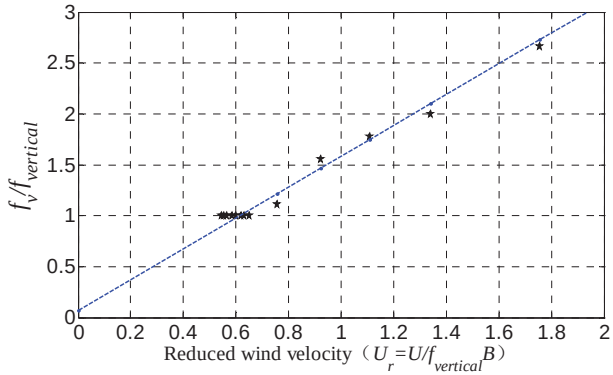

Figure 4. Variation of the dimensionless vortex-shedding frequency with the reduced wind velocity (f_v is the vortex-shedding frequency).

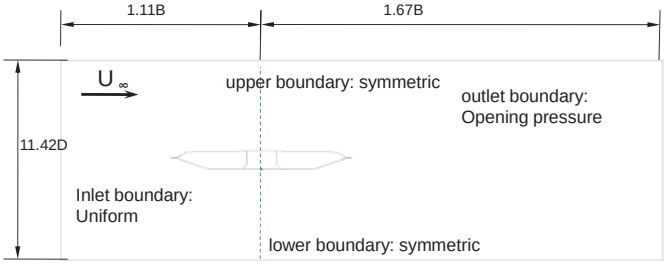
3 NUMERICAL INVESTIGATION OF VORTEX-INDUCED VIBRATIONS OF A TWIN BOX GIRDER

3.1 *Computational method*

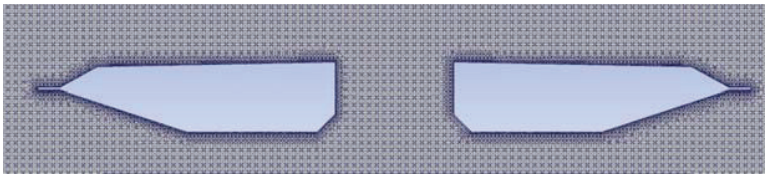
In the wind tunnel test, the motion of a structure is easy to measure. However, it is very difficult to accurately measure the fluid structures of a flow field, which usually requires very expensive instrument, e.g., PIV. To obtain characteristics of flow structures when the body is undergoing vortex-induced vibration, a hybrid method that combined experiments with numerical simulations (Li et al., 2010) is employed in this paper. For the problem of flow-induced vibration of a bluff body, the analytical model includes two parts: one is fluid dynamics based on the incompressible Navier-Stokes equations; and the other is the dynamics based on the equation of the motion of the body. The two parts are coupled through the no-slip condition, i.e., the velocities of the fluid and the body are identical at the interface. In traditional computational process, the fluid and structure motion equations are solved simultaneously. For the hybrid method, the motion of the structure is already known, which is first obtained from the wind tunnel test or field monitoring, i.e., the flow velocities on the interface are also known. Therefore, the flow-induced vibration problem becomes a moving boundary problem of the flow. Only fluid dynamic equations need to be solved and the motion of the interface is measured from the wind tunnel test or field monitoring, so it is more accurate than the traditional computational method to obtain the flow characteristics.

The computational domain is discretized with an unstructured mesh, as shown in Figure 5. The majority of y^+ values, which are nearest to the wall, are in the range of 0.105-1.2 (only 5.67% of y^+ values higher than 1.2).The numerical simulations are performed with ANSYS CFX 11 code based on the finite volume method. The large eddy simulation (LES) with a Smagorinsky subgrid scale model is employed in the computational process. The advection term is discretized using the Central Difference Scheme in the spatial domain, and the transient term is discretized by the Second Order Backward Euler Scheme in the time domain. The time step is set at 0.001s, and the convergence criteria is such that if the RMS of normalized residual taken over the whole domain is less than 10^{-4}, the iteration process stops.

At the inlet boundary, a steady uniform flow velocity is given. At the outlet boundary, an opening pressure condition is applied, and for the upper and lower surfaces of the computational domain, symmetric conditions are employed.



Section view of computational domain



Mesh

Figure 5. Section view and mesh of the computational domain.

3.2 *Energy transfer between flows and the twin box girder*

In the vortex-induced vibration process, if the work performed by the aerodynamic force on the body is positive, i.e., the energy of flows is transferred to body, the vibration of the body will gradually increase. The energy transfer is mainly influenced by the amplitude of the fluctuating force and the phase between the fluctuating force and body motion.

The aerodynamic force is calculated by integrating the surface pressure of the twin separated box girders. Lift force coefficient per length is defined as:

$$C_{\mathrm{L}} = \frac{F_L}{\frac{1}{2}\rho_{air} U^2 BL}, \tag{1}$$

where, C_{L} is the lift force coefficient, F_{L} is the lift force, U is the inflow velocity, B is the width of model and L is the length of the model.

The phase between the lift force and vertical displacement is calculated by the following equation:

$$\theta(\omega) = \begin{cases} \arccos \dfrac{real(P_{ly}(\omega))}{\sqrt{\left(real(P_{ly}(\omega))\right)^2 + \left(imag(P_{ly}(\omega))\right)^2}} & if\ imag(P_{ly}) \geq 0 \\ -\arccos \dfrac{real(P_{ly}(\omega))}{\sqrt{\left(real(P_{ly}(\omega))\right)^2 + \left(imag(P_{ly}(\omega))\right)^2}} & if\ imag(P_{ly}) < 0 \end{cases}, \tag{2}$$

where, $\theta(\omega)$ is the phase lag between lift force and vertical displacement, P_{ly} is the cross power spectrum of lift force and vertical displacement and ω is the circular frequency of vertical vibration (ω is equal to the oscillation frequency).

The total work of lift force performed on the twin box girder is obtained as follows:

$$W = \frac{1}{N}\int_{y(KT)}^{y(KT+NT)} F_L dy, \tag{3}$$

where, W is the work of lift force on the body, T is the period of vertical vibration and K and N are the numbers of cycles.

Figure 6 shows the mean lift force coefficient, RMS of fluctuating lift force coefficient, phase angle between lift force and vertical displacement and work of lift force acting on the twin box girder at U_{r}=0.570, 0.583, 0.603, 0.616 and 0.650. At U_{r}=0.570, 0.583 and 0.603, the phase between lift force to vertical displacement are -72.0°, -95.0° and -110.0°, respectively, which are nearly in phase with the vertical velocity of body vibration, indicating that the aerodynamic lift force mainly provides negative damping characteristics. However, the net work acting on the structure is very low, which is attributed to a small-fluctuation lift force, so the amplitude of vibration is small at the beginning of oscillation. At U_{r}=0.650, although the phase of the lift force to vertical displacement is about -144.0°, which deviates from the direction of the vertical velocity, the large-fluctuation lift force resulted in large work of lift force on the body, so a dramatic response of the body is observed. It is found that the phase lags between lift force and vertical displacement are very different from those for a circular cylinder, in which phase lags are less than 45.0° in initial branch of oscillation, and lead to an increase in oscillation (Feng, 1968). Unlike a circular cylinder, no phase jump over the vortex-induced vibration process appears for the box girder.

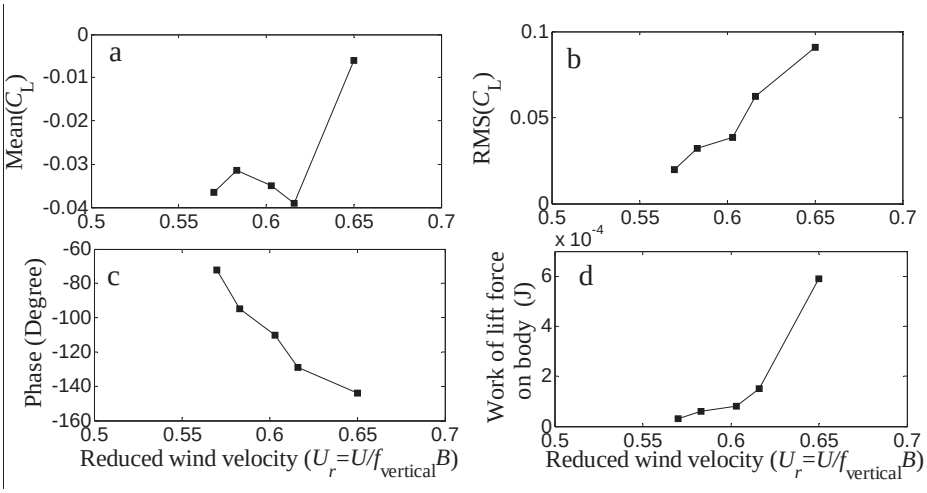


Figure 6. Lift force characteristics and work performed by the lift force at U_r=0.570, 0.583, 0.603, 0.616 and 0.650. (a) mean lift force coefficients, (b) RMS of fluctuating lift force coefficient, (c) phase between lift force and displacement, and (d) work performed by the lift force

The work of lift force on the body can also be rewritten as:

$$W_k = \frac{1}{N}\int_{y(KT)}^{y(KT+NT)} \int_S \left\{ -p\delta_{jk} + 2\mu\left(\frac{\partial u_j}{\partial x_k} + \frac{\partial u_k}{\partial x_j} \right) \right\} n_j dS dy$$

$$= \int_S \frac{1}{N}\int_{y(KT)}^{y(KT+NT)} \left\{ -p\delta_{jk} + 2\mu\left(\frac{\partial u_j}{\partial x_k} + \frac{\partial u_k}{\partial x_j} \right) \right\} n_j dy dS \qquad (4)$$

To obtain the energy transfer over the whole surface of the body, a work density function $P(x,y,z)$ on the surface of the twin box girder is defined as:

$$P(x,y,z) = \frac{1}{N}\int_{y(KT)}^{y(KT+NT)} \left\{ -p\delta_{jk} + 2\mu\left(\frac{\partial u_j}{\partial x_k} + \frac{\partial u_k}{\partial x_j} \right) \right\} n_j dy. \qquad (5)$$

The work density of flow over the surface of the twin box girder at U_r=0.570 and U_r=0.650 at z=630 mm is shown in Figure 7. The positive values of the work density show that the flow energies are transferred to body, while the negative values indicate that the energy of body motion is transferred to the flows. At U_r=0.570, the beginning of vortex-induced vibration, the energy of flows is transferred to the body in the regions of X/B=[0.217 0.412] for the lower surface and X/B=[0.190 0.450] for the upper surface due to the influence of shedding vortices in the near wake. However, for the case of U_r=0.650 (the amplitude of response is largest), besides the work density becoming much larger, the region where the energy of the flows transfers to the body is located mainly near the gap. This implies that the vortices in the gap play a critical role to vortex-induced vibrations of twin box girders.

3.3 *Flow pattern evolution when the twin box girder undergoes vortex-induced vibration*

In the vortex-induced vibration process, the structure motion and vortex interact with each other, forming a feedback loop system. Therefore, the vortex structure and vortex-shedding modes have significant effects on the structural oscillation. Although the vortex structures can be recognized according to many criteria, for example, Q-criterion (Hunt, 1988), Δ-criterion (Dallmann,1983, and Chong, 1990), λ_2-criterion (Jeong and Hussain, 1995), etc. , there still lacks a common agreement, and these methods have their respective advantages and limitations. In this study, the λ_2-criterion is selected to obtain the vortex structure. Jeong and Hussain (1995) argued that, if discarding unsteady straining and viscous effects, the existence of a minimum pressure value and existence of a vortex core are consistent. By taking the gradient of the Navier-Stokes equation and decomposing it into symmetric and asymmetric parts, the following equation can be deduced:

$$\frac{DS_{ij}}{Dt} - \nu S_{ij,kk} + \Omega_{ik}\Omega_{kj} + S_{ik}S_{kj} = -\frac{1}{\rho} p_{,ij} \tag{6}$$

where, S_{ij} is the strain tensor, $S_{ij} = \frac{1}{2}\left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i}\right)$, Ω_{ij} is the rotation tensor, $\Omega_{ij} = \frac{1}{2}\left(\frac{\partial u_i}{\partial x_j} - \frac{\partial u_j}{\partial x_i}\right)$ and $p_{,ij}$ is the Hessian pressure.

The occurrence of a local pressure minimum in a plane requires two positive eigenvalues of the tensor $p_{,ij}$. Discarding the first term of Eq.(6), which represents an unsteady irrotational straining effect and the second term, which represents viscous effects, yields only $S^2+\Omega^2$ to determine the existence of a local pressure minimum. Therefore, the vortex core definition criterion is that the vortex is the location with two negative eigenvalues of $S^2+\Omega^2$. Assuming λ_1, λ_2 and λ_3 are the eigenvalues of $S^2+\Omega^2$ and $\lambda_1 \geq \lambda_2 \geq \lambda_3$, the vortex identification criterion is equivalent to the condition that $\lambda_2 < 0$.

Figure 8 presents the vortex core structures at U_r=0.570 and U_r=0.650. At the initial stage of vortex-induced vibration, i.e., U_r=0.570, the body motion leads to the boundary layers of the upstream box girder becoming unstable and generates vortices on the upper and lower sides of the gap. It is worth noting that these vortices are generated due to the flow by the body motion disturbance rather than the direct interaction of the upper and lower shear layers. The shedding vortices propagate downstream along the upper and lower surfaces of the downstream box girder and then merge with the vortices generated in the inclined regions of the downstream box girder. Finally, the merging vortices are shed alternately in the near wake of the downstream box girder with the 2S shedding mode, i.e., when the displacement is largest, the single vortex sheds from the opposite side. Due to the asymmetrical geometry of the wind nose (inclined regions of box girder), asymmetrical vortex structures are generated in the upper and lower sides of the near wake. For the lower side of the nose, the width of the inclined plane is very long ($L_{inclined}/B$=0.18), so the nascent vortex on the lower side of the wake is long and narrow, and the energy distribution of the vortex is not uniform. This special kind of vortex structure results in instability of the primary vortex on the upside of wake and rapid translation into 3-D structures. However, for the upper side of the nose, the dimensionless width of the inclined plane $L_{inclined}/B$ is only 0.056, so the primary vortex is more regular and stays stable when propagating downstream.

When the amplitude of the vortex-induced vibration is largest, the vortex-shedding phenomena and vortex structures change significantly. The interaction between the upper and lower boundary shear layers of the upstream box girder is enhanced through the gap, and thus, strong vortices generate around the gap. These vortices propagate downstream along the surfaces of the downstream box girder and finally break into small vortices in the nose region. In the near wake of the downstream box girder, because of body motion disturbance, the primary vortices, which appear at the initial stage of vortex-induced vibrations, disappear, and the flow transforms into turbulent flow. As shown in Figure 9, the vortex-shedding phenomena around the gap are very complicated. As the body reaches its maximum displacement, the nascent vortex of the side impinges on the windward wall of downstream box girder and cuts off the vorticity supply of the opposite vortex, so a free vortex forms. In addition, the flow from the opposite side separates around the windward corner of the downstream box girder and a new vortex begins to form at that moment. After approximately 1/4 of a cycle, i.e., the displacement of body is zero, the separated flow begins to re-attach, and the flow re-attaches on the surface of the downstream box girder completely as the body reaches the maximum displacement on the same side.

4 CONCLUSION

The experimental investigations of vortex-induced vibrations of a twin box girder model with a gap ratio L/D=1.70 are carried out in this study. The following conclusions can be obtained:

Under stationary conditions, there is no occurrence of regular Karman vortices in the gap, but regular vortex-shedding phenomena with St=0.15 appear in the near wake of the downstream box girder. Although the strength of the primary vortex is very weak in the stationary test, vortex-induced vibration of the twin box girder occurs in the dynamic test. The synchronization range is $0.570 \leq U_r \leq 0.668$. Furthermore, the largest RMS of non-dimensional displacement is only 0.029 at U_r=0.650, which is much smaller than that of circular cylinders.

A hybrid method is employed to investigate the flow characteristics around the twin box girders when undergoing vortex-induced vibrations. The results show that the regular vortices are generated only in the near wake of the downstream box girder with the 2S shedding mode at the initial stage of vortex-induced vibration. However, as the amplitude of oscillation becomes large, strong vortices are generated in the gap and the flow of near wake transforms into turbulent flow. The vortices impinge on the windward wall of the downstream box girder when propagating downstream and cause the flow to separate and re-attach periodically around the windward corners of the downstream box girder. Due to the effects of vortices in the gap, the pressure shows high fluctuating characteristics near the windward corner of the downstream box girder. The energy of body oscillation is generated mainly by the pressures of these regions.

ABSTRACT: In order to study the vortex-induced vibration and characteristics of high-order torsion vortex-induced vibration in streamline-like bridge deck section, model with pressure taps supported by spring was made for wind tunnel test, which included the torsion amplitude and time-history wind pressure in each tap. Based on the analyses of vibration spectrum in two vortex vibration areas, pressure fluctuation spectrum in each tap, and Strouhal number, this paper reveals the micro-characteristics of double vortex vibration area. This investigation indicates the possibility that occurrence of high-order vortex-induced vibration in streamline-like bridge section can be forecasted by analyzing surface pressure fluctuation spectrum of models; what is more, it is predicable to analyze the proportion of energy for the amplitude of model. Due to the same Strouhal number at same attack angle, we can decide whether the critical wind speed is lower than designed through forecasting critical wind speed of vortex-induced vibration under high speed wind.

1 INTRODUCTION

Contrast with vortex-induced vibration occurred in low wind, flutter attracts more attention rather than vortex-induced vibration under high speed wind in academic circles for a long time. With a lower critical wind speed in low-order modal, vortex-induced vibration takes a long time to accumulate energy. On the other hand, since vortex-induced vibration accumulates energy fast with a high critical wind in high-order modal [1], it is possible to stimulate vortex vibration in a short time and even cause aerodynamic instability. Therefore, concentration should be paid on high frequency vortex-induced vibration.

Second-order or higher order modal vortex-induced vibration has been found in the wind tunnel test of Tokyo Bay Aqua-Line Bridge [2]. For Jiaojiang Second Bridge, vortex-induced vi-

bration appeared twice in high speed wind range from 19m/s to 27m/s in +3 attack angle; torsion vortex-induced vibration appeared twice only in high speed wind range from 32m/s to 36m/s [3]. Except for vortex-induced vibration in base-order modal, there is possibility occurring vortex-induced vibration in the situation that critical wind speed is less than designed. Therefore, studying vortex vibration performance of common streamline-like section of long-span bridges, this paper introduces vortex-induced vibration phenomena under high speed wind, using time-history pressure of surface taps to analyze vortex vibration performance of the section.

2 TEST BACKGROUND

Taking a bridge as an example, the section deck model was tested in CA-1 wind tunnel at Chang'an University. In the scale of 1:25, the model is placed aluminum alloy skeleton inside, cowered by hard plastic, filled in bubble, with the width of 1.2 meters.

Vibration test and pressure test were conducted simultaneously. Fig.1 shows the arrangement of model in wind tunnel. Hanged by springs, two-dimension rigid section model is used for vibration test, with two supporting arms to limit the degree-of-freedom only in vertical and torsion. Depending on vibration signal sent from four acceleration sensors installed at rigid supporting arms, we can simulate the frequency in damp ratio of 0.5% and wind speed ratio of 1:4.

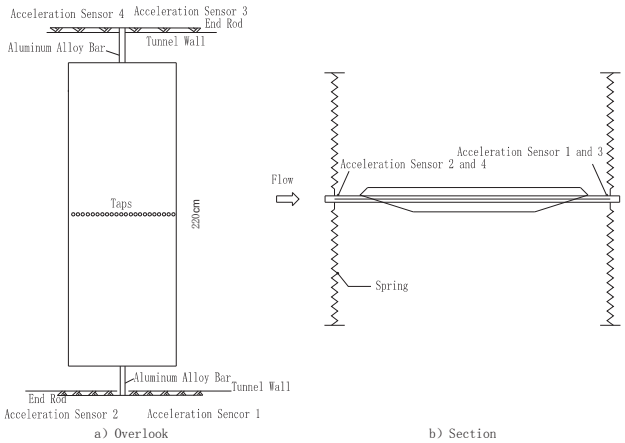

Fig.1 Arrangement of wind tunnel test

With 88 taps in the middle, which each diameter is 1mm, the model can meet the requirement of pressure test. Fig.2 displays the distribution of surface pressure taps.

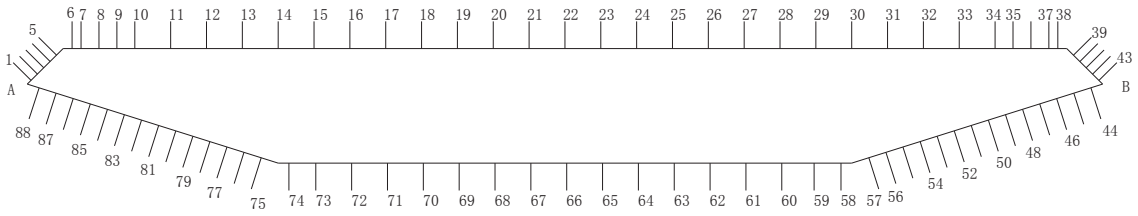

Fig.2 Taps distribution

We tested the model in the uniform flow at attack angles which were +5°、+3°and 0°. The results demonstrates that vortex-induced vibration occurred when attack angle was +3°, and there were two areas of vortex vibration. Accordingly, this paper studies the two areas in the condition of +3°attack angle.

2.1 Relationship between Wind Speed and Amplitude

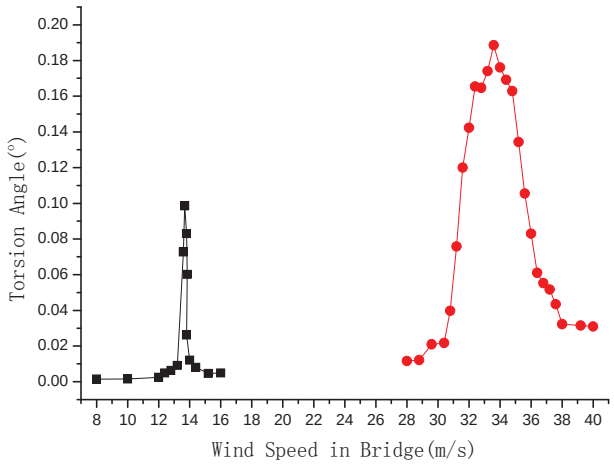

Fig.3 Relationship between amplitude and wind speed

Fig.3 shows the relationship between amplitude and wind speed. The amplitude here means standard deviation of time-history torsion angle under each wind speed. From Fig.3, vortex-induced vibration occurred twice when the wind speed ranges from 8.0m/s to 40.0m/s. The first one occurred in low wind speed from 12m/s to 16m/s. The second occurred in high wind speed, which range is 29.6m/s~40m/s. Apparently, the range of vortex vibration is wider under high speed wind, and the amplitude difference is more as well. The first maximum amplitude occurred when the wind speed was 13.6m/s under torsion angle of 0.1°, and the second maximum amplitude occurred when the wind speed was 33.6m/s under torsion angle of 0.19°,which shows the difference between two maximum amplitude is almost double. Since the speed range of the sec-

ond vortex vibration is 29.6m/s~40.0m/s, which is contained in the range of checking wind speed of the bridge, there is great possibility of occurring vortex vibration in reality.

2.2 Spectrum

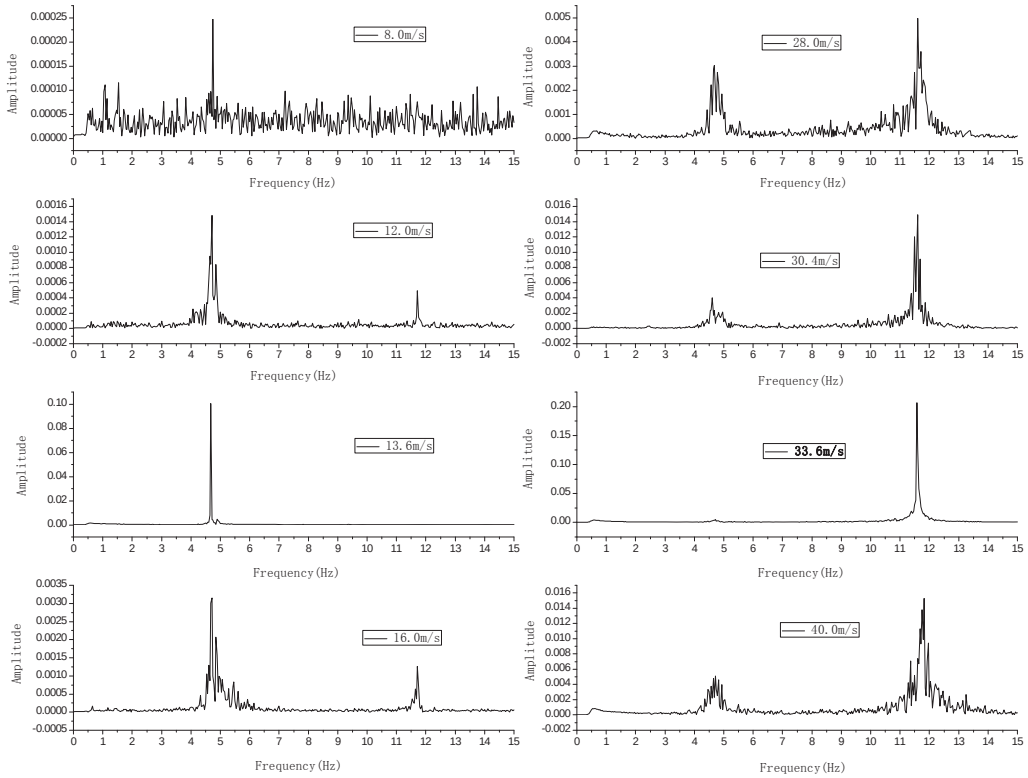

Fig.4 Torsion vibration spectrum

Fig.4 shows vibration spectrum of the model under eight different speeds of wind, including different wind speeds when the model was vibrationless, beginning vortex vibration, appearing the maximum amplitude, and has finished vortex vibration. Following the increase of wind speed, the vibration is getting intense when the frequency around 4.7Hz to 11.6Hz in two vortex vibration area. The dominant frequency is 4.7Hz in first vibration area, and is 11.6Hz in the second. After that, the vibration grows to be much intense, which becomes the max in the wind speed of maximum amplitude. The frequency becomes complex after the vortex-induced vibration ended, which indicates that the model restarted normal vibration. Containing high level of energy, the two vortex-induced vibration shows similar spectrum, with the frequency of 4.7Hz and 11.6Hz. When the wind speed is low, energy of the model increase gradually since 4.7Hz

vortex shedding frequency is same with the first-order torsion frequency; when the wind speed is high, the same phenomenon happened in the frequency of 11.6Hz.

2.3 Spectrums of each tap pressure fluctuation

The spectrum of time-history pressure reflects the characteristic of pressure fluctuation at each surface tap, and indicates the relationship between surface pressure and vibration [5].

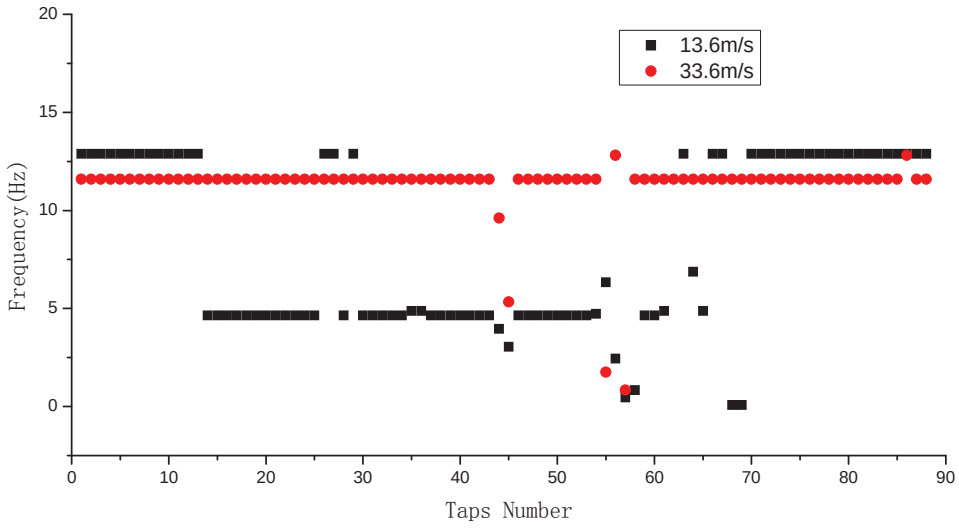

Fig.5 Frequency at the highest amplitude in spectrum

Fig.5 shows the frequency at the highest amplitude in pressure fluctuation spectrums. Only 1/2 surface taps shows 4.7Hz dominant frequency, with most of the other half centers in high frequency, and a small part disperses in different frequency, when the first vortex-induced vibration occurred (13.6m/s). Almost the all surface taps shows 11.6Hz dominant frequency when the second vortex-induced vibration occurred (33.6m/s).

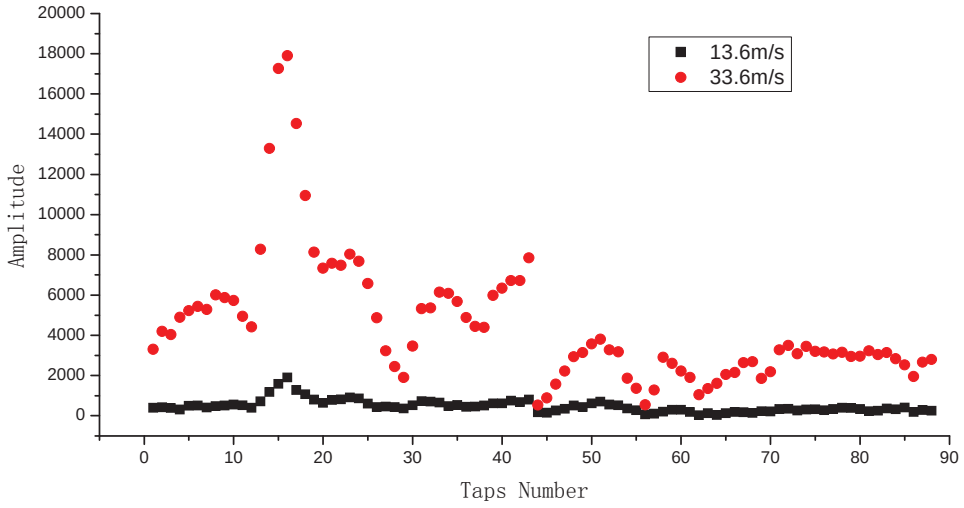

Fig.6 Amplitude of each tap vortex shedding frequency

Fig.6 depicts the spectrum amplitude of the vortex shedding under the wind speed of 13.6m/s and 33.6 m/s respectively. It is observed that the energy of the vortex shedding of the second spectrum amplitude is significantly bigger than that of the first one, which is also the case in Fig.5. This is because most of the excellence frequencies concentrate on vortex shedding frequency under the wind speed of 33.6m/s, which is dispersed under 13.6 m/s. Therefore the energy of vortex frequency is also dispersed under the wind speed of 13.6 m/s, which leads to a significantly smaller amplitude.

The above analysis reveals that airflow spiral produced by airflow crossing the section contains a variety of energy frequencies. When one vortex frequency corresponds with the frequency of the structure, vortex-induced vibration occurs. The amplitude of vortex-induced vibration is influenced by the proportion of energy of vortex frequency, and the energy of vortex frequency is determined by the frequency composition of all vortex and its degree of concentration in section tail. To illustrate, energy concentrates around 4.7 Hz and 12.5 Hz to a large extent under the 13.6 m/s wind speed, which incurred vortex-induced vibration at the structure frequency of 4.7 Hz. However, since some energy around the vortex shedding around 12.5 Hz is dispersed, the amplitude under the wind speed of 13.6m/s is significantly smaller than that of 33.6m/s. Meanwhile, since vortex shedding frequency consists of some high frequency, it is likely to bring out structure high frequency vortex-induced vibration: the structure experiences another vortex-induced vibration under the wind speed of 33.6m/s.

2.4 Strouhal Number

Under certain conditions, fluid on the surface will induce interchanging vortex shedding, which puts merged objects in the fluid under a force vertical to the flow. Both the direction and magnitude of the force change in a complicated manner with time. Its main frequency and vortex shedding frequency f and incoming flow velocity U, the characteristic size of the objects D meets Strouhal relationship.

$$S_t = \frac{fD}{U} \tag{1}$$

Fig.4 shows the main frequency and corresponding wind speed of the two vortex-induced vibration, which could be used to calculate the Strouhal number St. according to Eq.2. In the calculation, the characteristic size is the height of the beam. The Strouhal numbers in the two vortex-induced vibrations are listed in Table.1.

Table.1 St. Number of two vortex-induced vibration

No.	Test Wind Speed (m/s)	Vortex Shedding Frequency (Hz)	St. Number
1	3.4	4.7	0.165
2	8.4	11.6	0.165

Table.1 tells us that under the same attacking angle, the St. Number is fixed. Provided that there is a large component of high frequency vortex in the wake, a preliminary prediction of vortex vibration critical wind speed could be made according to the St. Number obtained in low wind speed, which casts light upon the whether the structure is safe.

3 CONCLUSIONS

- Time-history surface pressure is very informative. According to an analysis into the frequency composition of section surface pressure spectrum, a preliminary prediction to the possibility of vortex-induced vibration in high wind speed and its amplitude could be achieved.
- A disturbance of the concentration of each tap pressure fluctuation dominant frequency on first-order torsion frequency, which causes a dispersion on different frequencies, could weaken the amplitude of vortex-induced vibration.

Multi-mode vortex-induced vibration of a long rectangular shallow beam

Zhenqing Chen[a], Xugang Hua[a], Wen Chen[a], Zhiwen Huang[a],

[a] *Wind Engineering Research Center, Hunan University, Changsha, China*, *zqchen@hnu.edu.cn*

ABSTRACT: Two sectional models with the same side ratio of B/D=6 but different length scales are used to investigate the characteristics of multi-mode vortex-induced vibration (VIV) for long-span suspension bridges. The models are elastically suspended with springs of varying stiffness and a total of 11 cases are tested in smooth flow. Strouhal number of the models is found to be constant for all the cases regardless of model vibration frequency and model length scale. The vertical maximum non-dimensional amplitudes of each model are almost the same for different vibration frequencies, but the vertical amplitudes between the two models differ significantly. It is also observed that the torsional amplitudes drastically reduce with torsional frequency. A novel multi-elastically supported shallow beam is proposed as a simplified aeroelastic model of suspension bridge, which is capable of reproducing as many as closely-spaced vertical modes of suspension bridges. Ideally important modes of the aeroelastic model are expected to be excited in turn so as to further explore the multi-mode vortex-induced vibration of suspension bridges, in particular to study the effects of span-wise correlations of vortex-shedding forces on VIV under different vibration modes.

KEYWORDS: Vortex-shedding; Vortex-induced vibration; Suspension bridge; Aeroelastic model; Shallow section.

1 INTRODUCTION

Multi-mode vertical vortex-induced vibration (VIV) has been observed on several steel box girder suspension bridges with main spans over 1500m. Under varying wind velocity, different natural modes of a suspension bridge may be excited in turn following the Strouhal law and vibration frequency usually lies between 0.2Hz and 0.4Hz [1~3]. Analytical and experimental predication of the VIV amplitudes for every candidate vertical mode is a serious concern for wind-resistant design of suspension bridges. The vertical modes of a suspension bridge have the two salient features. They are closely-spaced such that there may exists more than ten modes in the frequency ranges of interests. The second feature is that the equivalent modal mass for every mode is nearly the same and approximately equals to the sum of stiffening girder and two main cables. As an example, Table 1 lists the modal characteristics of the first 8 vertical modes for a typical steel box suspension bridge with main span of about 800m. There are as many as 8 modes in the frequency range from 0.12Hz to 0.69Hz with an average increment of 0.07Hz, and the frequency distribution characteristics of suspension bridges differs from that of simply-supported beams (increase in a squared law) and that of taut strings (increase in a linear law).

The steel box girder in suspension bridges may be considered as a shallow beam and its height is usually about 4m. For such a shallow section, Strouhal number St is rarely below 0.1. The onset velocity of VIV does not exceed 25m/s, the maximum wind velocity for bridges open to traffic, when f<0.6Hz. The modes with frequency from 0.2Hz to 0.4Hz have VIV onset velocity of about 6~12m/s and are therefore most easily excited by vortex shedding than lower-order

modes. On the other hand, the limiting value of VIV amplitude is mainly determined by the maximum acceleration, and therefore it decreases with modal frequency. As a result, restricting the VIV amplitudes for higher-order modes is more rigorous than that of lower-order modes, and worthy of more attention.

Table 1 Modal parameters of the first 8 vertical modes for a suspension bridge with a main span of 800m

Mode number	Frequency (Hz)	Mode shape	Equivalent modal mass[1] (t/m)	Onset velocity of VIV[2] (m/s)
2	0.1181	1st asymmetrical vertical	37.1	3.44
3	0.1710	1st symmetrical vertical	33.8	4.98
5	0.2354	2nd symmetrical vertical	33.9	6.85
6	0.2645	2nd asymmetrical vertical	35.4	7.72
13	0.3588	3rd symmetrical vertical	33.8	10.5
18	0.4648	3rd asymmetrical vertical	46.0	13.6
26	0.5621	4th symmetrical vertical	33.8	16.3
34	0.6900	4th asymmetrical vertical	34.1	20.1

[1] The mass of stiffening box girder and the two main cables are 27.7t/m and 5.9t/m, the equivalent modal mass for every approximately equals to the sum of stiffening girder and the two main cables except for mode 18.
[2] Evaluated according on height of stiffening girder D=3.5m and a nominal value of Strouhal number St=0.12

2 EXISTING METHOD FOR MULTI-MODE VIV

2.1 *Mathematical model of VIV*

Excessive vortex-induced vibration may cause fatigue problems of structure and user comfort, and it is therefore necessary to limit the vibration amplitude. However accurate prediction of VIV amplitudes remains a difficult problem and the existing mathematical models are mainly semi-analytical and semi-experimental. The *empirical linear model* developed by Simiu and Scanlan in 1986 is chosen to discuss the multi-mode vortex-induced vibrations. The cross-wind dimension D of the cylinder (the box-girder height in the context of suspension bridges), is taken as characteristics length. The equation of motion of the cylinder during lock-in can be written as

$$m(\ddot{y}+2\varsigma\omega_n\dot{y}+\omega_n^2 y)=\frac{1}{2}\rho U^2 2D\left[Y_1(K_1)\frac{\dot{y}}{U}+Y_2(K_1)\frac{y}{U}\right]+\frac{1}{4}\rho U^2(2D)C_L(K_1)\sin(\omega_n t+\varphi) \tag{1}$$

where m is the cylinder mass per unit length; ρ is the mass density of air; U is the wind velocity; K_1, defined as $D\omega_n/U$, is the reduced frequency with ω_n being the natural frequency of cylinder; $Y_1(K_1)$, $Y_2(K_1)$ and $C_L(K_1)$ describe the aerodynamic damping, aerodynamic stiffness and motion-independent vortex-shedding forces at lock in, and they are functions of reduced frequency K_1. By defining the non-dimensional amplitude $\eta=y/D$, the steady solution for equation (1) can be expressed as

$$|\eta|=\frac{\rho D^2 C_L}{2m\sqrt{\left(K_0^2-K_1^2\right)^2+\left(2\gamma K_0 K_1\right)^2}} \tag{2}$$

$$K_0^2=K_1^2-\frac{\rho D^2}{m}Y_2(K_1) \qquad \gamma=\frac{1}{2K_0}\left[2\varsigma K_1-\frac{\rho D^2}{m}Y_1(K_1)\right] \tag{3, 4}$$

By analog, equation (2) may be regarded as the response of single degree-of-freedom (SDOF) system with reduced modal frequency K_0 and modal damping ratio of γ under forced sinusoidal

excitation with frequency K_1; during lock in, K_1 decreases with wind velocity U and the maximum vibration amplitude η develops when $K_1=K_0$. By this analogy, one can identify the aerodynamic parameters $Y_1(K_1)$, $Y_2(K_1)$ and $C_L(K_1)$ from the experimental K_1-η curve obtained from sectional model wind tunnel tests. The Simiu-Scanlan model only predict the the maximum amplitude for $K_1=D\omega_n/U$, and it cannot also provide the range of wind velocity at lock-in.

The VIV amplitude described by equations (2)~(4) are implicit functions of aerodynamic parameters $Y_1(K_1)$, $Y_2(K_1)$ and $C_L(K_1)$. Substituting equations (3) and (4) into equation (2) yields

$$|\eta| = \frac{C_L}{2\sqrt{Y_2^2 + \left(2K_1^2 S_C - Y_1\right)^2}} \tag{5}$$

where S_C is the Scruton number defined as $S_C=m\varsigma/\rho D^2$.

The vibration frequency remains constant for the full lock-in range and it equals to the structural frequency, that is $\omega_n=2\pi f$. The relationship between the apparent Strouhal number and K_1 is

$$S_t = \frac{fD}{U} = \frac{K_1}{2\pi} \tag{6}$$

By letting $Y_1=Y_2=0$, equation (5) reduces to the case of the most *simple linear model* of vortex-shedding forces considering only the motion-independent term. In such case, the solution of VIV amplitude reduces to

$$|\eta|_L = \frac{C_L}{16\pi^2 S_t^2 S_C} \tag{7}$$

where $|\eta|_L$ represents the solution of SDOF system for the *simple linear model* of vortex shedding. It is clear that the non-dimensional amplitude is in inverse proportion with S_t^2 and S_C for the *simple linear model*.

2.2 *Prediction for multi-mode VIV*

The existing method for predicting the lock-in wind velocity as well as vibration amplitude for every possibly-excited mode bases its theoretical foundation on equation (7). In more detail, experimental results of vortex-induced vibration for a particular mode is determined by sectional model wind tunnel tests while those for the remaining modes is evaluated by equations (6) and (7). The procedure is as follows.

(1) Conduct sectional model tests for one particular mode P to determine the St number, lock-in range and maximum vibration amplitude η_P for that mode.

(2) Assume St is constant and calculate the wind velocity of VIV for remaining modes, for example mode Q, as follows

$$V_Q = V_P \cdot \frac{f_P}{f_Q} \tag{8}$$

where V_P may be the onset wind velocity of VIV, wind velocity interval of VIV and wind velocity of VIV with maximum vibration amplitude.

(3) If the modal damping ratios are the same for all modes, it is obvious that η is in inverse proportion with equivalent modal mass m. As such, the relationship of vibration amplitude between mode P and mode Q is given as

$$\eta_Q = \eta_P \cdot \frac{m_P}{m_Q} \tag{9}$$

where m_P and m_Q are the equivalent modal mass for modes P and Q. Equation (9) is only valid for the *simple linear model* of vortex-shedding force, and may become invalid for the *empirical linear model* of Simiu-Scanlan type if Y_1 and Y_2 are non-trivial.

(4) Consider further correction of vibration amplitude due to three-dimensional mode shape as well as the span-wise correlation of vortex-shedding forces. One noticeable example is the correlation method developed by Ruscheweyh which has been included in the Eurocode [4, 5]. However, Ruscheweyh's method is suitable for chimneys and other vertical structures. Chimneys may experience vortex-induced vibration for the first or second modes, which differs appreciably from higher-modes of long-span suspension bridges. Investigation on span-wise correlation of vortex-shedding forces for higher-modes is very rare if not none. The current Chinese code for wind-resistant design of highway bridges does not consider the correction of vibration amplitude due to imperfect correlation of vortex-shedding forces.

A series of investigations are underway to develop method for predicting maximum vibration amplitudes for higher-order modes of suspension bridges. Some key issues needing further research are summarized as follows:

(1) Variation of *St* number with vibration frequency for the same model;
(2) Variation of VIV amplitude with vibration frequency for the same *Sc* number;
(3) Effect of aerodynamic damping on VIV for different modes;
(4) Equability of modal damping ratio for different modes;
(5) Span-wise correlation of vortex-shedding forces under different mode shapes;
(6) Determination of allowable vibration amplitude for higher-order mode.

In the following, selected results for (1) and (2) are presented and discussed.

3 WIND TUNNL TESTS OF RECTANGULAR SECTIONS AT DIFFERENT VIBRATION FREQUENCY

As a first step for studying the multi-mode vortex-induced vibrations, two rectangular sectional models having the same side ratio of B/D=6 but different length scale are elastically suspended by springs with varying stiffness to simulate different vibration modes. The wind tunnel tests are conducted in the high-speed test section of HD-2 wind tunnel at the Hunan University, the dimension of the test section is 3m(W)×2.5m(H)×17m(L).

3.1 *Section models and experimental setup*

The side ratio of both sectional models is 6, and the length of the models is 1.54m. The model A has a height of 12cm and a width of 72cm while the model B has a height of 6.7cm and a width of 40cm. The inner part of the model is constructed with mental materials to have sufficient rigidity while the surface of the model is covered with ABS plates to ensure the smoothness of the surface. Large plates are connected at both model ends to improve the flow conditions. As shown in Figure 1, the model is elastically suspended in wind tunnel by springs, and the model may move in vertical and torsional directions but the motion in along-wind direction is restrained by a long steel wire. The incoming wind velocity is recorded by Croba. The model displacements at upstream and downstream locations are measured by two laser displacement transducers, the model accelerations at upstream and downstream locations are measured by two micro-accelerometers. The test is conducted in smooth flow (with turbulent intensity less than 1% for mean wind velocity larger than 3m/s) and only zero wind attack angle is considered.

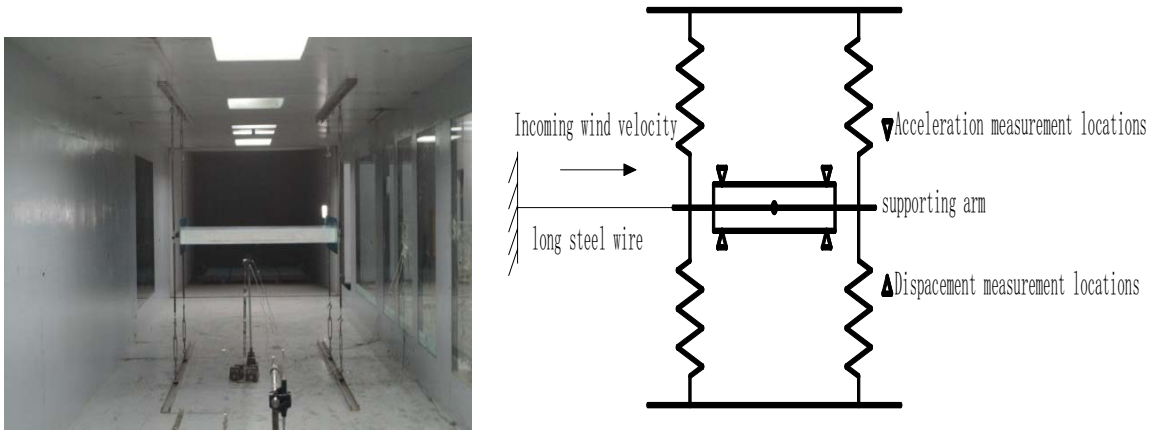

Figure 1. Elastically-suspended section model and its supporting frames

3.2 *Data processing*

The data are recorded after the model vibration become stable. The sampling frequency is 100Hz and sample duration exceeds 45s for each record. For each test case, the wind velocity, two accelerations and two displacements are measured. The two displacements $u_1(t)$ and $u_2(t)$ (or accelerations) are used to calculate the vertical and torsional displacements, as follows.

$$h(t)=\frac{1}{2}\left(u_1(t)+u_2(t)\right) \qquad \alpha(t)=\frac{1}{2L}\left(u_1(t)-u_2(t)\right) \tag{10}$$

where L is the half of distance of measurement points of laser transducer. The standard deviation of the response is calculated from vertical and torsional displacements.

3.3 *Experimental results*

A total of 11 testing cases is carried out, 8 for the model A and 3 for the model B. The experimental parameters of each case for the model A and the model B are summarized in Table 2 and Table 3. The equivalent modal mass for each case are precisely calculated based on finite element modal analysis of the free vibration system consisting of rigid sectional model, springs, connecting arms and long steel-wire, and the results are shown in the tables.

Table 2. Experimental parameters for the model A

Test case	6	1	7	2	8	3	4	5

Table 3 Experimental parameters for the model B

Test case	9	10	11
Vertical frequency f_v (Hz)	2.42	3.54	5.03
Vertical damping ratio (%)	0.19	0.25	0.25
Total physical mass (Kg)	9.67	10.20	10.89
Equivalent modal mass (Kg)	7.63	8.16	7.89
Sc number	1.71	2.41	2.33
Torsional frequency f_T (Hz)	5.08	7.52	9.57
Torsional damping ratio (%)	0.26	0.29	0.26
f_T/f_V	2.10	2.12	1.90

Wind tunnel experiments for the 1st~5th cases of the model A are first carried out and the vertical damping is 0.25%. For each case, two vertical VIV and two torsional VIV develop with increase of wind velocity. The variation of non-dimensional vertical displacement is shown in Figure 2. The first vertical VIV for the five cases are very similar; the second vertical VIV for the 3rd~5th cases are very similar but differs from those for the first and second cases. The anomaly in the second vertical VIV for both cases is probably caused by the simultaneous occurrence of vertical and torsional VIV such that vertical VIV transits into torsional VIV. In order to validate this assumption, three additional cases with larger torsional-to-vertical frequency ratio are tested. It is observed that the second VIV for the 6th~8th cases is very similar to those of the 3rd~5th cases.

It is also important to mention that the torsional vibration amplitude reduces drastically with torsional model frequency, and that the model with the case 8 does not develop torsional vibration even at the lower damping ratio of 0.16%. As there is no interference between vertical VIV and torsional VIV for the 3rd~8th cases, it is believed that the experimental vertical VIV data are reliable for these cases.

Wind tunnel experiments for the model B are then conducted for the 9th~11th cases. Due to the large value of torsional-to-vertical frequency ratio, vertical VIV and torsional VIV are well separated. The results of vertical VIV are shown in Figure 3.

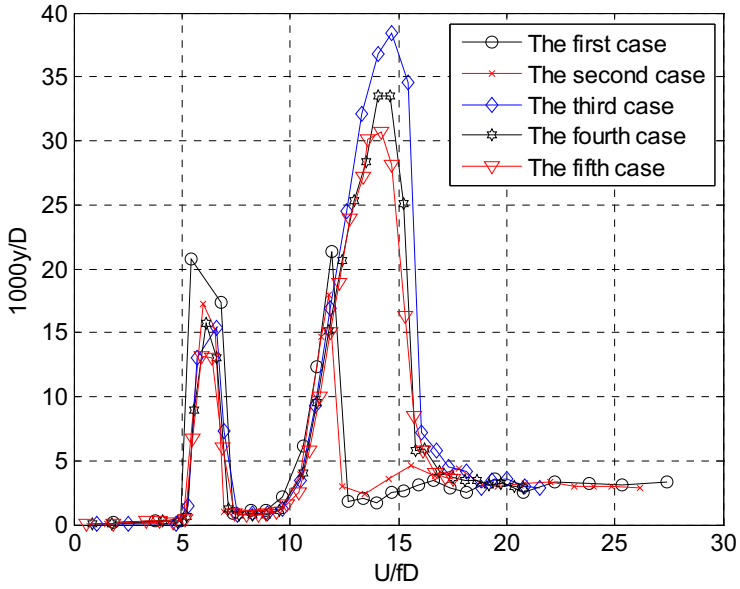

Figure 2. Variation of non-dimension vertical amplitude for the model A

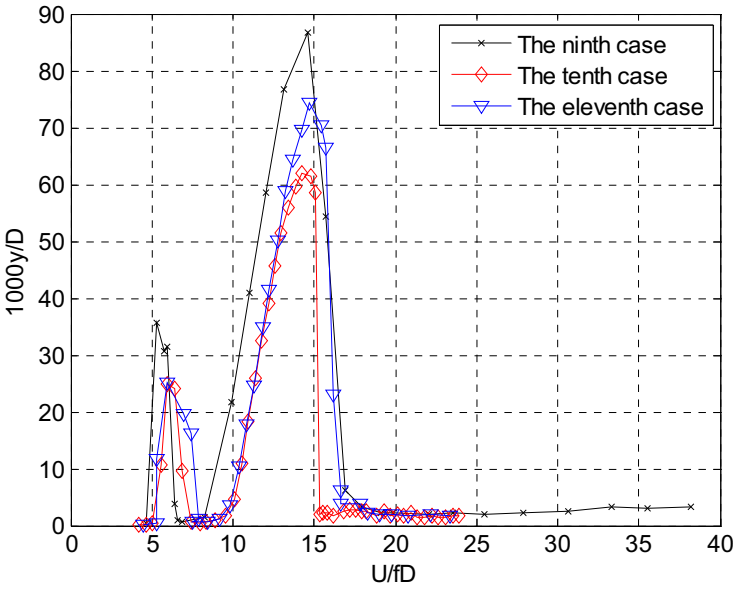

Figure 3. Variation of non-dimension vertical amplitude for the model B

3.4 *Analysis and discussion*

(1) There are two obvious vertical VIV for all the cases of the model A and the model B. The *St* numbers for all the 11 cases are calculated from onset wind velocity of two vertical VIV. The mean value of *St* numbers for the first and the second VIV are 0.206 and 0.107, respectively, and their stand deviation is 0.01 and 0.003. It is found that *St* numbers of the first and second vertical VIV are almost the same for all the cases. Vibration frequency and length scale of the model have minor effects on *St* number. Therefore it is reasonable and of sufficient accuracy to derive the wind velocity of VIV of other modes simply based on experimental data on one particular mode. The mechanism associated with the development of two vertical VIV rather than a single VIV remains further investigations.

(2) The mass *m* and damping ratio ς vary slightly for all the cases, and therefore the corresponding *Sc* number will be slightly different, as shown in Tables 2 and 3. In order eliminate the effect of *Sc* numbers on vibration amplitude, the *Sc* number for the 6th case is taken as reference value, and vibration amplitude for other cases of the model A are normalized with respect to the 6th case. As the vibration amplitude is inversely proportional to *Sc* number, the *Sc*-corrected non-dimensional vibration amplitude for all other cases is calculated as

$$|\eta|_n' = |\eta|_n \cdot \frac{S_{cn}}{S_{c6}} \tag{11}$$

where the subscript *n* represent the case *n*; $|\eta|'$ is the *Sc*-corrected vibration amplitude. The variations of *Sc*-corrected vibration amplitude for the model A are show in Figure 4. After correction, the discrepancy in vibration amplitude is further reduced for the model A. Figure 5 shows the *Sc*-corrected vibration amplitude for the model B where the 9th case is taken as reference. Both Figures 4 and 5 imply that vibration frequency does not have important effects on vibration amplitude. It may be concluded the assumption *that the non-dimensional vibration amplitudes for different vertical VIV modes of a bridge is the same* is valid and of sufficient accuracy for practical applications. However, the VIV torsional amplitude reduces drastically with torsional frequency,

and the above assumption is completely invalid for torsional VIV; however this observation appears to be consistent with realistic situations where the actual bridges rarely develop torsional VIV for higher modes. Further investigations are needed to better understand torsional VIV.

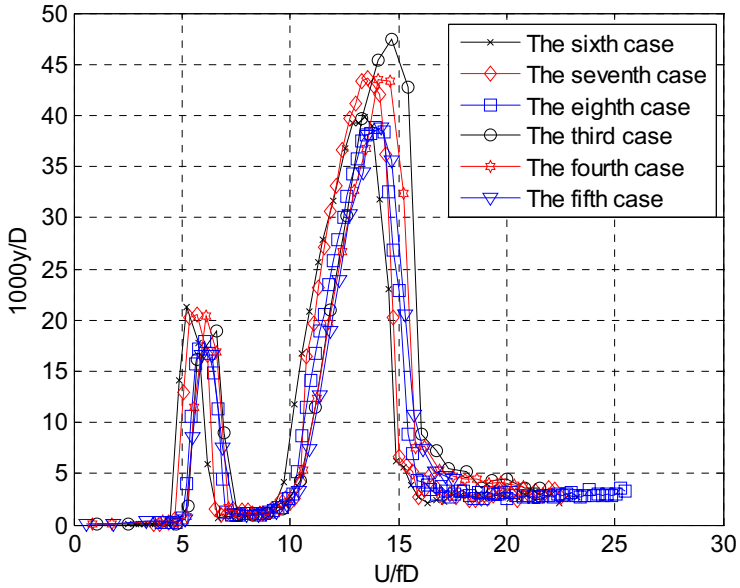

Figure 4. Variation of *Sc*-corrected vertical amplitude for the model A

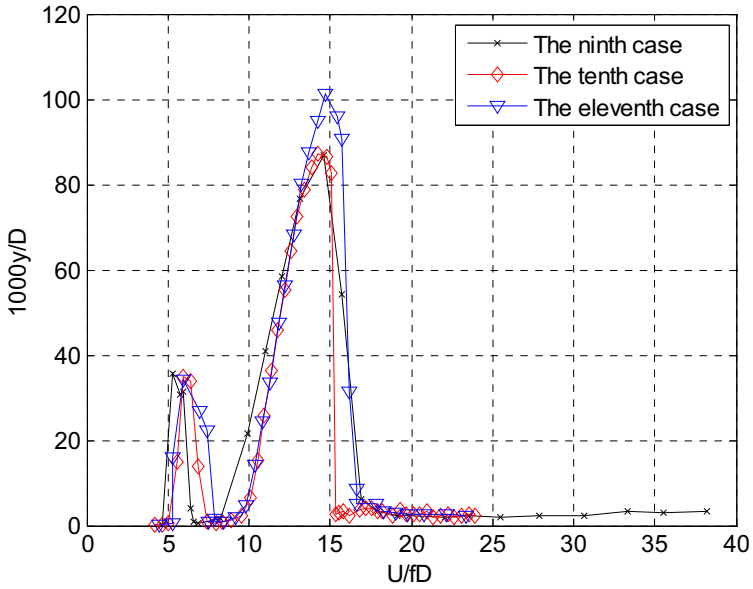

Figure 5. Variation of *Sc*-corrected vertical amplitude for the model B

(3) The *St* number for the second VIV is nearly half that for the first VIV. If the *simple linear model* of vortex-shedding forces stands, the maximum amplitude for the second VIV will be theoretically four that for the first VIV. However, the maximum amplitude for the second VIV is about two that for the first VIV, implying the *simple linear model* is insufficient. Due to the incorporation of Y_1 and Y_2 in the *empirical linear model* of Simiu-Scanlan type, the vibration am-

plitude is not simply in inverse relation with St^2. It may be concluded equation (7) is not of sufficient accuracy for structures with shallow cross sections.

(4) While the different cases of each model A or B have almost the same vibration amplitudes, the difference in vibration amplitude between the model A and the model B is quite large. The average non-dimensional amplitudes of the two vertical VIV for the model A is 19.28 and 45.02, while those for the model B is 35.97 and 91.71. The vibration amplitude for the model B with smaller scale doubles. Detailed comparisons are given in Table 4. Larger and smaller models will be used to further quantify the effect of length scales on vertical VIV amplitudes.

Table 4 Comparison of *Sc*-corrected non-dimensional amplitude for the models A and B

	L (m)	B (m)	D (m)	The first vertical VIV		The second vertical VIV

4 NOVEL MULTI-ELASTICALLY SUPPORTED AEROELASTIC MODEL

In order to investigate the span-wise correlations of vortex-shedding forces for different vibrational mode shapes as well to directly measure the vertical VIV amplitudes for every mode, an aeroelastic model capable of reproducing closely-spaced vertical modes is necessary. A scaled aeroelastic model of the full bridge may fulfill such requirement, but it is practically infeasible due to the small scale ratio, usually at the order of 1/200. The taut-strip model is capable of reproducing a pair of vertical and torsional modes of suspension bridges and can be used to investigate the flutter characteristics. The stiffness of the taut-strip model is provided by two internal parallel taut strings, and the vertical frequencies of the taut strings increase linearly with model number. For example, if the first vertical frequency is f_1, the modal frequencies of other higher-order modes will be $2f_1$, $3f_1$, $4f_1$, …. Such frequency distribution is not the case for the vertical modes of suspension bridges, as exemplified in Table 1.

In this study, a novel multi-elastically supported scaled aeroelastic model of shallow beam is proposed as simplified representation of a suspension bridge, which is capable of reproducing as many as closely-spaced vertical modes of suspension bridges The method for design such a model is developed. In the aeroelastic model of this kind, only the stiffening girder is included, and the girder model is elastically supported by springs at multiple locations. The key in developing the new aeroelastic model is to determine the appropriate number of elastic supports as well as the support stiffness with the assumed mode shape method.

An aeroelastic model of rectangular cross section with the side ratio B/D=6 has been designed and constructed, and hopefully very important mode of the aeroelastic model may be excited by vortex-shedding one by one to further understand the variation of vibration amplitude for different vertical modes. The model is 8m long, 2cm high and 12cm wide. The model is intended to simulate multiple vertical modes of a suspension bridge with main span of 1600m. Froude number is followed in the model design. The stiffness of the rectangular cylinder is provided by a thin steel plate, while the outer configuration is made by foam materials. The modal frequencies and mode shapes of the spring-supported aeroelastic model will be tested by sinusoidal excitation and will be compared with finite element predictions to evaluate the shear effect of shallow beam on higher modes. The carefully-calibrated aeroelastic model tests will be finally conducted in the smooth and turbulent flows to measure the VIV vibration amplitude of each mode as well

as to investigate the relationship between vibration amplitude and other (structural and wind) influencing parameters. The experiments will be conducted in the new 8.5m(W)×2m(H)×15m(L) test section of the HD-2 wind tunnel. Many investigations are still underway.

Benchmark wind tunnel study of wind loading on rectangular sign structures

Delong Zuo, Douglas A. Smith, Kishor C. Mehta

Wind Science and Engineering Research Center, Texas Tech University, Mail Box 41023, Lubbock, TX, USA

ABSTRACT: Wind-tunnel tests were conducted to study wind loading on elevated rectangular sign structures of various configurations. Based on these tests, the wind-induced force and moment acting on the sign models were evaluated. The data obtained from the wind tunnel tests were analyzed in the context of the results of previous wind tunnel tests as well as those of a full-scale investigation. It is revealed that the configuration of the rectangular sign faces significantly affects the loading on these structures. It particular, the outcomes of the present study indicate that the torque acting on rectangular sign structures is overestimated by a standard that guides the design of such structures.

KEYWORDS: rectangular sign, wind loading, wind tunnel tests.

1 INTRODUCTION

Rectangular boxes and plates are frequently used as signs to display information and to function as a structural component. These sign systems with rectangular faces are structurally quite simple: They usually consist of a rectangular sign board or box and a simple support, such as a mono-pole or a truss. In some other cases, the rectangular signs are simply fixed to the ground. Despite the structural simplicity of these structures and that fact that rectangular boxes and plates are among bluff bodies of the simplest shapes, the wind loading of sign structures can be complex and is dependent on the size of the sign, the ratios between the three dimensions of the sign, whether the sign is elevated or located on the ground and, in the case of elevated sign, the amount of the clearance between the sign and the ground.

Perhaps due to the perceived simplicity of the structure, to date, very few studies have been dedicated to expressly investigate the wind loading of sign structures. Previous studies related to wind loading of rectangular sign structures evolved from wind tunnel experiments conducted in smooth, uniform flow (e.g., the early work done by Flachsbart, as summarized in [1]) to turbulent uniform flow (e.g., [2]) to both wind tunnel and full-scale studies in turbulent boundary layer flow (e.g., [3-9]). Most of these studies, however, were conducted to study wind loading on free-standing walls, which resemble a class of rectangular signs on the ground. Only very few studies (e.g., [5, 9]) were dedicated to the study of sign structures, and the focus of these studies were on signs formed by thin plate-like rectangular elements. This paper presents the outcomes of a benchmark study, which is a subset of a more comprehensive research effort, conducted to assess wind loading on sign structures of a number of configurations. These outcomes are interpreted in the context of the results from previous studies on wind loading on rectangular sign structures and the specifications of design standard.

2 EXPERIMENTAL CONFIGURATIONS

2.1 *Models*

Models of four sign structures with rectangular sign faces were tested in the wind tunnel at a length scale of 1:50. The first has a single-plate of 3 mm in thickness, which will subsequently be referred to as the single-plate sign model. The second is composed primarily of two parallel thin plates of 3 mm in thickness as the sign faces, which will be referred to as the double-plate sign model. This model is open on all sides, and the two sign faces are connected by eight 6mm by 6 mm struts, four at the top and the other four at the bottom of the sign at equal spacing. The third is a model also composed of two thin plates of 3 mm in thickness as the sign faces, but these two plates form a $30°$ angle instead of being parallel to each other. The two faces of this model are also connected by eight 6mm by 6 mm struts, four at the top and the other four at the bottom of the sign at equal spacing. This model will be subsequently referred to as the V-shaped sign model. The fourth is cubic in shape with all the sides closed, which will subsequently be referred to as the box sign model. The sign double-plate, the V-shaped and the box sign models were printed out by a three-dimensional printer, and the sign face of the single-plate sign model was an aluminum plate. All four sign models were supported by a circular steel rod of 0.95 cm in diameter. Figure 1 schematically shows the configuration and major dimensions of the models. In this figure, $b = 15.2$ cm, $h = c = 7.6$ cm, and $t = 3.7$ cm. At a length scale of 1:50, these dimensions correspond to full-scale sign faces with a width of 7.6 m and a height of 3.8 m. In current design practices, sign structures are often characterized by their aspect ratio (b/h) and clearance ratio ($h/(h+c)$). These specimens represented sign models with an aspect ratio of 2 and a clearance ratio of 0.5.

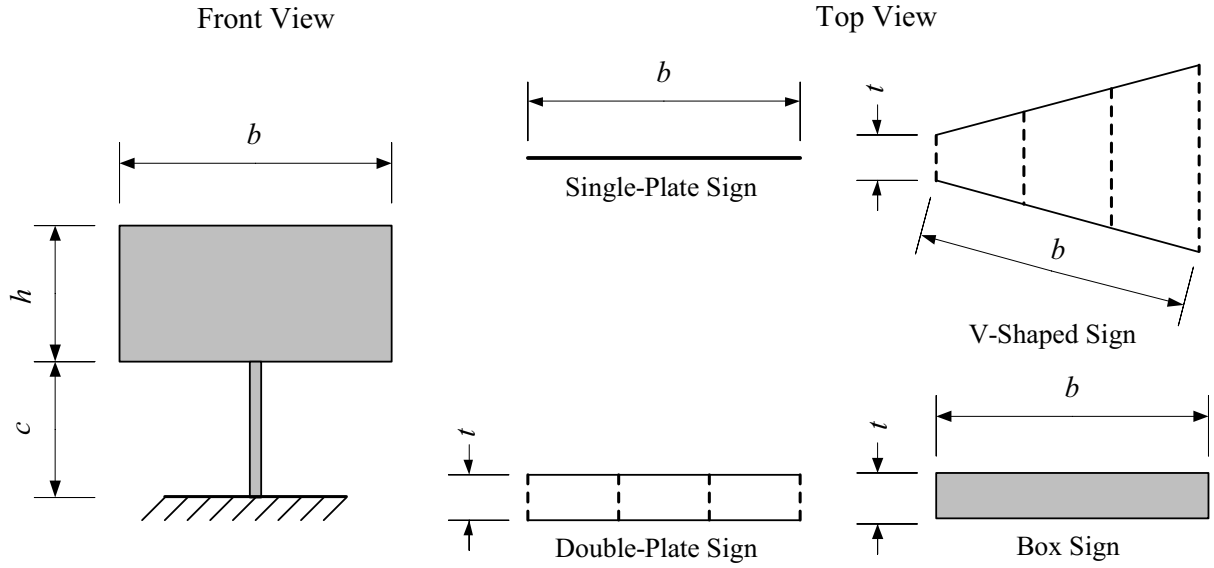

Figure 1 Sign models tested in the wind tunnel (not to scale)

2.2 *Simulation of boundary layer*

A wood grid system right outside of the settling chamber of the wind tunnel, a barrier upstream of the boundary layer section and a combination of a carpet and wood blocks were used to simulate atmospheric boundary flows representing those over exposure C specified by the loading standard published by American Society of Civil Engineers [10] (subsequently referred to as ASCE 7-10). Figure 2 shows the mean wind speed profile of the simulated atmospheric bounda-

ry layer at a length scale of 1:50. In this graph, the mean wind speeds at the measurement heights were normalized by that measured at a height of 0.2 m above the wind tunnel floor. A least-squares fit of the height against mean wind speed assuming that the profile is logarithmic in nature yields an equivalent full-scale roughness length value of $z_0 = 0.015$ m, which is close to the representative roughness length scale associated with exposure *C* specified by ASCE 7-10. Also shown in Figure 2 is the estimated auto-spectral density function of the along-wind speed at a height of 0.2 m above the wind tunnel floor as well as the corresponding Kaimal spectrum ([11]) at this height. In this figure, n is frequency, U is the mean wind speed, σ_u is the standard deviation and $S_n(n,z)$ is the auto-spectral density function. It can be observed that the simulated boundary layer has slightly higher energy content at higher frequencies and slightly lower energy content at lower frequencies than the flow represented by the Kaimal spectrum. This is a typical shortcoming of larger scale wind tunnel simulations.

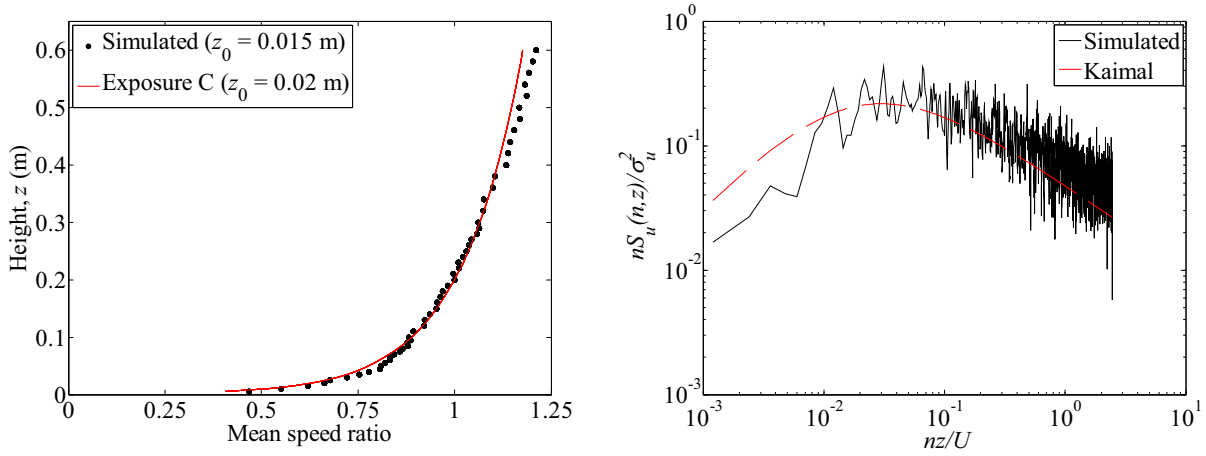

Figure 2 Mean wind speed profile of boundary layer flow and spectrum of along-wind speed at a height of 0.2 m above wind tunnel floor

2.3 *Measurements*

During the tests, the rods that supported the sign models were clamped to a six-component force transducer (ATI Industrial Automation, Inc. Gamma series, calibration SI-32-2.5), which has a resonance frequency of more than 1000 Hz for all components, for direct measurements of the forces and moments acting on the sign structure models. The mean test wind speed was approximately 10 m/s at a height of 20 cm above the wind tunnel floor, which is equivalent to 40 m/s at 10 m above ground level. The reference wind speeds for calculation of the reference dynamic pressure were measured by a Cobra probe (Turbulent Flow Instrumentation, series 100), which was placed at a position that was at the same height as the top of the sign model and at least one sign face width away from the side of the model. The single-plate, double-plate and box sign models were tested for 6 orientations represented by yaw angles of $0°$ to $75°$ at a $15°$ increment, relative to the mean direction of the wind, respectively; and the V-shaped sign model was tested for 13 orientation represented by yaw angles of $-90°$ to $90°$ at a $15°$ increment. Figure 3 schematically indicates the definition of the yaw angle (β) for the four types of sign models tested. For the V-shaped sign model, clockwise rotation of the sign axis relative to the direction normal to the wind direction results in positive yaw angles and counterclockwise rotation result in negative yaw angles. In addition to testing the whole sign models, a separate series of tests were also performed for the supporting rods without the sign faces attached. With the reasonable assumption that the effect of the secondary flow induced by the rod can be neglected, this enables estimation of the net forces and moments acting on the sign faces only.

All the measurement channels were sampled at a frequency of 250 Hz. Ten tests were conducted for each sign configuration as well as the rod to facilitate estimation of the coefficients representing the wind-induced forces and moments. The duration of each test is 72 seconds, which is equivalent to 15 minutes at full-scale.

3 RESULTS

3.1 *Mean force and eccentricity coefficients*

To estimate the mean force coefficients, the forces acting on the sign structure models and those acting on the supporting rods were first evaluated independently. For all specimens, the forces measured by the two orthogonal axes of the force transducer were decomposed into an along-wind drag component and a cross-wind lift component. The mean drag and lift forces acting on the rod are estimated as the mean value of the drag and lift force time histories obtained from 10 tests of the rod. These mean drag and lift forces acting on the rod are subtracted from the drag and lift force time histories obtained from the 10 tests of each sign structure model to yield time histories of the net drag and lift forces acting on the faces of this sign model. These net drag and lift time histories were then used to compute the resultant net horizontal force, which will subsequently be denoted $F_i(t)$, in which i is the test number and t is time. For each net force time history, the corresponding force coefficient time history is estimated as

$$C_{Fi}(t) = \frac{F_i(t)}{\frac{1}{2}\rho U^2 A} \tag{1}$$

where ρ is the air density calculated based on the temperature, barometric pressure and relative humidity measured in the wind tunnel, U is the mean wind speed measured at the height of the top of the sign, and A is the area of the sign faces. For each sign model, a 15-minute mean force coefficient, $\overline{C}_{Fi} = \text{mean}(\overline{C}_{Fi}(t))$ is computed based on time histories obtained from each individual test. The mean force coefficient of a sign model is then estimated as the average of these 10 15-minute mean force coefficients. That is

$$\overline{C}_F = \frac{1}{10}\sum_{i=1}^{10} \overline{C}_{Fi} \tag{2}$$

Figure 4 shows the mean force coefficients of the four sign models tested for the yaw angles tested. It can be seen that the mean aerodynamic behavior of the 4 sign models were quite different. While the largest mean force coefficient for all four models are expectedly associated with smaller absolute values of yaw angles, the detailed evolution of these mean force coefficients with the yaw angle is quite model dependent. For the single-plate sign model and the box sign model, the mean force coefficients remain mostly constant for yaw angles of $0°$ to $30°$. At yaw angles of $45°$ and above, however, these two models behaved very differently due to the difference in the depth of the signs. In particular, while the single-plate sign is seen to attain a maximum mean force coefficient at a yaw angle of $45°$, the mean force coefficient of the box-sign at a yaw angle of $45°$ is much smaller than those at yaw angles of $0°$ to $30°$. By comparison, the evolution of the mean force coefficients of the double-plate sign is quite similar to that of the single-plate sign except that the existence of a second rectangular plate make the mean force coefficients of the double-plate sign slightly lower at yaw angles of $0°$, $15°$ and $45°$ and slightly higher yaw angles of $30°$, $60°$ and $75°$ than those of the single-plate sign at the corresponding yaw angles. By contrast, the loading of the V-shaped sign model is the most different from that of the other three sign models due to the fact that the orientation of this sign relative to wind is asymmetrical about the yaw angle of zero degree.

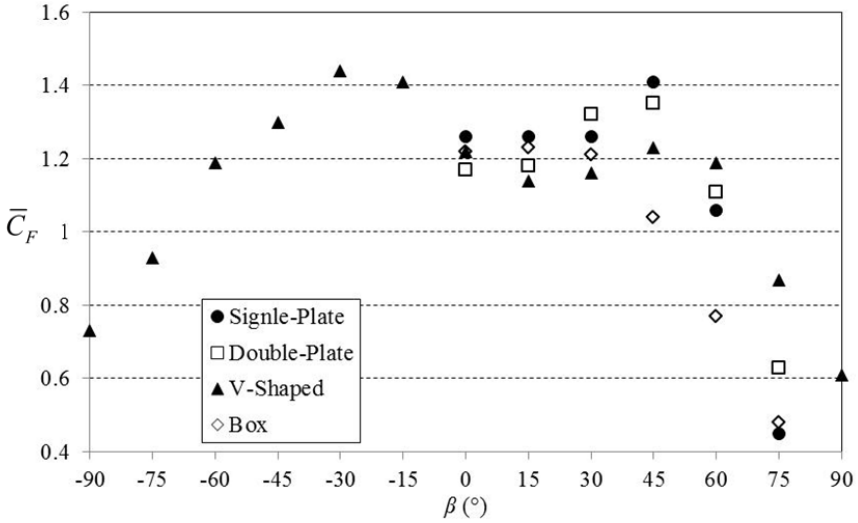

Figure 4 Mean force coefficient vs. yaw angle

While the mean force coefficients of the single-plate, double-plate and V-shaped sign models shown in Figure 4 are quite similar to those reported by Letchford [5] and Warnitchai [9] for corresponding equivalent sign models tested at the same yaw angles in similar simulated boundary layers flows, it is noteworthy that, as can be observed in , the critical (i.e., maximum) force coefficient of the box sign model, which was not tested by either Letchford [5] or Warnitchai [9], is considerably lower than those of the other three sign models, which are quite similar. This suggests that closing the sides of rectangular sign structures results in reduction of wind loading of these structures. Also, in the standards and specifications that guide the design of rectangular sign structures (e.g., [10]), the force coefficients are mostly derived based on wind tunnel tests of single-plate sign models, this means that the currently design practice likely overestimates the wind loading on box sign structures.

Table 1 Critical mean force coefficients

	single-plate	double-plate	V-shaped	box
$(\overline{C}_F)_{\max}$	1.41	1.35	1.44	1.23

To characterize the mean torque acting on the sign structure due to wind loading, an eccentricity coefficient, which is the moment arm of the torque normalized by the width of the sign model, is defined as:

$$C_{ei}(t) = \frac{T_i(t)}{F_i(t)b} \tag{3}$$

where $T_i(t)$ is the time history of the torque acting on the base of the supporting rod during the ith test run. For each sign model, a 15-minute mean eccentricity coefficient, $\overline{C}_{ei} = \text{mean}(\overline{C}_{ei}(t))$ is computed based on time histories obtained from each individual test. The mean force coefficient of a sign model is then estimated as the average of these 10 15-minute mean force coefficients. That is

$$\overline{C}_e = \frac{1}{10}\sum_{i=1}^{10}\overline{C}_{ei} \tag{4}$$

Figure 5 shows the mean eccentricity coefficients of the four sign models tested for the yaw angles tested. It can be seen that the difference in the mean force coefficients of the 4 sign models were also present in the wind-induced torque acting on them. It can be seen that for the single-plate, double-plate and box sign models, the mean eccentricity coefficients exhibit a general trend of increasing with increasing yaw angle. For yaw angles of $0°$ and $15°$, the mean eccentricity coefficients of the single-plate, double-plate and box sign models are almost the same. With increasing yaw angle, the mean eccentricity coefficients of the single-plate and double-plate sign models become much higher than those of the box sign model at the corresponding yaw angles, with the double-plate sign having the largest mean eccentricity coefficient at a given yaw angle. Compared with these three sign models, the behavior of the torque acting of the V-shaped sign model is much more complex again owning to the fact that the orientation of this sign relative to wind is asymmetrical about the yaw angle of zero degree.

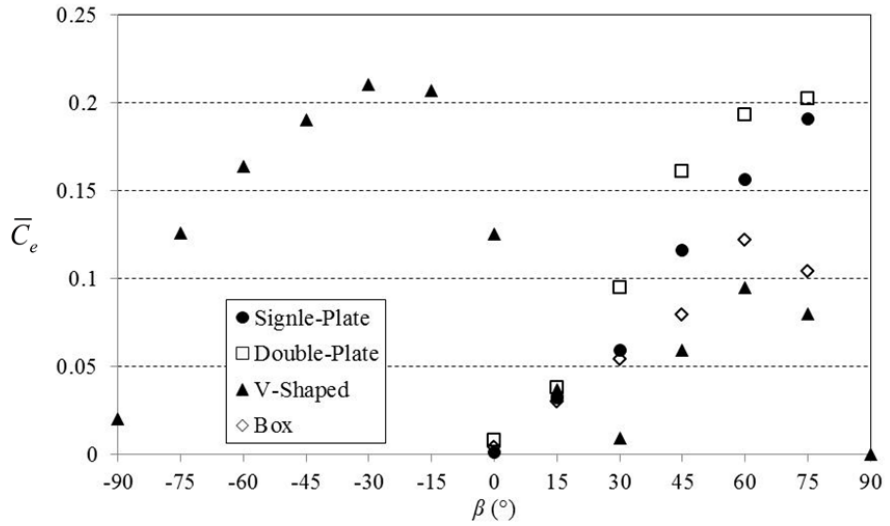

Figure 5 Mean eccentricity coefficient vs. yaw angle

3.2 *Force and eccentricity coefficients based on extreme values*

In addition to the mean coefficients, the measurements made in the tests were also used to estimate the pseudo-steady force coefficients. For each sign model, at each yaw angle, the maximum force coefficients was identified based on the force coefficient time history obtained from each test. the 10 maximum force coefficients were then fitted to a type I Fisher-Tippett extreme value distribution using the Lieblein method [12]. The mode and dispersion of the fitted extreme value distribution were used to estimate the mean hourly extreme force coefficient as

$$\hat{C}_F = \text{mode}_{10\text{ minute}} + [0.577 + \ln(6)] \times \text{dispersion}_{10\text{ minute}} \tag{5}$$

The pseudo-steady force coefficient is then estimated as

$$\tilde{C}_F = \frac{\hat{C}_F}{G^2} \tag{6}$$

where G is the gust factor calculated based on the expression [13]

$$G = 1 + 0.42\ln(3600/t_0) \tag{7}$$

In this study, t_0 is taken as 3 seconds, the gust factor obtained using equation (7) therefore represents that associated with 3-second gusts.

Figure 6 shows the pseudo-steady force coefficients of the four sign models against the yaw angles. The mean force coefficients based on full-scale equivalent 15 minute records and the pseudo-steady force coefficients based on hourly extreme values are comparable since both time durations fall in the spectral gap (e.g., [14]). Comparison of Figure 6 with Figure 2 reveals that for the critical loading cases associated with small yaw angle (i.e., less then $60°$), the pseudo-steady force coefficients for all four models are close to the corresponding mean force coefficients. At larger yaw angles, the pseudo-steady force coefficients for a given sign model differs from the corresponding mean coefficients because for these yaw angles, the effect of the structure-induced turbulence becomes more pronounced.

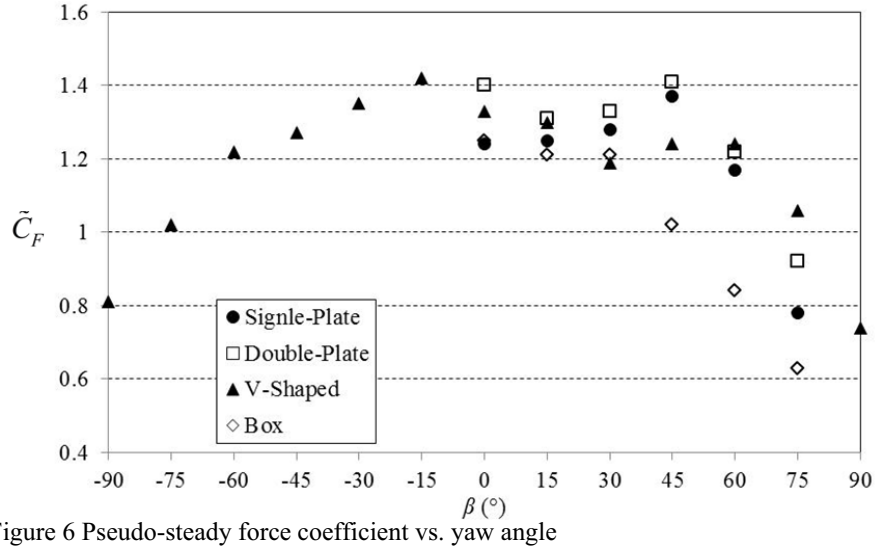

Figure 6 Pseudo-steady force coefficient vs. yaw angle

Table 3 lists the critical pseudo-steady force coefficients for the four sign models tested. It is apparent again that while the critical pseudo-steady force coefficients of the single-plate, double-plate and V-shaped sign models are close, that of the box sign model is considerably lower. This again suggest that it is likely to be conservative if force coefficients derived based on study of wind loading on single-plate signs are used to design box sign structures.

Table 3 Critical pseudo-steady force coefficients

	single-plate	double-plate	V-shaped	box
$(\tilde{C}_F)_{\max}$	1.37	1.41	1.42	1.25

Using the same procedure used to estimate the hourly extreme force coefficients, the hourly mean extreme force ($\hat{F}$) and absolute torque ($|\hat{T}|$) acting on a sign model. These mean extreme values can then be used to estimate a mean extreme value based eccentricity coefficient for this sign model:

$$\tilde{C}_e = \frac{|\hat{T}|}{\hat{F}b} \tag{8}$$

Figure 7 shows the mean extreme value based eccentricity coefficients against the yaw angles tested. It is evident that for the single-plate, double-plate and box sign models, the eccentricity coefficients increase with increasing yaw angle. It also can be seen that except for the case of zero yaw angle, for the same yaw angle, the single-plate and the double-late sign models have higher eccentricity coefficients than the box sign model. In addition, the graph suggests that, as in the case of mean eccentricity coefficient, the relationship between the mean-extreme value based eccentricity coefficients of the V-shaped sign and the yaw angles are much more complex.

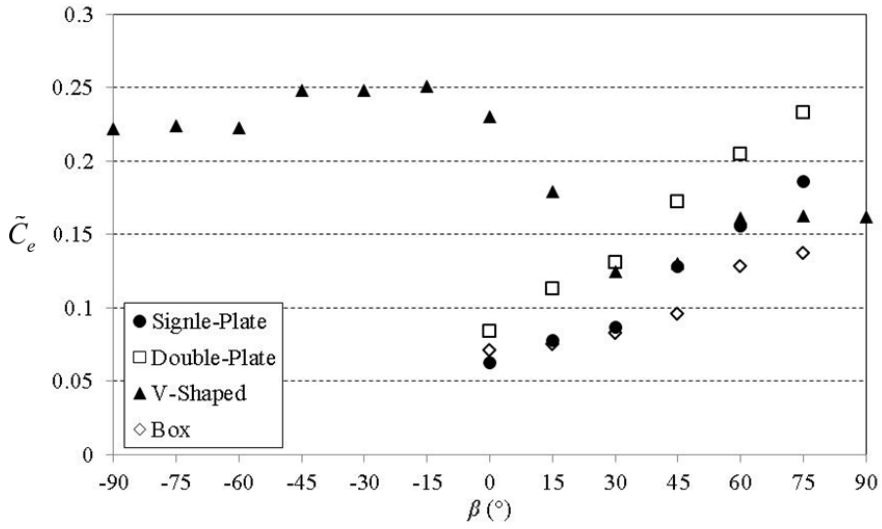

Figure 7 Mean extreme value based eccentricity coefficient vs. yaw angle

For a typical design situation, the design extreme torque is likely calculated based on the design extreme force, which is the maximum extreme force for all the possible yaw angles. For codification purposes, an alternative synthesized eccentricity coefficient can be defined as

$$\tilde{C}_e' = \frac{|\hat{T}|}{\hat{F}_{\max} b} \tag{9}$$

in which $\hat{F}_{\max}$ is the maximum of the mean extreme force for all wind directions.

Figure 8 depicts the synthesized eccentricity coefficients against the yaw angles. This graph indicates that for a given yaw angle, the two sign models consist of two plates as sign faces, i.e., the double-plate sign and the V-shaped sign generally have larger synthesized eccentricity coefficients. It also suggested that although the synthesized eccentricity coefficients of the single-plate sign model and the box sign model are close for small yaw angles (i.e., up to $30°$), with increasing yaw angle, the synthesized eccentricity coefficients of the single-plate sign model becomes much larger than the corresponding ones of the box sign model.

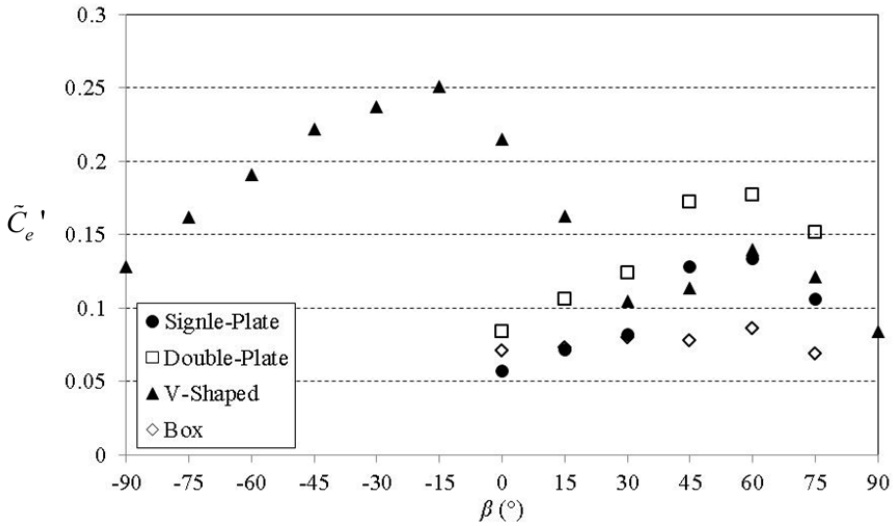

Figure 8 synthesized eccentricity coefficient vs. yaw angle

Table 4 lists the critical (i.e., maximum) synthesized eccentricity coefficients for the four sign models tested. Except that of the V-shaped sign model, these synthesized eccentricity coefficients are smaller than that specified in a typical standard. For example, in ASCE 7-10, the eccentricity coefficient recommended for the design of rectangular sign structures is 0.2. This value is obviously overly conservative for box sign structures similar to full-scale equivalent of the box sign model tested in the wind tunnel.

4 CONCLUSIONS

Models of four types of sign structures with rectangular faces are tested in a wind tunnel as a benchmark study of wind loading on rectangular sign structures. The data obtained from the wind tunnel tests were used to evaluate the wind-induced force acting on the models represented by mean and pseudo-steady force coefficients of these four types of structures as well as the wind-induced torque about the vertical sign axis represented mean and mean-extreme loading based eccentricity coefficients. It is revealed that for the four models with the same sized sign faces, different configuration of the signs can result in quite different loading on the structures. In particular, it was found that rectangular sign structures with all sides closed are subjected to less wind loading in terms of both horizontal force and torque about the vertical axis than are

signs consisting of either a single-plate or two plates with open sides. This means that design specifications derived based on study of wind loading of single-plate sign structures can potentially overestimate the wind force acting on box type sign structures. In addition, the outcome of the study also suggests that current design practice potentially overestimate the torque acting on many types of rectangular sign structure.

Instantaneous forces and moments on inclined flat plates

Xavier Ortiz, Arman Hemmatti, David Rival, David Wood
Dept Mechanical and Manufacturing Engineering, University of Calgary, Canada

ABSTRACT: This work was motivated by the need to improve knowledge of extreme wind loads on photovoltaic structures mounted on flat roofs at the high angles required in high latitudes. Traditionally these loads have been assessed from pressure distributions on model installations in an atmospheric boundary layer tunnel. Because we have no access to such a facility and because of concern over the possible interaction of lift and drag in producing the overturning moment, it was decided to measure the instantaneous forces and moments on model flat plates over a range of inclination and distance from the floor. The average lift and drag agree well with the available measurements in ESDU 70015 [1]. The instantaneous forces appear most complex for the smaller aspect ratios. As the wind tunnel floor is approached, there is a reduction in high frequency components. It is shown that the centre of the late is close to the centre of pressure for nearly all cases, but the fluctuation level of the pitch (overturning) moment is large.

KEYWORDS: Flat plate lift and drag, instantaneous forces, PV wind loads, unsteady moments

1 INTRODUCTION

This paper is motivated by the need to understand the extreme wind loads on photovoltaic (PV) modules and arrays retrofitted to flat roofs at high angles of inclination. PV arrays can be installed in either closed or open frames; only open frames are considered here. The support structures or frames are usually held in place using ballast, or occasionally by anchoring. The usual recommended ballast of approximately 100 kg per m^2 of PV area (which equates to 100 kg per 170 W of maximum electricity production) has exceeded the structural loading capacity of the roof for a number of potential installations around Calgary.

These wind loadings can be estimated using international standards, but neither the standard CEN/EN1991-1-4 [2] nor ASCE/SEI 7-10 [3], give explicit guidance for calculating the wind load. For Canada, the National Building Code [4] and the Alberta Building Code [5] are similarly unspecific regarding wind loads on PV structures mounted on flat or pitched roofs. The Dutch standard NVN 7250-2007 [6], gives specific guidance for determining forces and moments exerted on PV modules and arrays mounted on flat roofs, based on the pressure coefficients obtained from the experiments at TNO on PV arrays with an inclination angle of 35°. Blackmore [7] is a guide to calculate wind loads in UK, but it is not included in the standard BS 6399 Part 2 [8]. None of these standards uses direct force or moment measurements of individual modules.

Most wind engineering studies have concentrated on measuring the average pressure distribution on model modules and arrays and inferring the overturning moments, eg Miller & Zimmerman [9] and Tieleman *et al.* [10]. Some authors, eg Chevalier and Norton [11] measured the moments as well, but the data is limited: the pitch (overturning) moment was not reported. More recently, Radu *et.al.* [12] determined wind force coefficients on solar collector arrays mounted on a typical five story building.

Between 2005 and 2008, the European Active Roofer program carried out wind tunnel experiments in pitched and flat roofs to determine the wind loads. Those results were incorporated in the latest version of NVN 7250 [6] and Ref. [7]. Geurts and van Bentum [13] show how to use Ref. [2] to calculate wind loads on PV arrays mounted on flat roofs.

All the published studies determine wind loads on PV structures as function of average pressure coefficients, in order to incorporate these values into the equations specified in the current standards. Given the advent of accurate, fast response force and torque sensors, such as the one described in the next section, it is now easy to measure the wind loads directly, and so avoid some of the potential errors involved in inferring forces and moments from measured pressures. For example Ref. [6] assumes the centre of pressure of an inclined module is at the equivalent of the quarter-chord position, and assumption we show below to be significantly in error at high angles.

Flat plates are also the fundamental geometries for a number of other wind engineering and aerodynamic applications. For example, it is common in wind turbine design to account for blade behaviour at high angles by invoking the lift and drag properties of a thin flat plate at the appropriate aspect ratio, *AR*. The determination of the forces on, and flow around such plates has received little attention since the pioneering experiments of Fage & Johansen [14]. It is to be expected that the vortex shedding processes depend sensitively on aspect ratio and, of course the wake flow impinges on downwind modules. Investigation of the vortex dynamics is underway but is not reported herein.

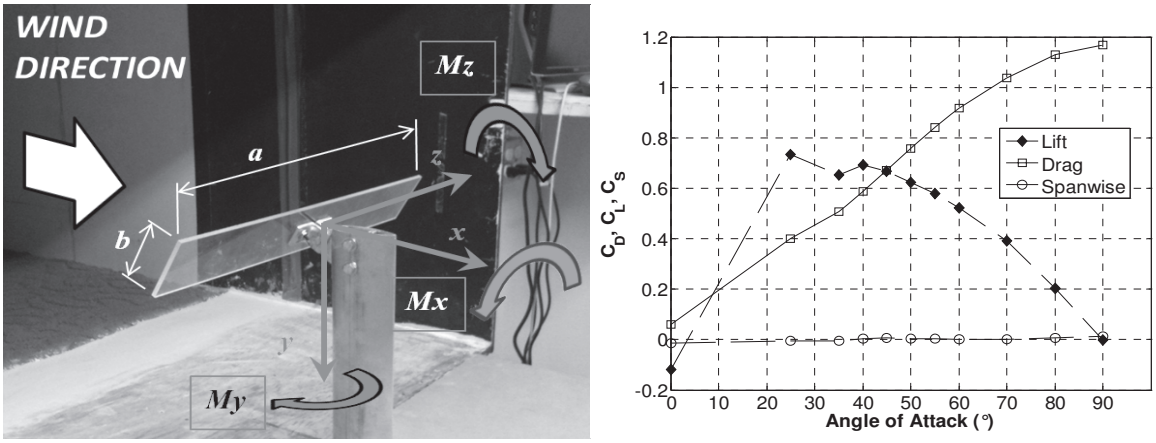
2 WIND TUNNEL EXPERIMENTS

Wind tunnel experiments have been carried out in the Environmental Wind Tunnel at University of Calgary. This tunnel has a cross-section of 0.76 m x 1.37 m. The nominal wind speed was 19 m/s measured using a pitot-static tube connected to a micro-manometer. The model sizes were chosen to keep the blockage below 3.5 %. Table 1 shows the eight different *AR*s that were tested. $AR = 0.6$ represents a typical single PV module in "portrait" orientation, $AR = 1.66$ is the same module in "landscape", while $AR = 3.6$ (see Figure 1(a)) represents an array of six modules in portrait, a common grouping. Measurements were made at eleven different angles of attack, α (0°, 25°, 35°, 40°, 45°, 50°, 55°, 60°, 70°, 80°, 90°) and five different clearances between the model and the wind tunnel floor, *H*. In practice, the wind direction can vary significantly from being parallel to the *x*-axis as indicated in Figure 1, but this is the only direction studied so far.

The flat plates were attached to a sting to simulate an open support structure. The selected sting was an aluminum symmetrical streamline strut tubing of very high rigidity with chord of 68.5 mm and maximum thickness of 29 mm. Instantaneous forces and moments were measured by an ATI multi-axis force/torque sensor holding the sting to a solid frame. The force sensing ranges was 65 N in the x-direction and the y-direction, and, 200 N in the z-direction as defined in Figure 1. The moment sensing range was 5 Nm. Resolution was 1/80 N for force and 10/13333 Nm for torque. The frequency response was up to 40 kHz per channel. The sensor output signal in the range of +/- 10 V was connected to a National Instruments data acquisition board NI-DAQ USB 6212. The resolution of the board is 16 bit. One bit is used to transmit the sign (+ or -) of the signal, the other 15 are used to digitize the instantaneous value per channel, corresponding to a resolution of 0.61 mV. The sampling rate was 1 kHz. Forces and Moments were recorded for 60 s using the NI LabView Signal Express Software. MatLab was used for data reduction.

The $\boldsymbol{x}$ co-ordinate (and drag) is in the free-stream direction, $\boldsymbol{y}$, the direction of lift, is normal, and $\boldsymbol{z}$ is the spanwise direction parallel to the shortest side of the models for $AR < 1$ and the longest side when $AR > 1$, as shown in Figure 1(a). All moments are about the centre of the flat plate.

Forces and Moments acting on the sting were measured prior the tests with the flat plate to allow these to be subtracted from the averaged measurements.



(a) (b)

Figure 1: (a) Experimental stand showing a flat plate of AR = 3.58; (b) Force coefficients as a function of angle of attack for AR =3.58 in the free-stream .

The experimental set-up was checked by measurements of normal plates in the free stream. The mean results are summarized in Table 1 where the drag coefficient is compared to the equation given by ESDU [1]:

$$C_D = \quad 1.11 + 0.02(a/b + b/a) \tag{1}$$

C_S is the spanwise force coefficient, C_L is the lift force coefficient, a is the breadth and b is the height of the flat plate. Re is the Reynolds number based on the shortest dimension at each AR. Equation (1) expresses the fact that, in the absence of Re effects, the drag on a normal plate of $AR = a/b$, is the same as on a plate of the "complementary" $AR = b/a$.

Table 1: Measured forces and moments on a normal flat plate in the free stream.

AR	a(m)	b(m)	Re	C_D	C_D from Eq. (1)	C_L	C_S
0.40	0.094	0.232	1.18×10^5	1.077	1.157	0.0168	0.0124
0.60	0.142	0.236	1.78×10^5	1.074	1.145	0.0164	-0.023
1.00	0.168	0.168	2.10×10^5	1.067	1.140	0.0096	-0.030
1.66	0.236	0.142	1.78×10^5	1.081	1.145	0.0111	-0.015
2.48	0.232	0.094	1.18×10^5	1.101	1.157	0.1133	0.0004
3.58	0.364	0.101	1.27×10^5	1.169	1.178	0.0023	-0.014
6.00	0.400	0.066	8.27×10^4	1.155	1.225	0.0201	0.0039
9.00	0.457	0.051	6.39×10^4	1.182	1.281	0.0227	0.0148

All entries in the last column should be zero. They are not, but are significantly smaller than the drag coefficient. The measured C_D is in reasonable agreement with Equn (1); the difference is 6.9% at the lowest AR and 7.7% at the highest.

Additional measurements of the average force coefficients as a function of angle of attack α, for AR =3.58 are shown in Fig.1(b). The results are unremarkable but further demonstrate the adequacy of the experimental arrangement. Similar data were obtained for all plates.

3 TIME-AVERAGED RESULTS

Figures 3 and 4 summarize the time-averaged results in terms of the mean lift and drag coefficients determined using the model surface area *ab*, *not* the projected area. Figure 3 shows the free stream results where it can be seen that the low AR plates exhibit a local peak in lift around 45°. This peak disappears at higher AR. Although not shown, the lift (L) and drag (D) closely follow the relation $\tan \alpha = D/L$ that comes from assuming that the loads are due solely to the pressure distribution.

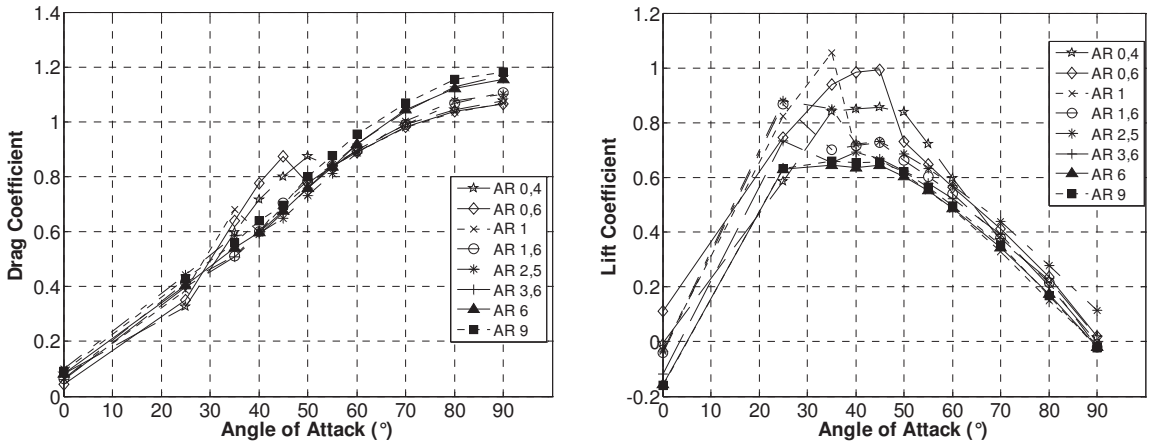


Figure 3: Free stream Drag and Lift coefficient as a function of AR and α.

Figure 4 shows the same coefficients at closest proximity to the tunnel floor. In all cases the drag is reduced but the lift behaviour is more complex and non-monotonic in AR.

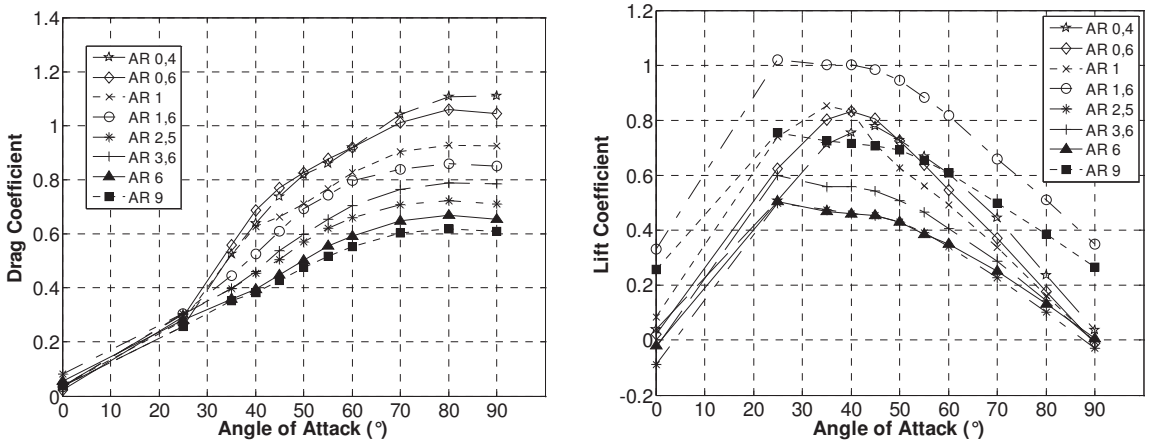

Figure 4: Drag and Lift coefficient at Minimum Clearance as a function of AR and α.

4 INSTANTANEOUS RESULTS

The following figures show a small sample of the extensive time-dependent measurements. Figures 5 and 6 show typical traces of the instantaneous drag for two widely different *AR*s in the free-stream and at mimimum clearance. There are clearly dominant frequencies in all traces but the free stream traces have more high frequency content. This may be due to the increased importance of sting drag which is a subject of current experimentation.

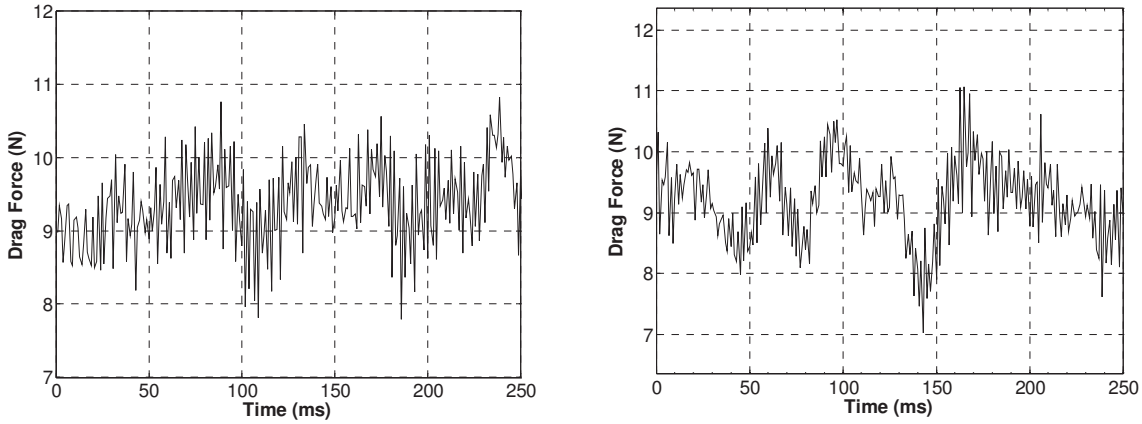

Figure 5: Instantaneous drag in the free stream and at minimum clearance for $AR = 0.60$ and $\alpha = 90°$.

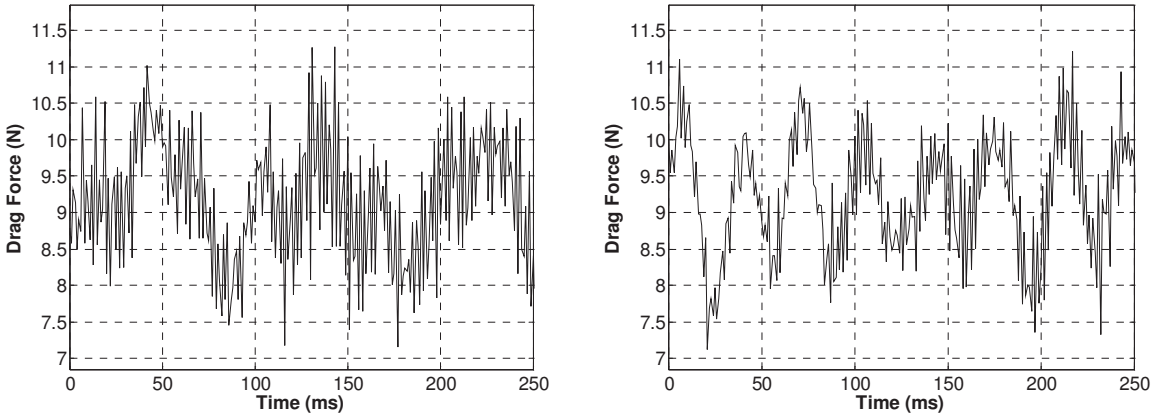

Figure 6: Instantaneous drag in the free stream and at minimum clearance for $AR = 3.58$ and $\alpha = 90°$.

Similar traces for the pitch moment for $AR = 0.6$ in Figure 7 again show the high frequency content in the free-stream is reduced at minimum clearance.

The dominant frequencies are clearly seen in the spectral densities in Figures 8 and 9. In figure 8, the peaks in the drag spectra at 11 and 18 Hz are replicated in the pitch moment as is the (probable) second harmonic at 22 Hz, although to a lesser extent. The strong peak in the drag only around 30 Hz is thought to be due to vortex shedding from the sting and will be investigated further with new, thinner stings.

The spectra become simpler as the *AR* decreases, Figure 9, as is evident from the previous figures, although the strong 30 Hz component remains.

One major advantage of measuring the moments directly is that assumptions need not be made about the location of the centre of pressure as is done in most standards covering wind loads on PV structures.

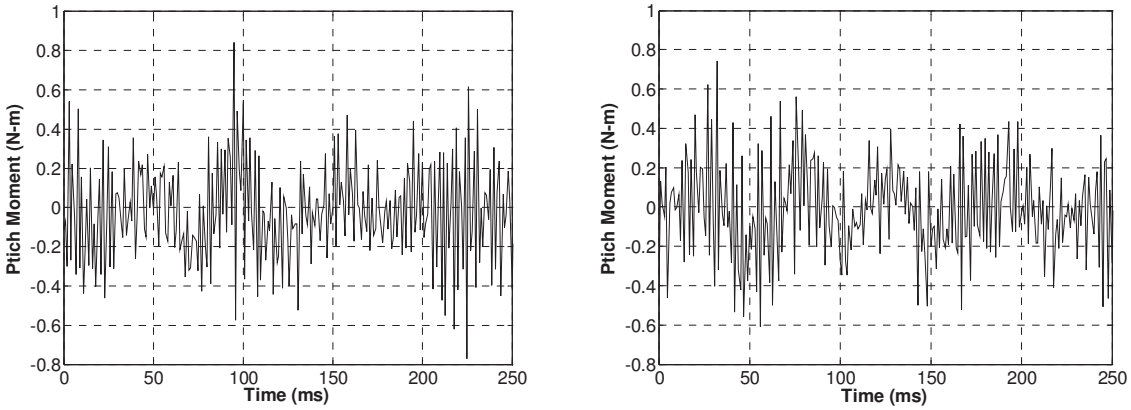

Figure 7: Instantaneous pitch moment in the free stream and at minimum clearance for $AR = 0.6$ and $\alpha = 90°$.

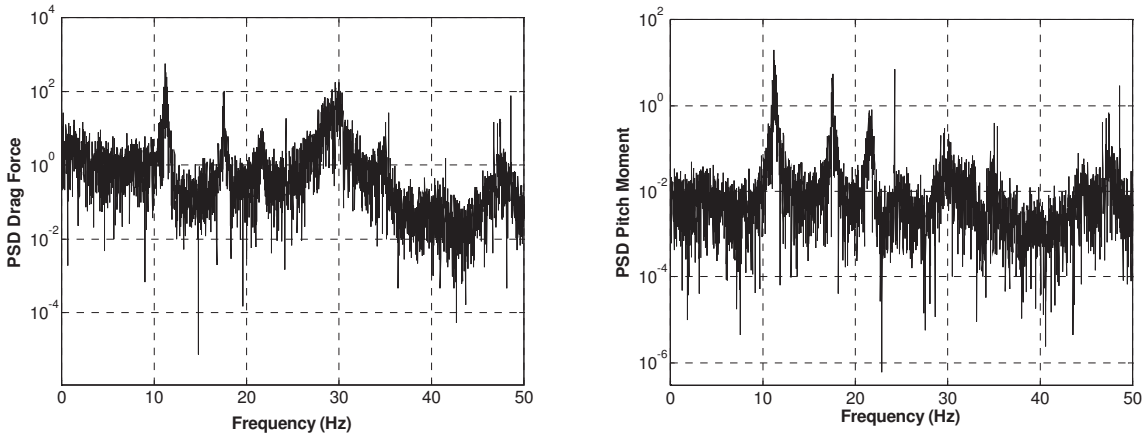

Figure 8: Power spectral density of drag and pitch moment in the free-stream for $AR = 0.6$ and $\alpha = 90°$.

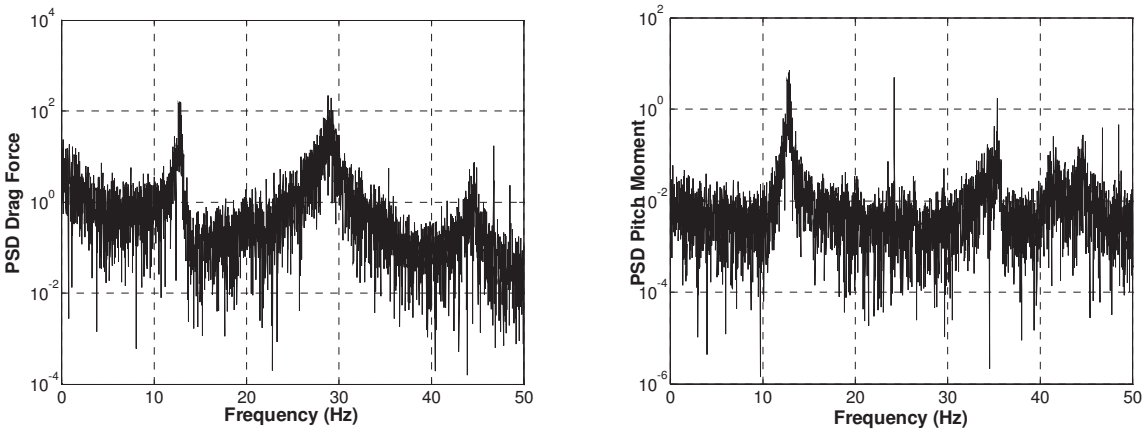

Figure 9: Power spectral density of drag and pitch moment in the free-stream for $AR = 3.58$ and $\alpha = 90°$.

Figure 10 shows the average free-stream and minimum clearance pitch moments compared to those calculated from the mean forces assuming the centre of pressure was the midpoint of the

plate. Although this assumption over-estimates the pitch moment at minimum clearance, it is remarkably accurate. Perhaps of greater significance for wind engineering purposes are the large variations in the instantaneous moments as indicated by the 95% intervals for the measurements. This suggests that the relationship between mean moment and the extreme moment at extreme wind speed needs re-evaluation.

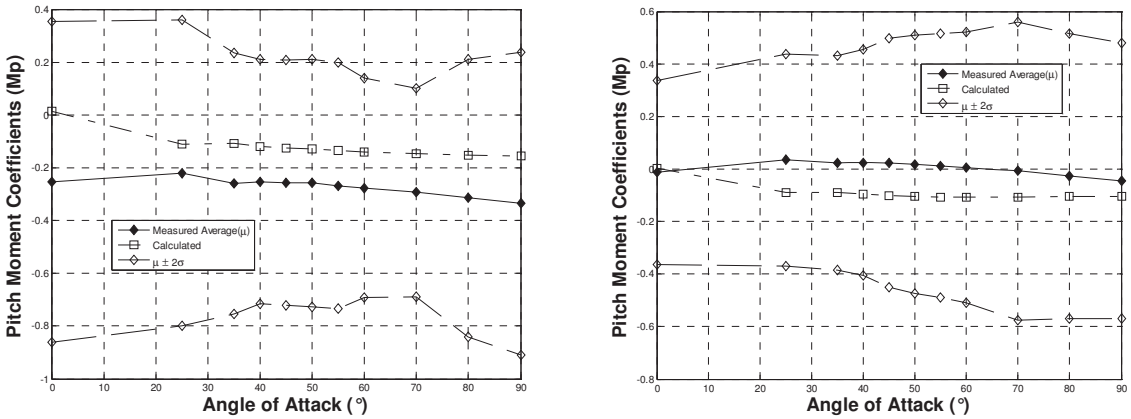

Figure 10: Mean pitch moment in the free-stream and at minimum clearance for AR= 3.58 and α=90°. The solid diamonds show the actual moment, the open squares show the moment calculated from the mean forces by assuming the centre of pressure is the middle of the plate. The open diamonds indicate the fluctuation level as measured by the position of two standard deviations from the mean.

5 CONCLUSIONS

The present experiments have investigated the instantaneous forces on thin, rectangular flat plate over a wide range of aspect ratios, angles of attack, and distances from the wind tunnel floor. The primary application was to determine extreme wind loads on photovoltaic structures at high angles. The mean forces agree well with the expectations of two-dimensionality and with the available previous measurements, mainly on normal flat plates in the free stream. In the free stream, an increase in aspect ratio increased the low frequency contribution to the instantaneous drag and simplified the spectra. As the wind tunnel floor is approached, the high frequency fluctuations reduce significantly. It is not clear, however, at this stage the extent to which the relatively thick sting contributed to these variations. For example, removing some of the high frequency content of the forces may be due to the reduced effect of the sting. Surprisingly the assumption that the centre of the plate is also the centre of pressure is remarkably accurate for the entire angle of attack range that was studied given the large fluctuation levels in the instantaneous pitch moments.

Wind tunnel studies on the effects of porous elements on the aerodynamic behavior of civil structures

M. Belloli[a], D. Rocchi[a], L. Rosa[a], A. Zasso[a]

[a] Politecnico di Milano, Dipartimento di Meccanica, via La Masa 1, 20156 Milano, Italy

ABSTRACT: This paper deals with the role of the porosity on the aerodynamic behavior of two civil structures: the Spire, a tall slender tower 80.44m high, and the buttresses of a tall building. The Spire is an original architectonic complement. Its covering, made of perforated steel plates, forms and intricate three-dimensional spiral characterized by five different diameters. The buttresses connect the building core around one fourth of its height to viscous dampers at their bottom, in order to increase the overall damping value of the building. The geometry of the buttresses is characterized by a variable cross-section along the longitudinal axis, permeable to the air. Wind tunnel tests on a 1:50 scaled rigid and aeroelastic model of the Spire and on a 3:10 scaled sectional model of the buttress were carried out in order to investigate the aerodynamic behavior of the structures using different geometry of the porosity or replacing with not-porous surfaces. The analysis carried out highlights the great influence of the porosity in the dynamic response of both structures, mainly in relation to vortex shedding induced vibrations.

1 INTRODUCTION

Nowadays porosity has a wide range of application in engineering and civil fields. In agricultural, porous screens have been largely used for many years in many functions: temperature regulating, shading, wind-breaking, anti-hail, anti-frost or for preventing the entrance of insects or birds. In some ventilation system, screens are used to control dust as filter function. As an alternative to these historical functions, the porosity finds new applications in civil structures. In fact modern buildings have required to reach higher energetic standards and this is achieved not only, using new construction materials, but also applying accessory elements to the structures. Porous structural elements are ones of the most common, since they have many functionalities: architectural design, temperature regulating function, shading function, wind-breaking effect and, last but not least, vortex shedding mitigation.

In literature there are many experimental and numerical CFD studies about flow through porous surface, e.g. [1,2,3]. Most of them regard wind loads on structures such as greenhouses, panels or roof [4,5,6,7,8,9]; these results reveals that the wind loads on perforated structure are generally lower than those on same non-porous surfaces. More systematic studies regard flow around porous cylinders [10,11]: in particular they show how vortex shedding can be reduced or suppressed manipulating the flow around the cylinder through the application of suction or blowing. Not a great number of experimental data are on the contrary available about wind interaction with permeable accessory elements in civil structures. For instance some recent studies attest that the porosity of a surface could modifies the wake formation and reduces the intensity of the vortex shedding and the overall crosswind load [12,13].

This paper deals with the role of the porosity on the aerodynamic behavior considering as illustrative examples two civil structures: the Spire, a tall slender tower 80.44m high, and the buttresses of a tall building. Wind tunnel tests were carried out in order to investigate the aerody-

namic behavior of the structures using different geometry of the porosity or replacing with not-porous surfaces. This analysis is very interesting as the structures could be subjected to atmospheric icing which can make non-porous parts of the perforated panels and so change their aerodynamic behavior.

1.1 *The Spire*

The Spire, which is erected on the top of a 139m new tall building, consists of a supporting lattice framework structure 80.44m high, covered with perforated steel plates. Considering the height of the building, the Spire maximum elevation from the ground is 220m (Figure 1). The external cover is not regular, but forms an intricate three-dimensional spiral characterized by five different diameters which decrease along the height of the structure. Changing the diameter along the height of the structure mitigates the vortex shedding phenomenon, but in the present case each section of the spire has an adequate length to introduce energy to the whole system and to induce oscillations of the spire to lead to fatigue damages [14,15].

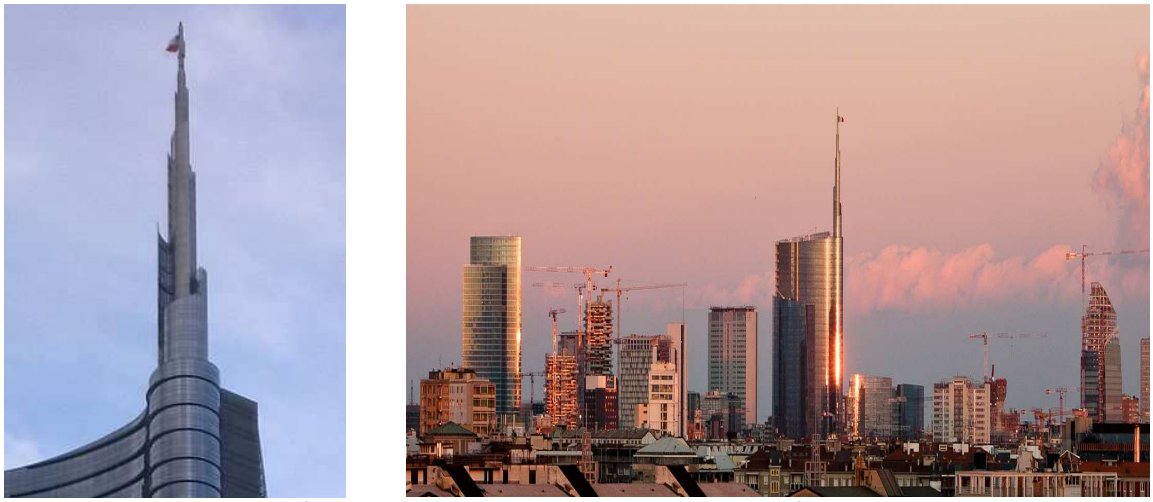

Figure 1. The Spire at the top of the new tall building. Its maximum elevation from the ground is 220m.

1.2 *The buttress*

The second structure studied in this paper are the long buttresses of a tall building, Figure 2(a). This building is an office tower 220m tall and it has a rectangular floor plan of 61.5m x 24m. The tower is characterized by two couples of external steel buttresses inclined with respect to the vertical axis and connected to the tower core around one fourth of its height along the front and the back facades. The buttresses are connected to their bottom ends to viscous dampers in order to increase the overall damping value of the building with respect to the minor side, providing beneficial effect to the base moment.

The length of the buttress is 61.6m end connections included. Their geometry is characterized by a variable cross-section along the longitudinal axis made by 3 Circular Hollow Section (CHS) interconnected rigidly by steel plates (Figure 2(b)); between the transverse connections the area within the three longitudinal CHS is permeable to the air. At mid span the three CHS reach the maximum c/c distance of 1.2m (see section 3, Figure 2); whereas at the two ends the three sections converge into a single circular tube (see sections 1 and 2, Figure 2).

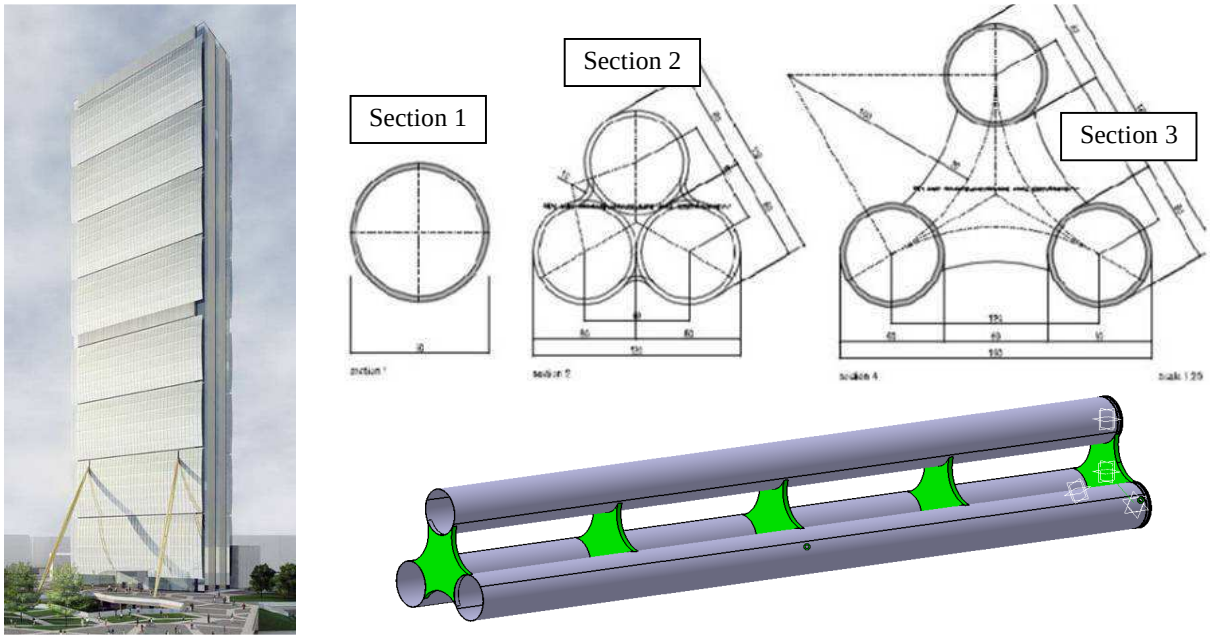

Figure 2. The 220m high tall building. (a) Global view. (b) Buttress geometry and transverse typical sections. The 3D view represents the central part of the buttress (section 3).

2 EXPERIMENTAL SET-UP

Wind tunnel tests were performed at the 1.5MW closed-circuit wind tunnel at the Politecnico di Milano, Italy. The large dimensions of the boundary layer test section (4m high, 14m wide and 36m long) allows a very large geometry scale to be used while maintaining lower blockage effects. The tests were performed in smooth flow condition (turbulence intensity I_u< 2%) which is considered on the safe side with respect to instability and vortex shedding excitation.

2.1 *The model of the Spire*

The experimental tests were performed using two models of the Spire: a rigid and an aeroelastic model. In this work we will focus on the results obtained on the aeroelastic model. A comparison between the results from the two models, to verify the presence of possible aeroelastic effects, can be found in [16], while a study about the local wind loads on the permeable panels by means of pressures measurements can be found in [17]. The large dimensions of the test section allowed to choose a geometry scale λ_L = 1/50. The aeroelastic model was designed as a spine model, adopting the Froude similitude criteria for scale reduction: the elastic properties of the real structure were reproduced by means of an aluminum bar made up by rectangular section of four different dimensions. An external cover, constituted of 16 modules, was adopted to reproduce the wind interaction shape and to match the correctly scaled mass. A more detailed description about the aeroelastic model set-up can be found in [17], while Figure 3(a) shows the model in the test section. Great care was taken for scaling the external surface geometry and porosity: in order to guarantee the kinematic similitude the perforated panels must be scaled not geometrically but the same loss coefficient must be maintained [7]. The loss coefficient k is defined as:

$$k = \frac{p_u - p_d}{\rho U^2 / 2} \tag{1}$$

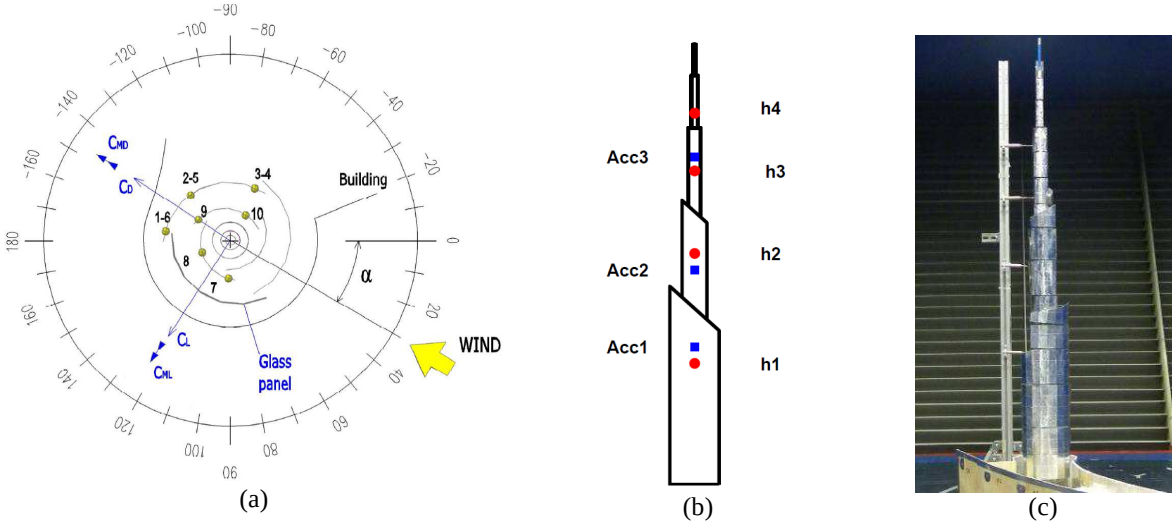
being p_u and p_d respectively the upstream and the downstream static pressure on either side of the grid, ρ is the density of the air and U is the mean wind speed. This coefficient is a indicator of the resistance to flow through a porous surface, including the effects of the open area β (defined as the ratio between the area open to through flow and the total area of the panel) as well as the shape of the perforations. The pressure loss coefficients were evaluate experimentally in a smaller wind tunnel, in which its entire round cross section (diameter = 400mm) was covered by the grid being tested.

(a) (b)

Figure 3. (a) The aeroelastic model in wind tunnel test section. (b) The perforated panels on the real structure.

In the real structure the panels have round hole perforation (radius 7.5mm) with triangular pitch of 21mm, Figure 3(b). Their open area β is 46.3% and the loss coefficient k varies between 4.5 and 4.8 (experimentally evaluated). On the models round hole perforated plates with radius 0.4mm and triangular pitch of 1mm were used. These plates were electrical discharge machining formed, they had an open area β=58% and a loss coefficient k very close to the real structure ($4<k<4.5$).

Global forces measurement is carried out by means of a dynamometric six-components force-balance linked at the base of the model. The exposure angle and the reference system is shown in Figure 4(a).



(a) (b) (c)

Figure 4. (a) Exposure angle and reference system. (b) Heights of the cobra probes (h) and the accelerometers (Acc). (c) The aeroelastic model made completely non-porous.

The model was instrumented with 6 accelerometers fixed on the structural bar in order to monitor the accelerations according to its bending modes (*x*-dir and *y*-dir). Vortex shedding excitation was investigated using four Cobra Probes, a multi-hole pressure probe developed by Turbulent Flow Instrumentation (TFI). They were fixed downwind the Spire at the heights shown in Figure 4(b); the same figure shows the positions of the accelerometers. In order to evaluate the effects of the porosity on the wind loads as well as the vortex shedding excitation, some tests were duplicated making impermeable the entire external surface of the aeroelastic model, Figure 4(c). Great care has been taken in order to keep the surface roughness unchanged adding the tape on the external surface.

2.2 *The model of the buttress*

The tests were carried out on a sectional model of the buttress (3/10 geometric scaled, aspect ratio L/B=6) realized in carbon fiber. The model is rigid and it was elastically suspended to realize a one degree of freedom system able to vibrate orthogonally to the incoming mean wind direction (cross flow direction), Figure 5. Structural modal damping was kept as low as possible in order to highlight the VIV phenomenon and it was adjustable by adding damping to the model through eddy current dampers or viscous dampers. In this way it was possible to change the Scruton Number and to investigate the oscillation amplitudes as a function of this parameter.

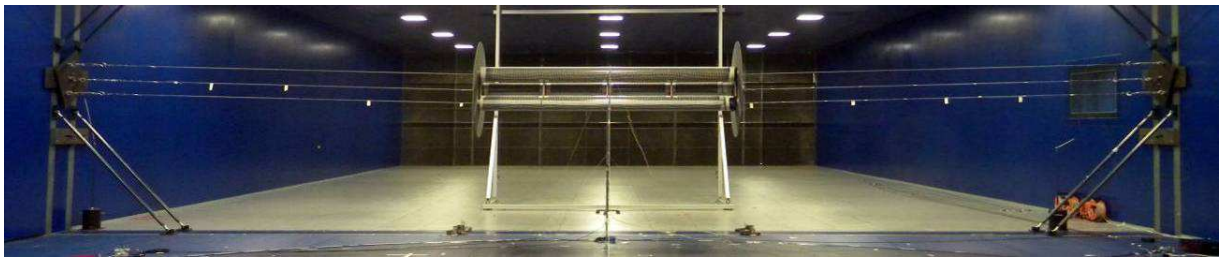


Figure 5. Overall view of the suspended model in the test section for dynamic tests.

Tests were performed at 3 angles of attack α, in according with Figure 6(a) and on different layouts. Porous screens: the gap between the cylinders is closed by a porous screen, Figure 6(b). Solid screens: the gap between the cylinders is completely closed, Figure 6(c). Different model surface finishing were also tested.

3 RESULTS

The analysis has demonstrated that the permeability has a great importance on the aerodynamic behavior of both structures. In the following the main results from the experimental wind tunnel tests are presented.

3.1 *The Spire*

Figure 7 shows the overall wind load at the base of the aeroelastic model of the Spire. The results are expressed in terms of the drag coefficient $C_D(\alpha)$ and $C_L(\alpha)$, Equation (2), where F_D is the drag force and F_L is the lift (side) force function of the exposition angle α, q_H is the mean wind pressure at the base of the Spire and A_{rif} is the reference area. The peak factor method for Gaussian process has been used for the evaluation of the peak values.

$$C_{D,L}(\alpha) = \frac{F_{D,L}(\alpha)}{q_H A_{rif}} \tag{2}$$

The figure shows the along-wind component $C_{D,}$ Figure 7(a) and the cross-wind component C_L, Figure 7(b), of the overall wind load measured at the base of the aeroelastic model of the Spire in the in-service configuration (perforated panels) and making not-porous all the panels (close configuration). Due to the three dimensional external shape of the covering both coefficients manifest a great variability changing the exposition angle α. Considering the drag coefficient C_D, the non-porous configuration shows a moderate increment of the mean value and a higher increment of the peak values. In particular at α=-30deg and α=-60deg the mean value is almost the same, but the peak value is nearly doubled. The effect of the porosity on cross wind coefficient is more relevant. The non-porous Spire does not manifest a modification in mean value, which stays close to zero, on the contrary the peak values show a great increment: the maximum peak occurs about at a=-90 deg, where its value is about ten-times larger than the equivalent from porous panels. The analysis of the wind load coefficients reveals that making non-porous the panels slightly increases the along-wind force on the structures and generates a strong cross-wind dynamic load. The increment of the cross wind dynamic is strictly linked to a strong vortex shedding excitation, described in the next paragraph.

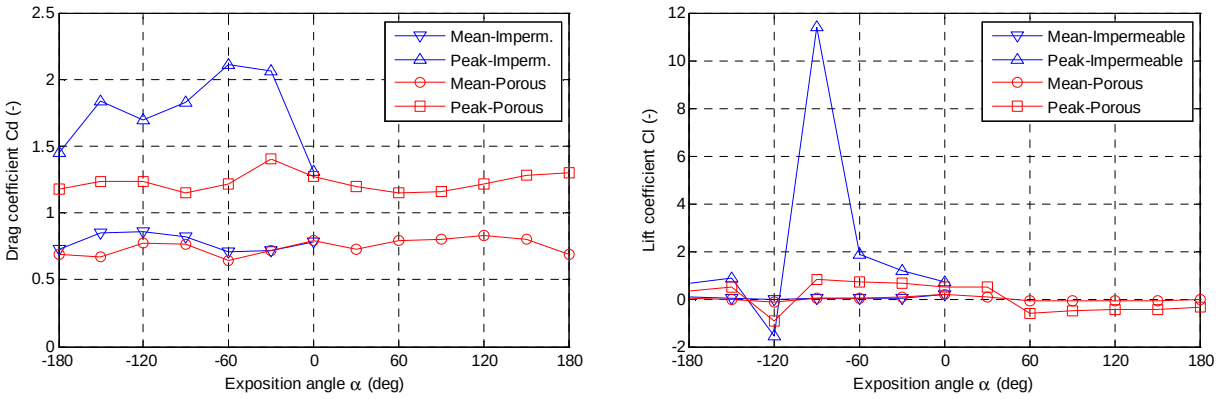

Figure 7. Overall wind load at the base of the Spire, smooth flow. Comparison between porous and non-porous panels. (a) Drag coefficient, C_D. (b) Lift coefficient, C_L (Note the difference in the y-axis scale).

The vortex shedding investigation has been performed analyzing the cross-wind velocities downwind the Spire measured by the four cobra probes. In the discussion of the results the cross-wind velocity v_i refers the probe at height h_i placed downwind a section of the Spire characterized by a diameter D_i. Figure 8 shows the spectra of the cross-wind velocities *vi* in the wake of the Spire the porous panels. The test speed was selected in order to generate from the section *D*2 a vortex shedding resonant with the first vibration mode of the structure (*f*1=5.09Hz). The peak at the frequency *f*1 in the spectra of the component *v*2, Figure 8(c), confirms this condition.

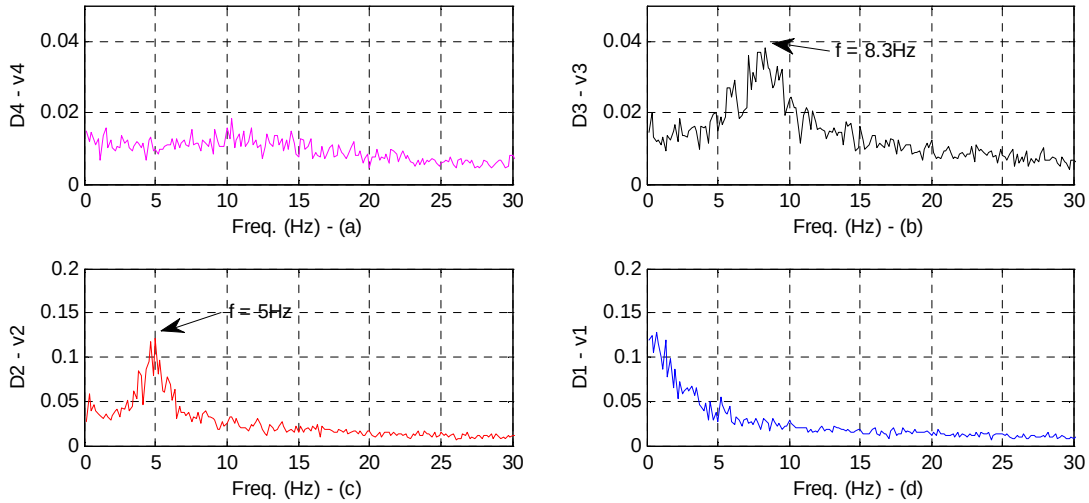

Figure 8. Aeroelastic model with porous panels. U=2.18m/s, SF. Spectra of the cross-wind velocities v_i downwind the Spire (Model scale data).

The section *D*2 has a full length scale of about 20m, a quarter of the total height of the structure, making its length not negligible compared with the respective mean diameter of about 5m. For this reason, even if changing the diameter along the height of the structure is known that mitigates the vortex shedding phenomenon, this section could have an adequate length to introduce enough energy to whole structure and induce vibrations [14,18,19]. The previous assumption, generally valid for non-porous circular surfaces, is disproved in the present case inspecting the spectra of the cross-wind velocities at the other levels. The excitation of the whole structure due to vortex shedding phenomenon is excluded by the following considerations: the spectra of the component *v*3, Figure 8(b), shows a peak at the Strohual frequency of the section *D*3 (*f*=8.3 Hz) and not at the first natural frequency of the model. The peaks in the spectra have a broad bandwidth, indicating a vortex shedding not fully synchronized. Lastly the crosswind displacements time histories calculated from the integration of the accelerometers signals are very low at all the levels considered (the maximum full scale peak to peak displacement is 5mm) and no regular vibrations are visible. On the contrary, the aerodynamic behavior of the Spire completely non-porous is totally different. Figure 9 shows the spectra of the cross-wind velocities *vi* in the wake of the Spire fully non-porous. The test speed was selected in order to have a vortex shedding generated by the section *D*3 resonant with the first vibration mode of the structure (*f*1=4.5Hz). The clear narrow bandwidth peak at the frequency *f*1 in the spectra of the component *v*3, Figure 9(b), confirms this condition. A narrow bandwidth peak at the same frequency is also present in the spectrum of the component *v*4, Figure 9(a), while downwind the sections at the lower levels, *D*1 and *D*2, a peak is also present but it is located at the Strohual frequency of the section and not at the first natural frequency of the model, Figure 9(c-d). This analysis reveal that vortex shedding induced vibration is now present, but due to the very low wind speed the energy introduced is not enough to induce an important vibration of the entire Spire.

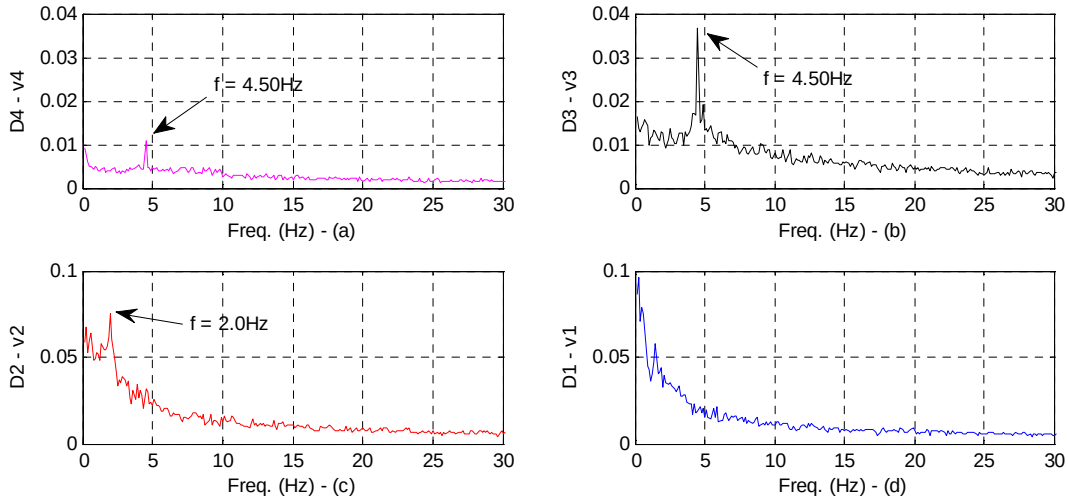

Figure 9. Aeroelastic model with panels fully non-permeable. U=1.28m/s, SF. Spectra of the cross-wind velocities v_i downwind the Spire (Model scale data).

The top-Spire cross-wind time history displacement calculated from the integration of the accelerometers shows an evident constant vibration of the Spire due the vortex shedding excitation. The vibration is small, 2mm model equal to 100mm full scale, nevertheless since the low but very frequent wind speed, it could be enough to lead to fatigue damages to the structure.

The absence of a vortex induced vibration on the permeable structure is given by the porosity: a detailed analysis by means of pressure measurements conducted in [16] has shown that permeability reduces the wind load because the air flows through the holes of the permeable panel, tending to equalize the mean pressure and attenuate the peak across the panel. As a consequence the vortex shedding excitation is strongly reduced.

3.2 *Isozaki tower buttresses*

Vortex induced vibration (VIV) tests were performed on the sectional model of the buttress. Aim of the tests was to compare the aerodynamic behavior of the buttresses using different screens layouts, different porosity in the area permeable to the air and different surface roughness. Aerodynamic stability of the buttress shape has been also investigated by studying the aerodynamic damping trend increasing the mean wind speed. The results are presented in function of the Scruton Number, defined as Eq.(3), where m is the mass per unit length of the body, h_s critical damping ratio, ρ is the air density and B is the overall dimension of the cross section.

$$Sc = \frac{2\pi m h_s}{\rho B^2} \tag{3}$$

The “solid screens” layout (Figure 6(c)) was firstly investigated. This configuration highlighted significant problems related to the fluid-structure interaction. In particular, considering the angle of attack α=-30deg (Figure 6(a)), the model showed significant vortex induced vibrations with also the presence of instability phenomena that led to large uncontrolled flow-induced vibrations unsuitable at low Scruton number (Sc=0.1, Figure 10(a)) and even at high value of Scruton number (u/B=4.5% at Sc=23, where u is the experimental displacement and B the model characteristic dimension, Figure 10(b)). Oscillations were still present even if the Scruton number was increased up to 50.

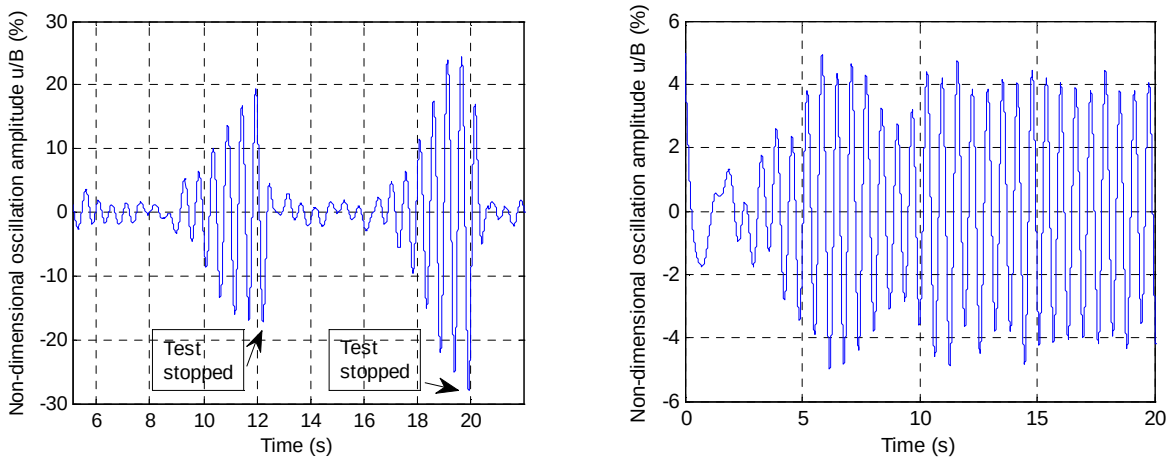

Figure 10. (a) Solid screens layout , α=-30deg, instability and VIV. (a) *Sc*=0.1. (b) *Sc*=25.

The choice was to use porous screens as an alternative configuration to the "solid screens". These screens have round hole perforation (radius 5mm) with triangular pitch of 14mm and porosity β=46%. This layout was stable at the angles of attack α=0deg and α=30deg, while vortex induced vibrations were still present at α=-30deg. Figure 11(b) shows the non-dimensional oscillation amplitude *u/B* (%) function of the Scruton Number *Sc:* it is possible to see that increasing the structural damping to provide a Scruton number higher than 12 the oscillations stopped. The stability of the structure was checked also changing the surface roughness of the model.

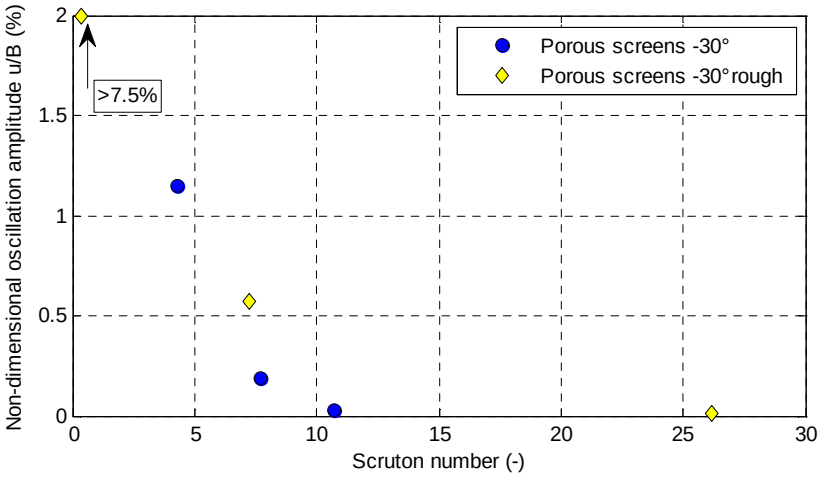

Figure 11. Porous screens layout, α=30deg. VIV in function of Scruton number at the most critical angle of attack.

4 CONCLUSIONS

The analysis has demonstrated that the permeability has a great importance on the aerodynamic behavior of the structures considered in the present work. Tests showed that the porosity of the external surface gives advance on both the mean load reduction as well vortex shedding attenuation. This is due to the passage of the flow through the panels which modifies locally the pressure distribution and, as a result, the wind loads and the dynamic response of the whole

structure. The realistic relevance of this analysis is even that the structures, due to their position, can be subjected to atmospheric icing which can make non-porous parts of the external panels.

In particular, the Spire with porous external panels is not affected by vortex shedding induced vibrations. since the energy introduced by the wind is not enough the induce a synchronous vibration of the entire structure. On the contrary the Spire fully non-porous suffers of a strong vortex shedding induced vibration which, due to the presence of four different diameter along the height, occur in a wide range of wind speeds.

The second structure studied were the long buttresses of a tall building. Also in this case the porosity of the screen between the cylinders gave stability to the structure which, if completely closed, suffered of significant vortex induced vibrations with also the presence of instability phenomena.

ABSTRACT: Aerodynamic forces on lattice tower-like structures have been measured in wind tunnel. The parameters of the incoming flow have been modified with use of sets of elements forming boundary layer. Three types of shafts have been used in measurements. Aerodynamic forces have been measured and aerodynamic coefficients have been calculated as functions of wind attack angle. The measurements have been made for bare structures, and for structures with cover modeling icing. The influence of wind structure on the functions of aerodynamic coefficients has been analyzed.

KEYWORDS: lattice towers, wind action, aerodynamic coefficients, icing, wind tunnel, boundary layer.

1 INTRODUCTION

Wind action on lattice structures is well understood and described in standards [1], [2], [3], [4]. The problem has been often analyzed numerically [5] or by experiments in wind tunnels [6]. However, in this paper wind inflow structure influence on wind action on vertical lattice structures like towers or shafts of guyed masts has been analyzed.

The results obtained with tests carried out in boundary layer wind tunnel have been presented here. The experiment contains measurements of aerodynamic forces performed with use of five component aerodynamic balance. Different cases of flow structure and various angles of wind attack have been used in the research. Such parameters as vertical mean wind speed profile, turbulence intensity profile and wind PSD functions have been used to characterize various flows.

The paper presents result of wind tunnel measurements for three lattice towers. Wind action analysis has been made with respect to the following parameters: 1. shaft cross-section (square or triangular), 2. members cross-sections (legs and bracing of square or circular cross-sections). Tests have been made for bare structures and with respect to icing on structures. Additional measurements of wind fields behind each model have been made, as well.

2 RESEARCH DESCRIPTION

The experiments have been carried out in the boundary layer wind tunnel in Wind Engineering Laboratory in Cracow, Poland. The geometry and the dimensions of the wind tunnel have been shown in Figure 1.

The modeling of the boundary layer in the wind tunnel is realized with use of nets, spires, barriers of various heights, and mechanically adjustable blocks. Forty five combinations of these elements have been analyzed. The elements forming boundary layer have been presented in Table 1 and in Figure 2. One of the boundary layer settings has been shown in Figure 2. The more detailed description of the research on wind structure in the wind tunnel of Cracow University of Technology is presented in [7].

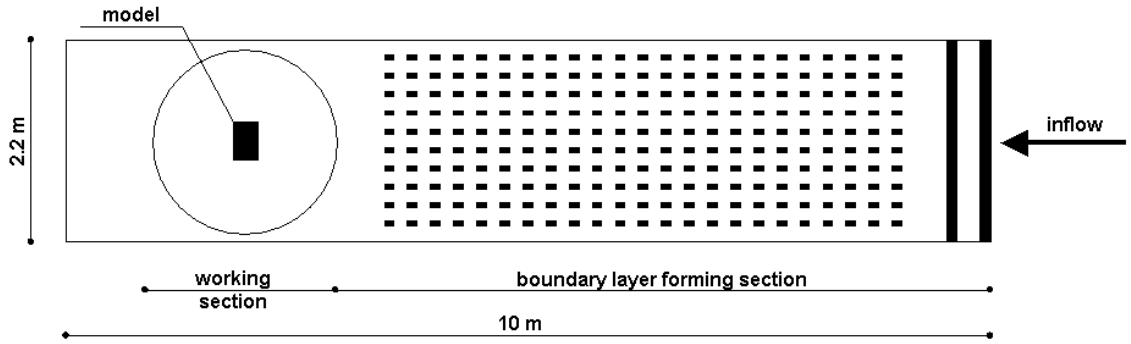

Figure 1. Working section of the wind tunnel with model.

Table 1. Elements forming boundary layer

Element types		Height	
Spires	80 cm	100 cm	120 cm
Spatial Flat	iv8 it8	iv10 it10	iv12 it12
Barriers	20 cm	30 cm	40 cm
Zigzag Even	bz2 br2	bz3 br3	bz4 br4
Blocks	0 cm kl0	10 cm kl10	20 cm kl20

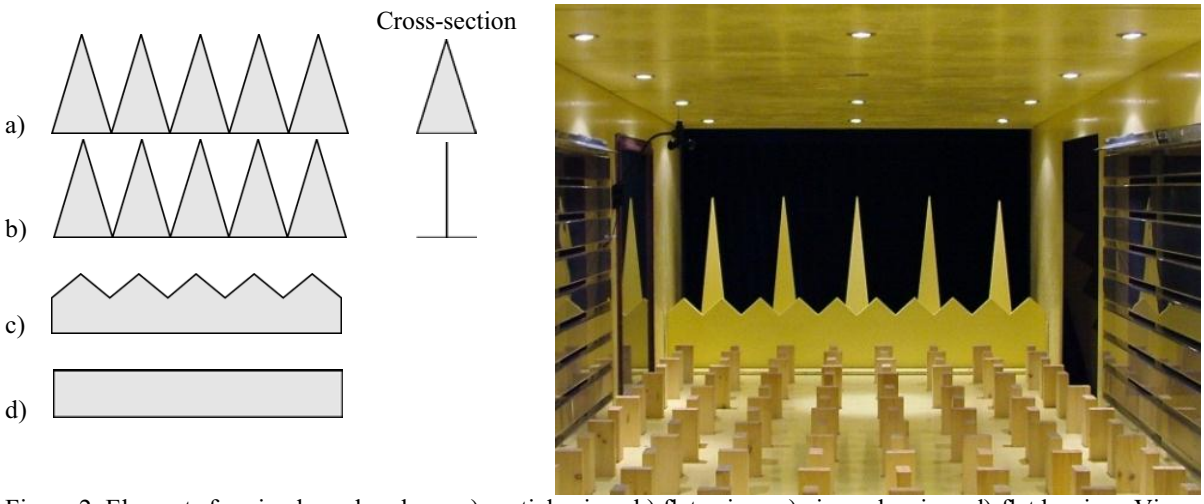

Figure 2. Elements forming boundary layer a) spatial spires, b) flat spires, c) zigzag barriers, d) flat barriers. View of the set of the elements in the wind tunnel.

Measurements have been made with use of six sets of elements forming boundary layer. These sets had been selected out of 45 tested settings giving various types of modeled terrain roughness. The selection has been made to obtain most differing parameters of the wind structures. The following parameters had been taken into account: vertical mean wind profile, turbulence intensity profile and wind frequency spectrum. Vertical mean wind profiles in the wind tunnel have been approximated with the following power-law formula [6]:

$$u(z) = k \cdot z^{\alpha} \quad \text{for} \quad z > z_{\min} \tag{1}$$

where k and α are the values obtained with least square method, z is the height above wind tunnel floor measured in cm. The wind profile coefficients have been reduced to make the wind

speed at the height of 70 cm equal in each wind speed profile. The wind speed obtained with the formula (1) is expressed in m/s. The calculated values of wind speed profile parameters have been presented in Table 2.

Table 2. Parameters for selected vertical mean wind profiles.

Profile	Symbol	k	α	z_{min}
1	bz2kl0	4.26	0.20	1.70
2	iv10bz4okl0	2.52	0.32	0.55
3	it10bz3kl0	2.99	0.28	0.85
4	iv10bz2okl10	1.63	0.42	0.25
5	it10bz3kl20	1.05	0.52	0.10
6	iv10bz4okl20	0.93	0.55	0.07

Vertical profiles of turbulence intensity and functions of wind spectrum have been approximated similarly. Graphs of vertical profiles of mean wind speed and turbulence intensity for six analyzed cases are presented in Figure 3.

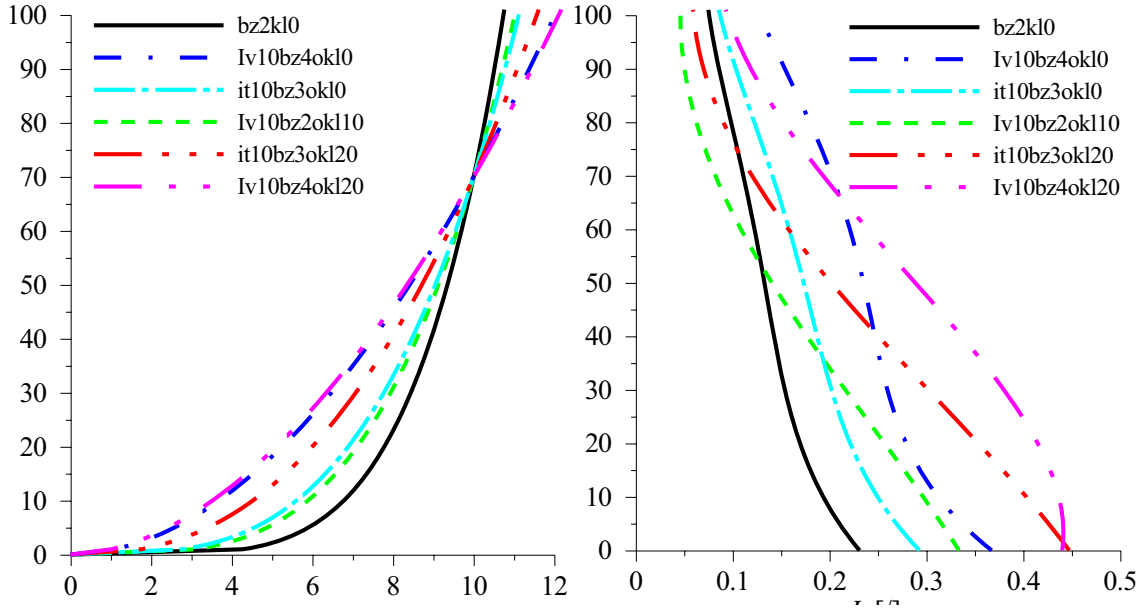

Figure 3. Vertical profiles of mean wind speed (left) and turbulence intensity (right).

Three lattice tower-like models of 1 m height and 10 cm shaft cross-section side dimensions with square or triangular shaft cross-sections, rectangular or circular cross-section members have been used. The models have been placed vertically on rotating table in the working section of the wind tunnel. The dimensions and characteristics of three models are collected in Table 3. The views of the models are presented in Figure 4.

Table 3. Parameters obtained for selected vertical mean wind profiles.

Model	Shaft shape	Member	Member cross-section	Material
m_kw_10x10_kw	Square 10 cm×10 cm×100 cm	Legs Bracing	Square 10 ×10 mm Square 5 ×5 mm	Aluminum Brass
m_kw_10x10_cicr	Square 10 cm×10 cm×100 cm	Legs Bracing	Circular 10 mm Circular 5 mm	Aluminum Aluminum
m_tr_10x10_circ	Triangular 10 cm×10 cm×100 cm	Legs Bracing	Circular 10 mm Circular 5 mm	Aluminum Brass

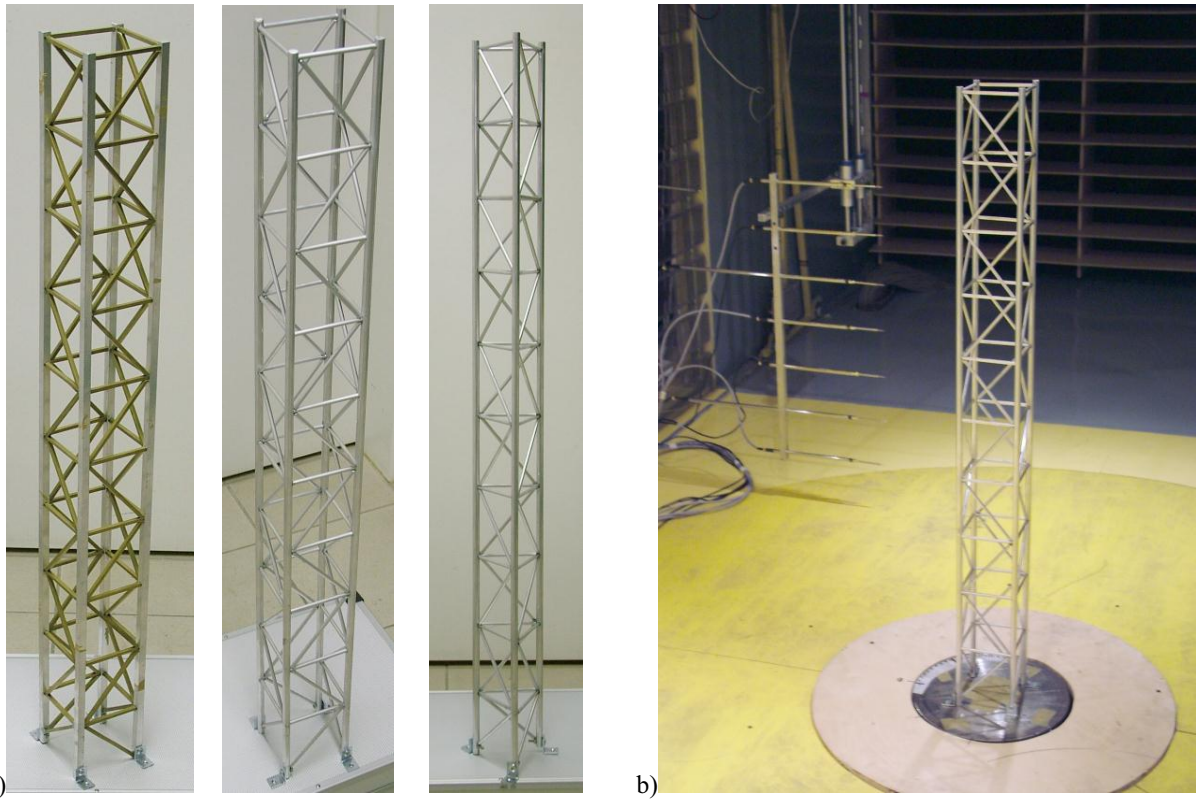

Figure 4. a) Lattice towers models, b) wind tunnel set-up with X hot-wire anemometers.

Each of the models has been used for further analysis of wind action on the iced structures. Icing has been modeled with use of the gypsum cover formed on structures. The gypsum layer modeling icing has been obtained with sinking models repeatedly in the liquid gypsum plaster. Then the models have been hanged in horizontal position to form asymmetric coating. Additional layers of the icing model have been made with pouring the liquid gypsum plaster on the lattice models. The process of ice cover modeling has been shown in Figure 5.

Figure 5. Forming of ice cover model.

One of the models and the model with the cover modeling icing set in the wind tunnel has been shown in Figure 6.

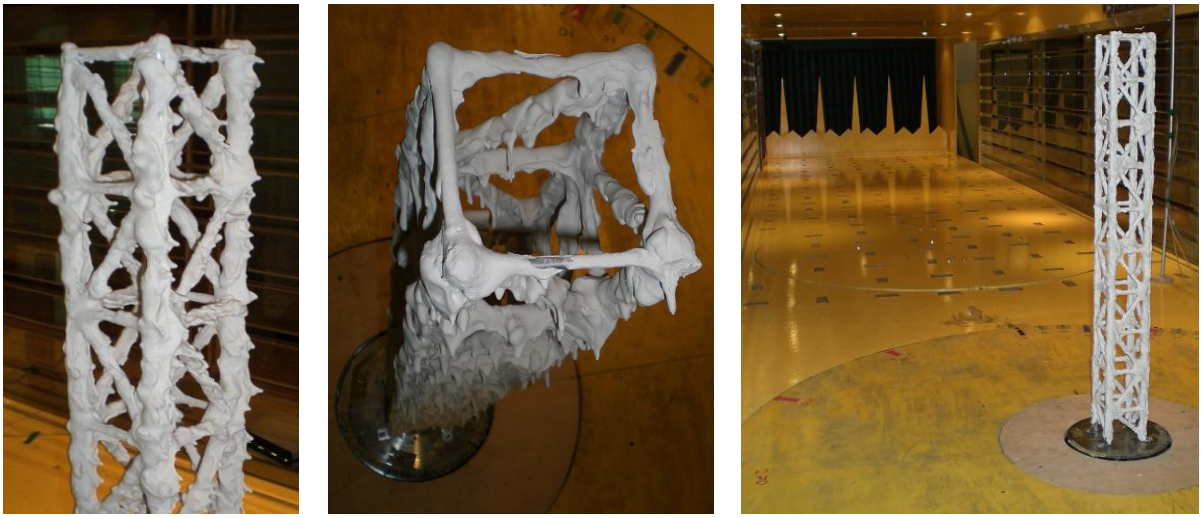

Figure 6. Lattice tower models with the cover modeling icing.

The angle of wind attack in the analysis has been changing from 0˚ to 90˚ for rectangular towers and from 0˚ to 120˚ for triangular ones (with the step of 5˚). The measurements for the iced models have been performed at angles from 0˚ to 180˚ due to non-symmetric ice cover.

The wind attack angle 0˚ refers to the mean wind speed direction perpendicular to one side of the lattice shaft (Fig. 7).

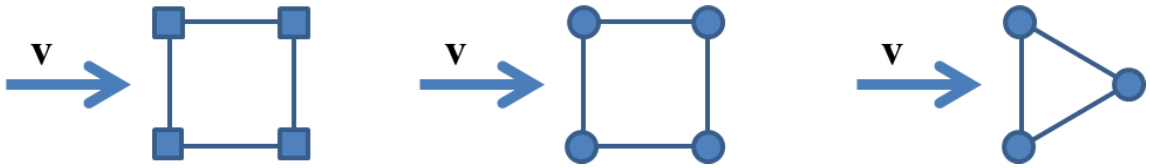

Figure 7. Models setting at wind attack angle 0˚.

3 RESULTS

The measurements have been made with use of five component aerodynamic balance. The following aerodynamic forces have been measured: drag ($\mathbf{P_x}$ – along mean wind speed) and lift ($\mathbf{P_y}$ – horizontal, perpendicular to drag force) and three components of aerodynamic moment. The setting of aerodynamic forces in respect to mean wind speed has been presented in Figure 8.

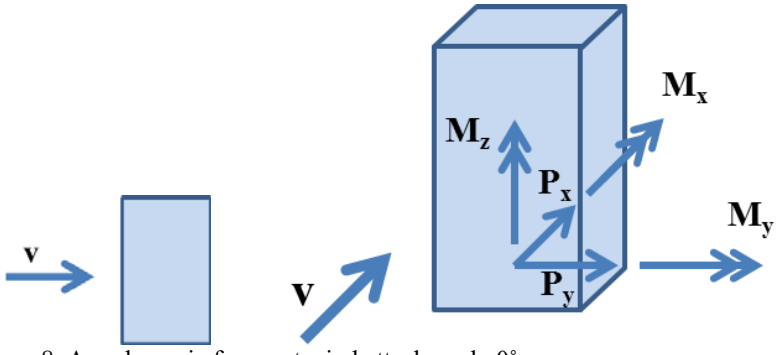

Figure 8. Aerodynamic forces at wind attack angle 0˚.

Functions of aerodynamic forces in reference to wind attack angle have been obtained for each model. Exemplary functions of aerodynamic forces are shown in Figure 9.

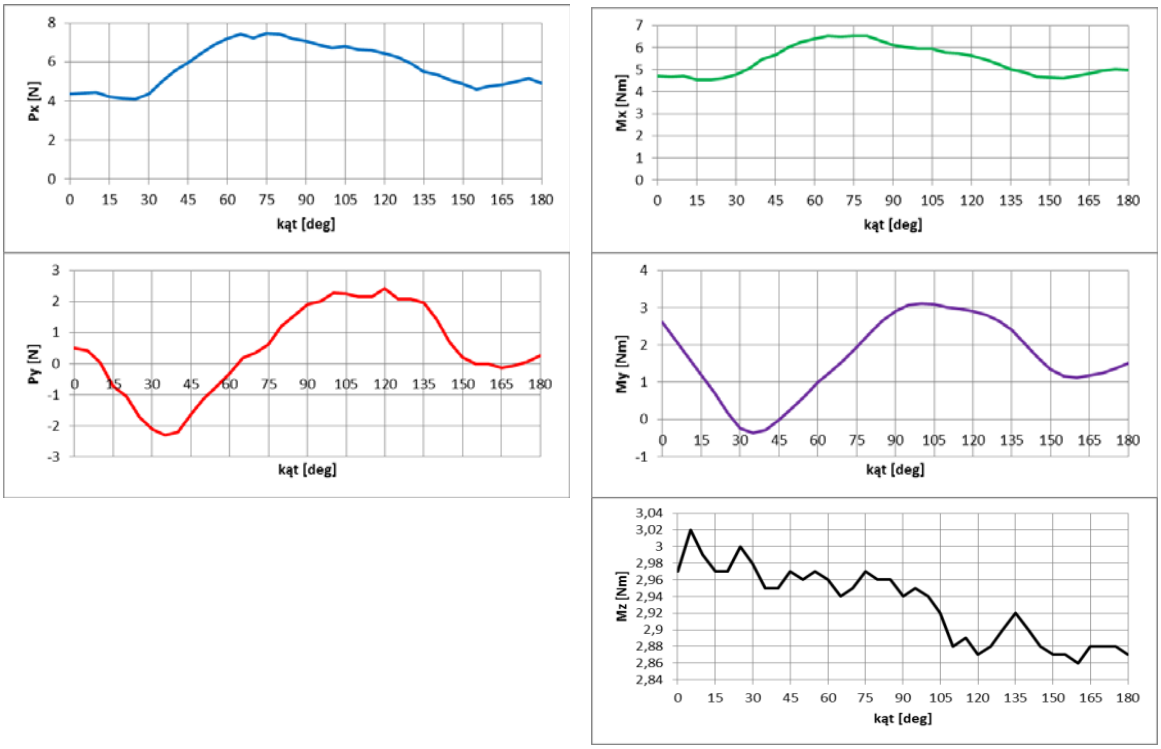

Figure 9. Exemplary functions of aerodynamic forces (*l1_tr_10x10_cir_bz2okl0*) – triangular shaft with ice cover, wind profile *bz2okl0*.

On the basis of measured aerodynamic forces in reference to wind attack angle, the aerodynamic coefficients have been calculated, for both types of structures: bare and with cover modeling icing. The values of aerodynamic coefficients have been obtained by dividing respective aerodynamic force by the value of the reference pressure measured at the height of 71 cm in the working section of the wind tunnel in undisturbed flow in front of models. Such reduction of aerodynamic coefficients allows estimation of wind structure influence on the results. The following formula has been used [6],[8]:

$$C = F \Big/ \left(\frac{1}{2} \rho v^2 \right) \tag{2}$$

where: C is aerodynamic coefficient (C_x, C_y, C_{Mx}, C_{My} or C_{Mz}), F is the value of the respective aerodynamic force at the given wind attack angle (P_x, P_y, M_x, M_y or M_z), ρ – air density, v – reference wind speed.

There have been aerodynamic coefficients presented in the next figures. The graphs are shown for each structure model, bare and iced, for all of the selected cases of sets of elements forming boundary layer with respective wind structures. Aerodynamic coefficients for bare structures have been shown in Figures 10-12. The graphs of aerodynamic coefficients for models with ice cover have been shown in Figures 13-15.

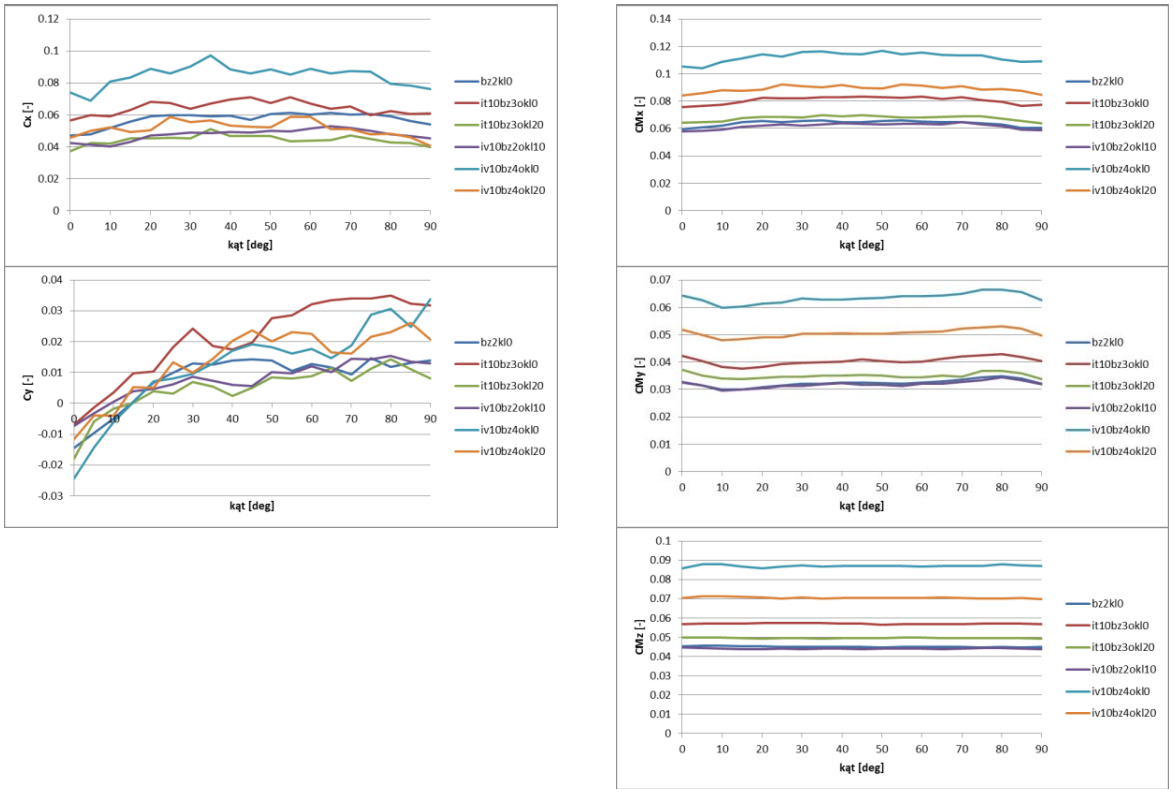

Figure 10. Aerodynamic coefficients – model *m_kw_10x10_cir*.

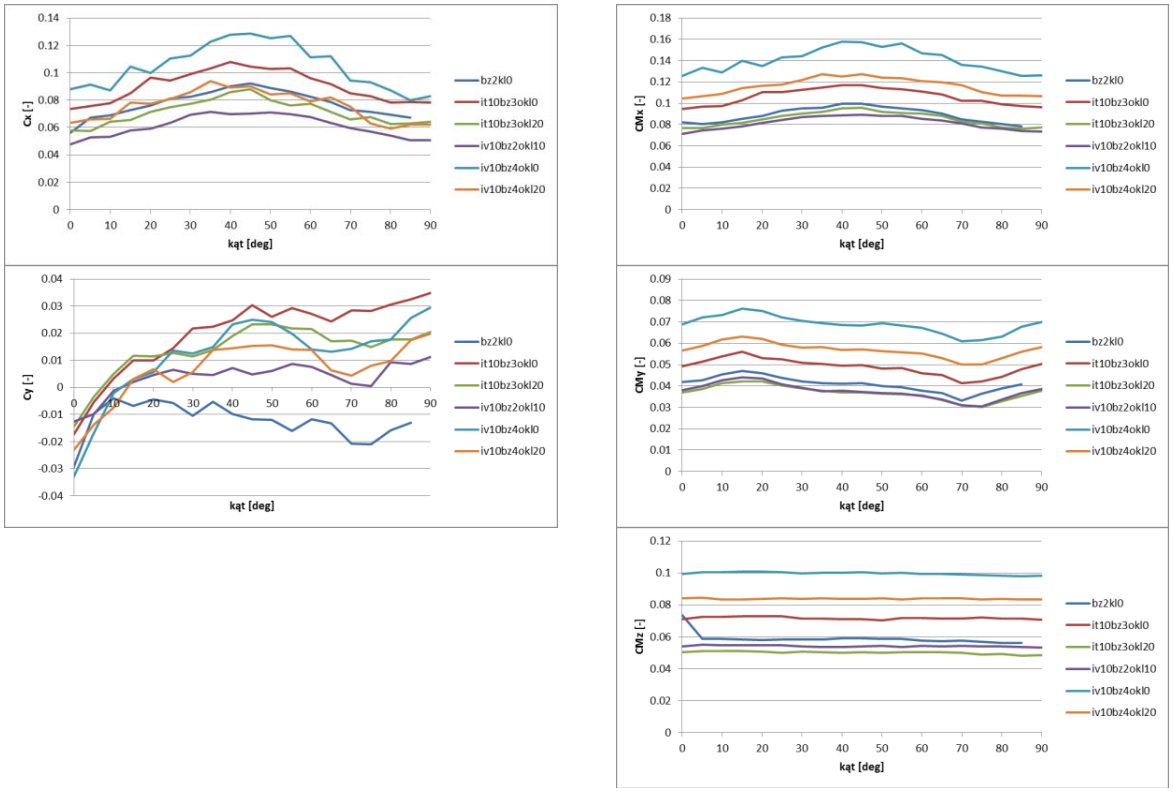

Figure 11. Aerodynamic coefficients – model *m_kw_10x10_kw*.

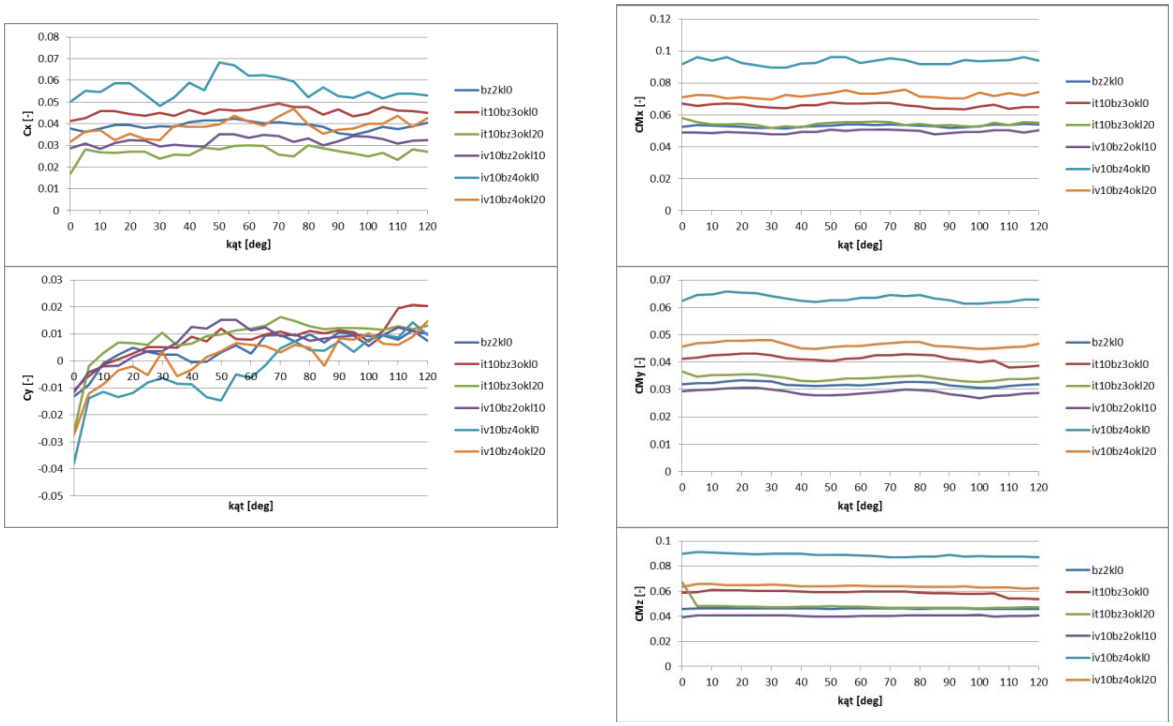

Figure 12. Aerodynamic coefficients – model *m_tr_10x10_cir*.

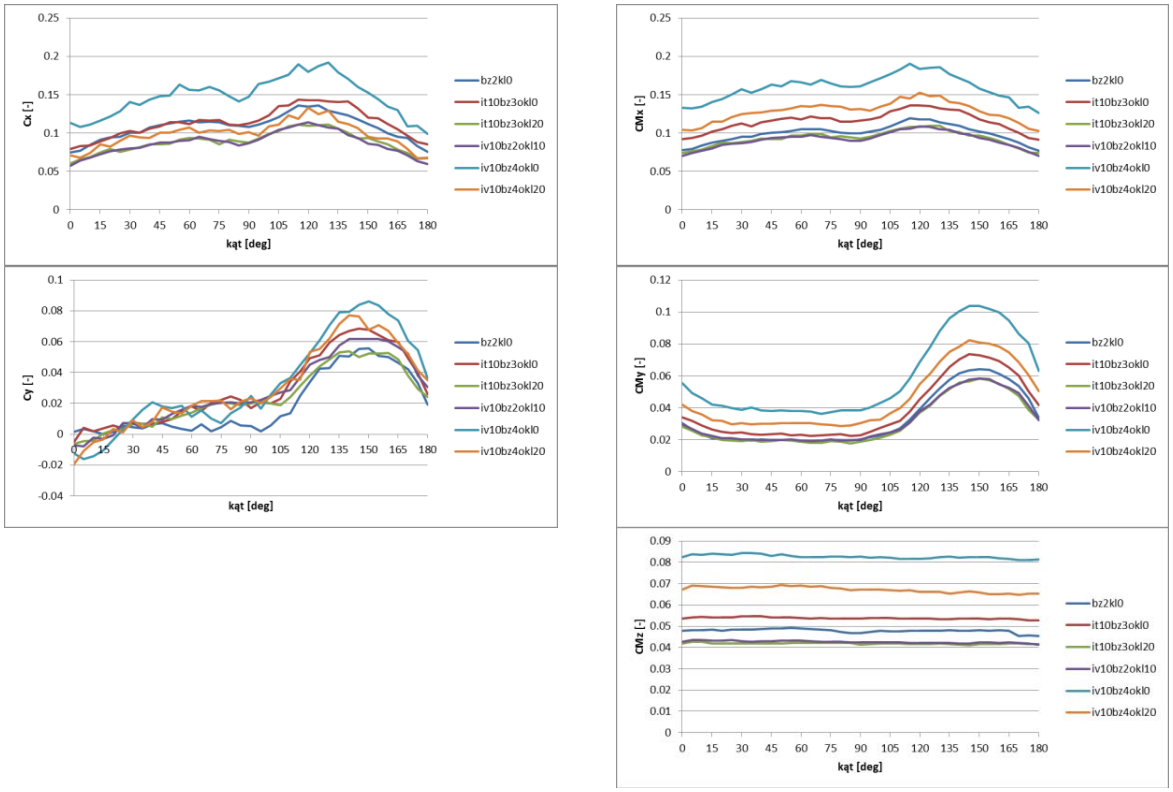

Figure 13. Aerodynamic coefficients – model *m_kw_10x10_cir* with ice cover.

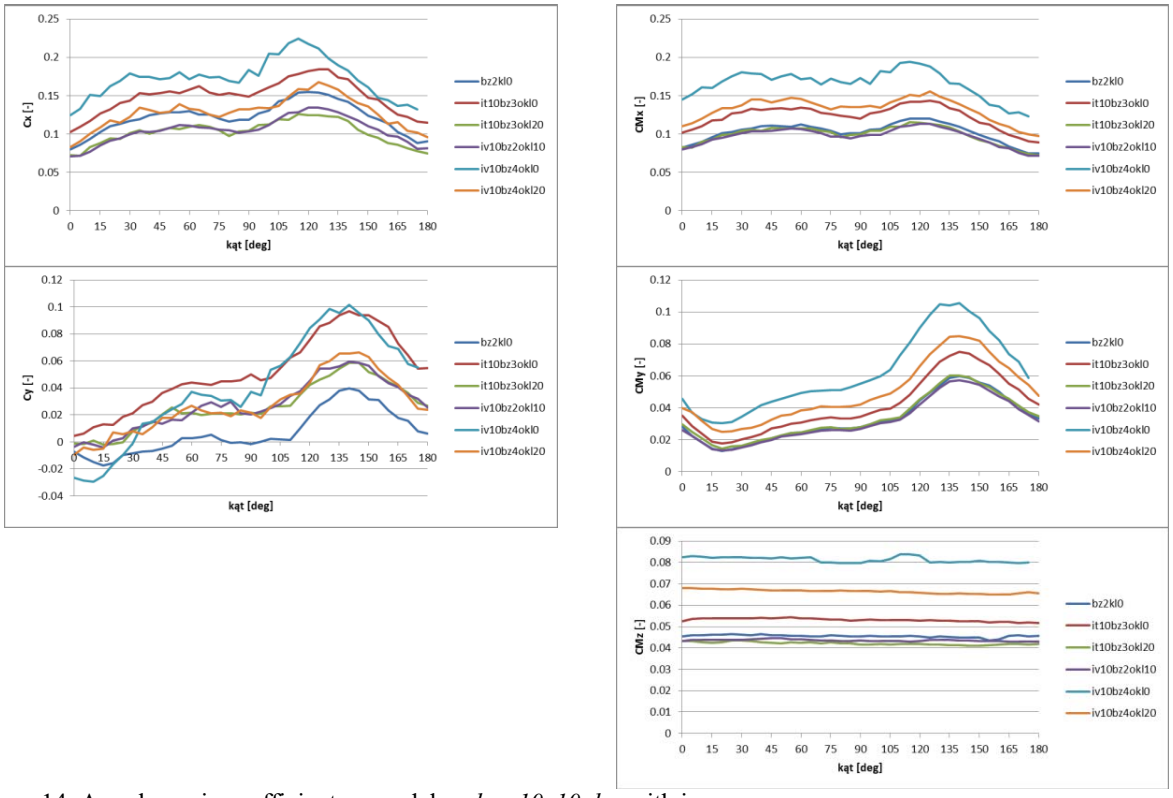

Figure 14. Aerodynamic coefficients – model *m_kw_10x10_kw* with ice cover.

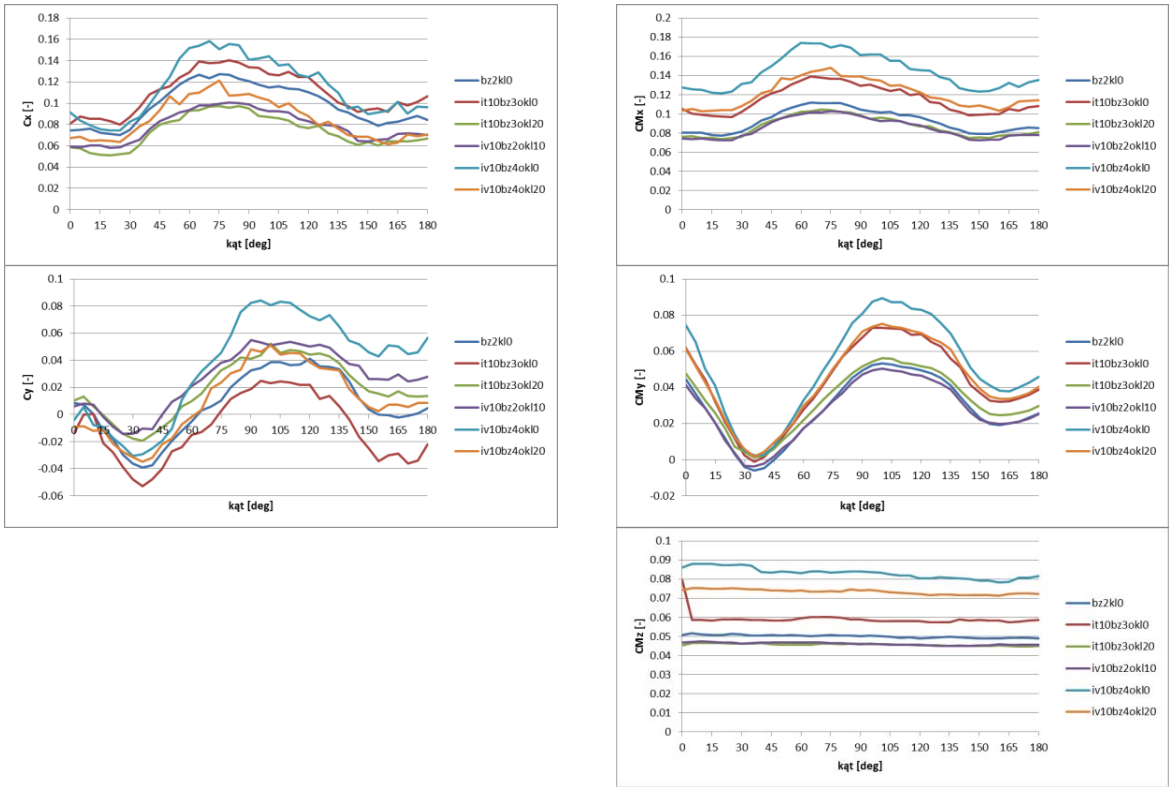

Figure 15. Aerodynamic coefficients – model *m_tr_10x10_cir* with ice cover.

The results show significant influence of wind structure on the wind forces and aerodynamic coefficients for such structures. The icing influence is clearly visible as qualitative and quantitative change in obtained functions. The shape of graph for iced structures is changed as the result of asymmetric ice cover.

4 CONCLUSIONS

The following conclusions can be drawn out:
- Wind load depends on the wind inflow structure.
- Wind action on shafts made with rectangular cross-section members is bigger than with cylindrical ones.
- Icing changes the area subjected to wind action, so the wind action is bigger, as well.
- It is impossible distinguish the influence of each of wind structure parameters to the wind action based on wind tunnel tests only. Supplementary numerical simulation can give a solution to the problem.

ABSTRACT: Dynamic response of guyed masts models to the wind action in the wind tunnel has been analyzed in the paper. Accelerations and forces in guys have been measured. Spectra of the response have been calculated. The influence of the wind structure on the response has been analyzed. The results obtained with experiments have been compared with the ones coming from numerical analysis.

KEYWORDS: guyed masts, wind action, wind tunnel, boundary layer, dynamic response.

1 INTRODUCTION

Analysis of the dynamic response of guyed masts has been presented in this paper. The problem can be approached in two ways, experimentally or numerically. The measurements can be made in-situ or on models in wind tunnel. Here in this paper, the results from the wind tunnel measurements of two guyed masts models have been presented. Triangular and rectangular shaft masts have been modeled and measured. The research consists of measurements of time series of accelerations in selected points located on the mast models and measurements of force time series in guys. Three cases of approaching flow structure have been used in experiment. Various wind profiles, turbulence intensity profiles and power spectral density functions have been obtained with sets of elements forming boundary layer. Various angles of wind attack have also been considered. The results obtained with experiments have been compared with the results coming from numerical analysis.

2 RESEARCH DESCRIPTION

The experiments have been carried out in the boundary layer wind tunnel of the Wind Engineering Laboratory in Cracow, Poland. The scheme of the working section of the wind tunnel has been presented in Figure 1.

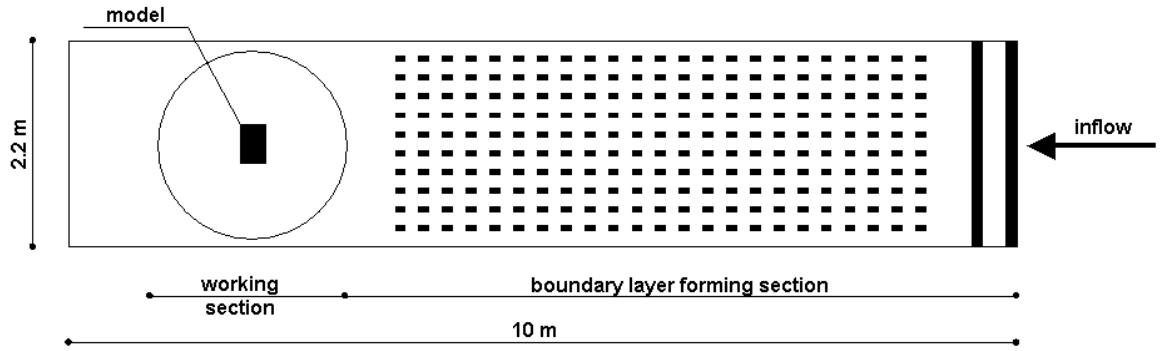

Figure 1. Working section of the wind tunnel with model location.

The influence of wind characteristics such as vertical mean wind speed profiles, turbulence intensity profiles and wind PSD functions on the response of structure models has been examined.

The measurements of masts models have been carried out for three setting of elements forming boundary layer. The settings have been selected with most varying values of obtained wind structure parameters. The following cases, out of 45 all tested ones and 6 previously used in wider analyses, have been selected for this research:

- *bz2kl0* – zigzag barrier of 20 cm height, no blocks (profile nr 1);
- *it10bz3kl0* – T-shape cross-section spires of 100 cm height, 30 cm zigzag barrier, no blocks (profile nr 3);
- *iv10bz4kl20* – triangular cross-section spires of 100 cm height, 40 cm zigzag barrier, blocks set at 20 cm (profile nr 6).

Vertical mean wind profiles measured in the wind tunnel have been approximated with the power-law formula [1]:

$$u(z) = k \cdot z^{\alpha} \quad \text{for} \quad z > z_{\min} \tag{1}$$

where k and α are the values obtained with least square method, z is the height above wind tunnel floor measured in cm. The wind profile coefficients have been reduced to make the wind speed at the height of 70 cm equal in each mean wind speed profile. The wind speed obtained with the formula (1) is expressed in m/s. The calculated values of wind speed profile parameters have been presented in Table 1.

Table 1. Parameters for selected vertical mean wind profiles.

Profile	Symbol	k	α	z_{min}
1	*bz2kl0*	4.26	0.20	1.70
3	*it10bz3kl0*	2.99	0.28	0.85
6	*iv10bz4okl20*	0.93	0.55	0.07

Similar procedure has been used in approximation of other wind structure parameters. The more detailed description of the research on wind structure in the wind tunnel of Cracow University of Technology is presented in [2].

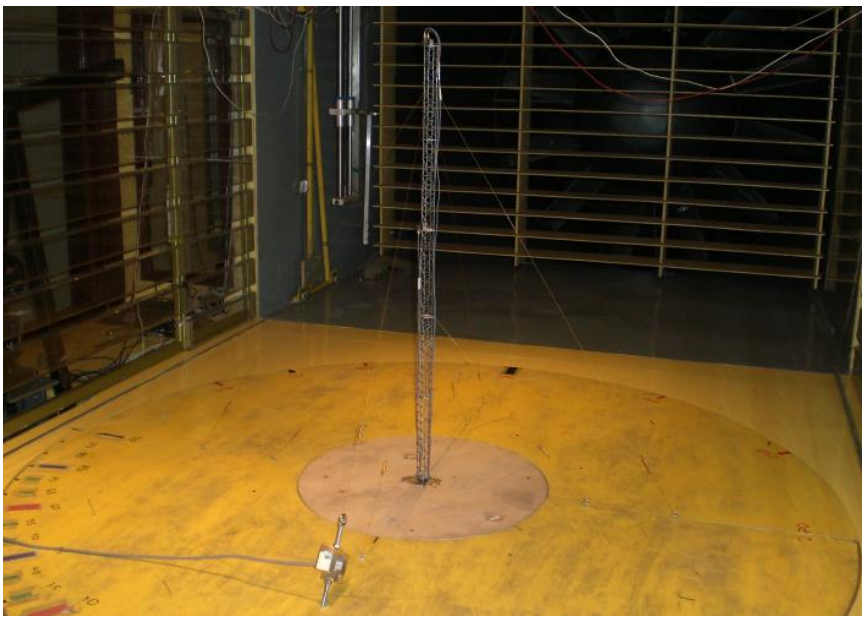

Figure 2. Guyed masts model in the wind tunnel.

Guyed masts have been placed vertically on rotating table in the working section of the wind tunnel. The response of two models have been measured:

- M1 (*m_tr_2x2_circ*) of triangular shaft cross-section (three planes of guys);
- M2 (*m_kw_2x2_circ*) of rectangular shaft cross-section (four planes of guys).

The view of the M1 model in the wind tunnel is presented in Figure 2. Both models are made from steel members of circular cross-section. Shaft legs are made of the 2 mm diameter rods, bracing – of rods of the 1 mm diameter. Each model is supported at the base (free rotations) and with use of two levels of guys made of steel wire of the 0.25 mm diameter. The guys are connected to the shafts at the levels of 40 cm and 90 cm with the guy yaw angles of 45° and 60°, respectively. The side dimension of each shaft cross-section is equal to 2 cm. The overall height of each model is 1 m.

The analysis has been made for various rotations of models with angle of wind attack varying from 0˚ to 180˚ with the step of 45˚ for rectangular mast model and 30˚ in the case of the triangular model. The exemplary shaft rotations with mean wind direction and the directions of measured accelerations have been presented in Figure 3.

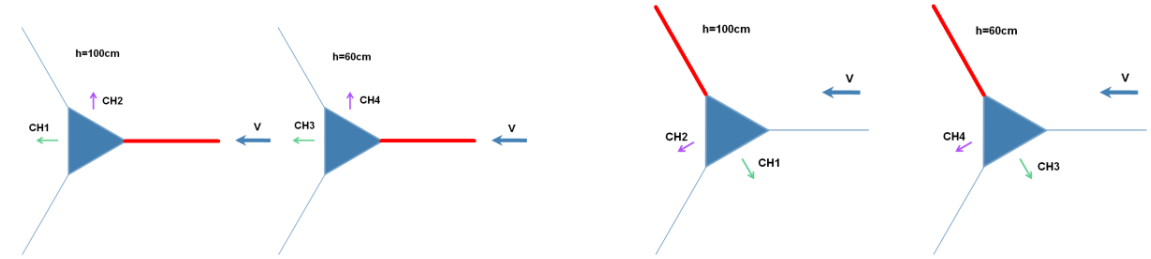

Figure 3. Exemplary rotations of triangular cross-section shaft mast: 0° – left, 120° – right.

The measurements have been made at 16 mean wind speed steps changing from 0 m/s to about 20 m/s.

2.1 Accelerations

The measurements of acceleration have been made in two perpendicular directions (along and across wind tunnel in base position) at two levels of each model: at the top (h=100 cm) and in the middle of upper span (h=60 cm).

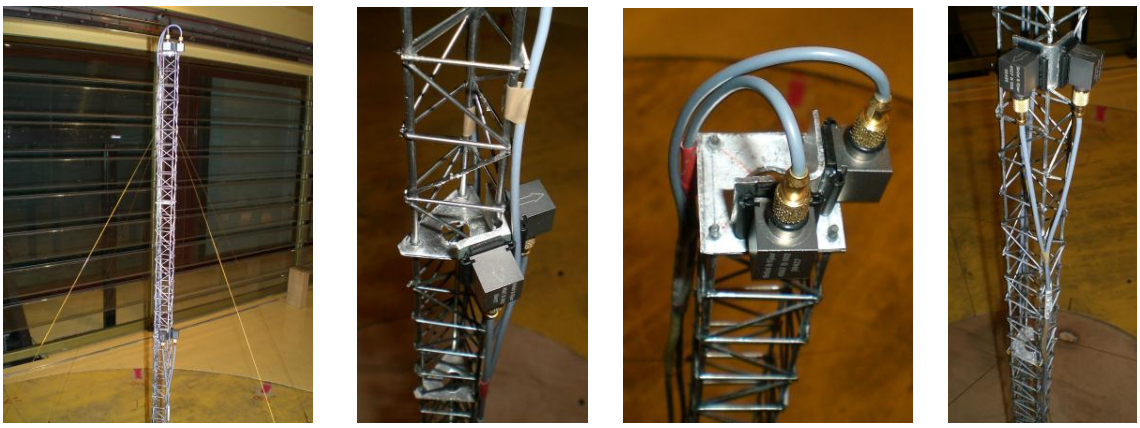

Figure 4. Accelerometers mounted at the mast model structure.

Brüel&Kjær accelerometers 4507B-002 connected to the PULSE measuring system have been used. The instrumentation of the model in wind tunnel is shown in Figure 4.

The measurements have been made with the sampling frequency 8192 Hz. The saved time series lasted for about 20 s for each analyzed case. The accelerations have been measured simultaneously with measuring of forces in guys and mean wind speeds.

2.2 Forces in guys

Hottinger S2/100 force transducer has been used in these measurements. The range of measured forces is -100 ÷ +100 N for this transducer. Time series of forces in guys under wind action have been measured. Forces in both upper (*og*) and lower (*od*) guys have been measured. Various characteristic positions (rotations) of the mast have been considered, allowing analysis of the guys at the windward and leeward sides of the mast. The measurements have been made simultaneously with measurements of accelerations with use of accelerometers, wind speed fields with use of hot wire anemometers and mean wind speeds with use of pressure scanner. Simultaneous recording allows further analysis of correlations of wind speeds in turbulent flows and the effects of its action on guyed masts. The mounted force transducer has been shown in Figure 5.

Figure 5. Force transducer for measuring forces in guys.

3 RESULTS

Time series of the accelerations at selected points of the models have been obtained. Accelerations in two perpendicular directions at the top of the model M1 are presented in Figure 6.

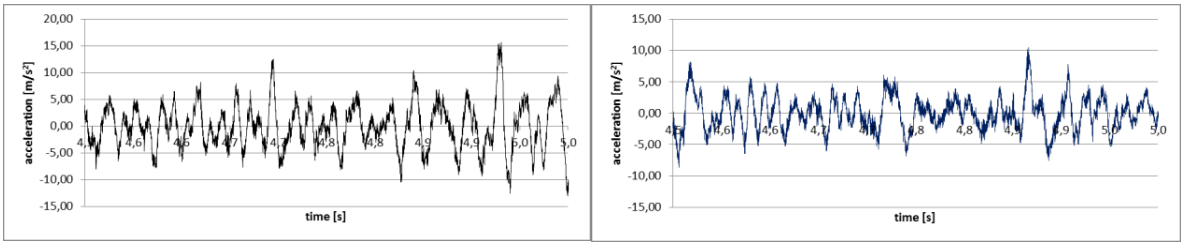

Figure 6. Exemplary time series of accelerations: along mean wind (left) and cross-wind (right) components.

There have been shown exemplary time series of accelerations in Figure 7 for the steps of mean wind speeds selected out of 16 measured ones. There are 6 s views on the left and 0.5 s zooms on the right presented for each time series.

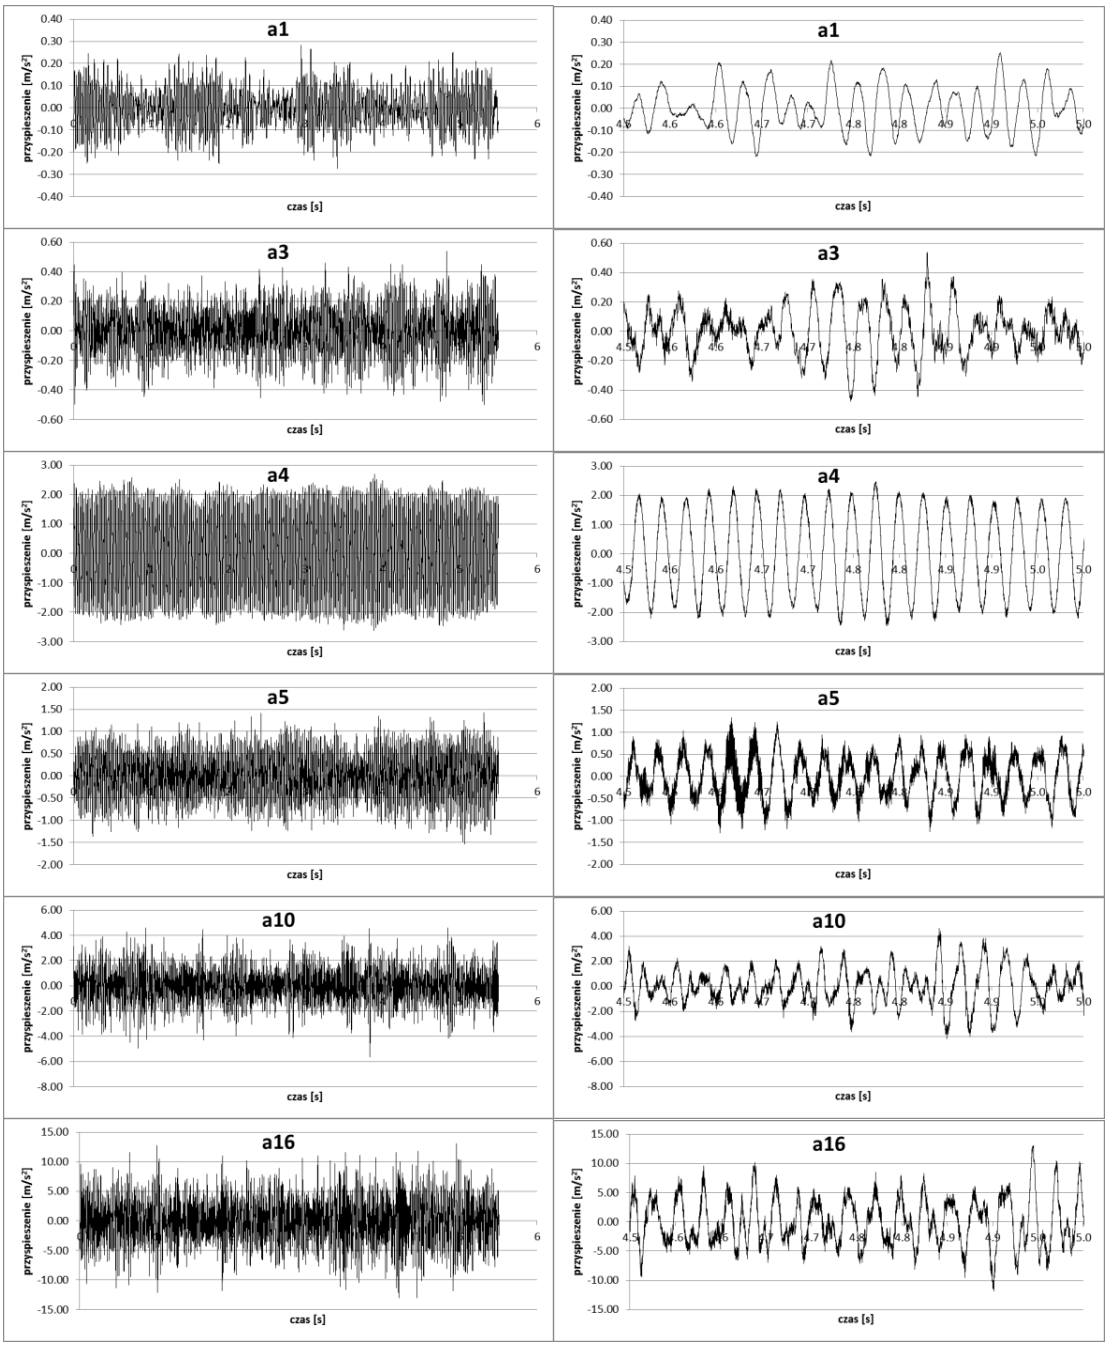

Figure 7. Along wind accelerations for triangular shaft model at the top of the structure (*od_m_tr_2x2_circ-bz2kl0*).

Spectral analysis of the measured variation of acceleration has been made as the next step of the research. Power spectral density functions have been calculated with use of the HBM Catman software. PSD functions have been presented in graphs. Exemplary graphs, respective to the time

series presented previously, have been shown below. Whole calculated spectrum is presented on the left, and 100 Hz zoom is shown on the right in Figure 8.

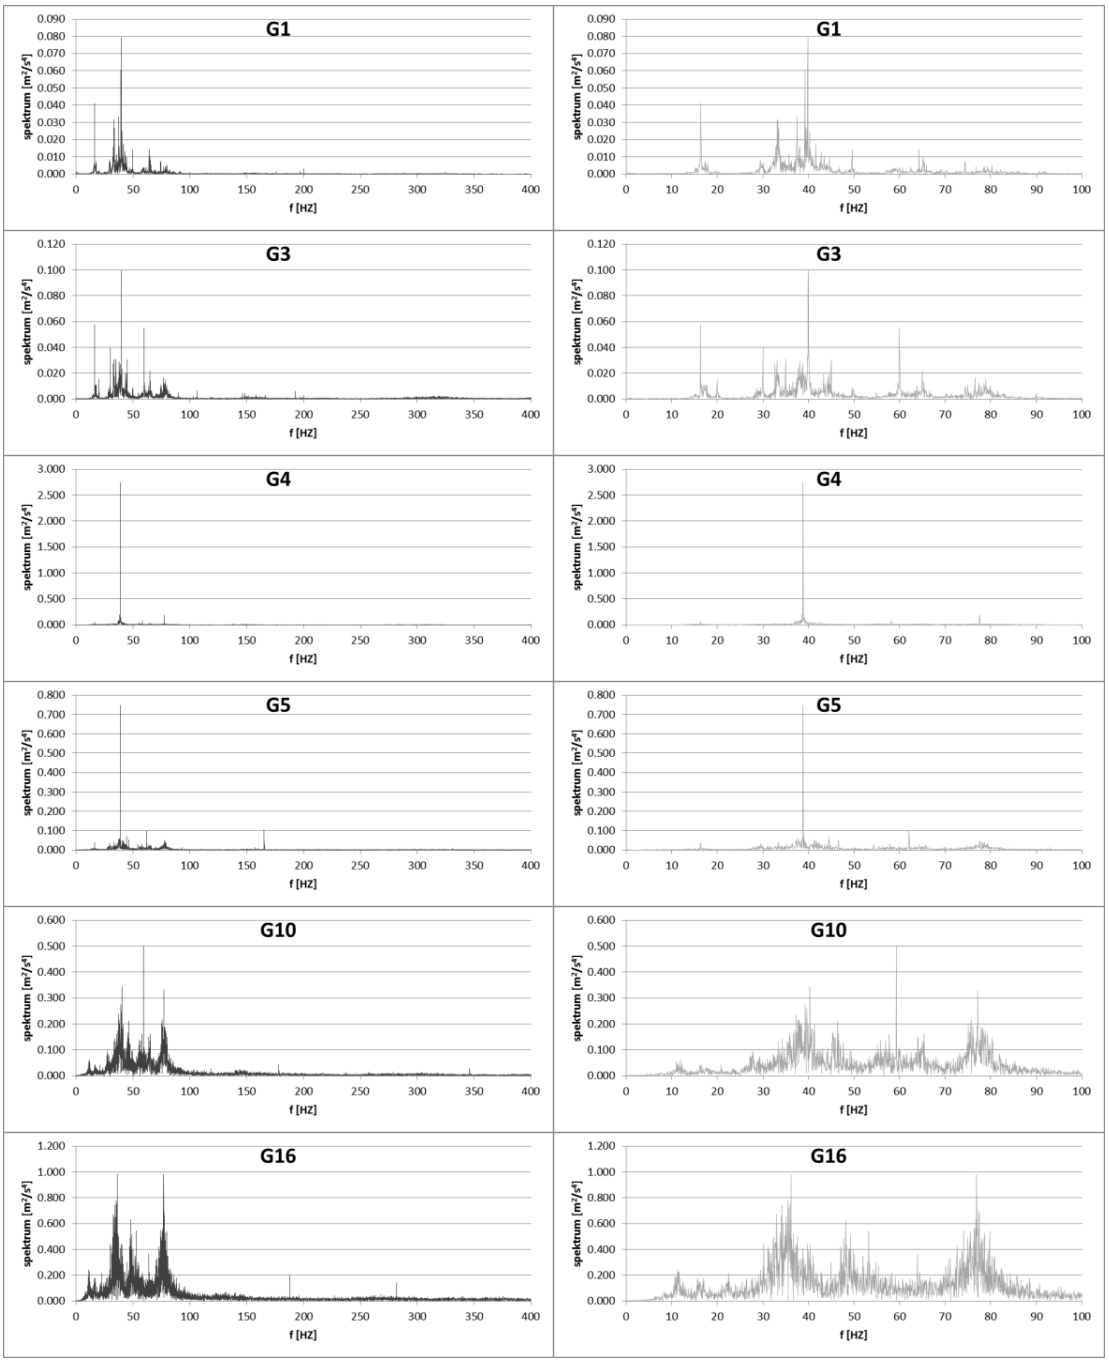

Figure 8. PSD functions for along wind accelerations measured at the top of triangular shaft model (*od_m_tr_2x2_circ-bz2kl0*).

Similar graphs, as for the accelerations, have been made for the forces in guys of the mast models. Exemplary graphs of force time series for the lower guy have been presented in Figure 9. There are 20 s long time series presented on the left, and 1 s zooms shown on the right.

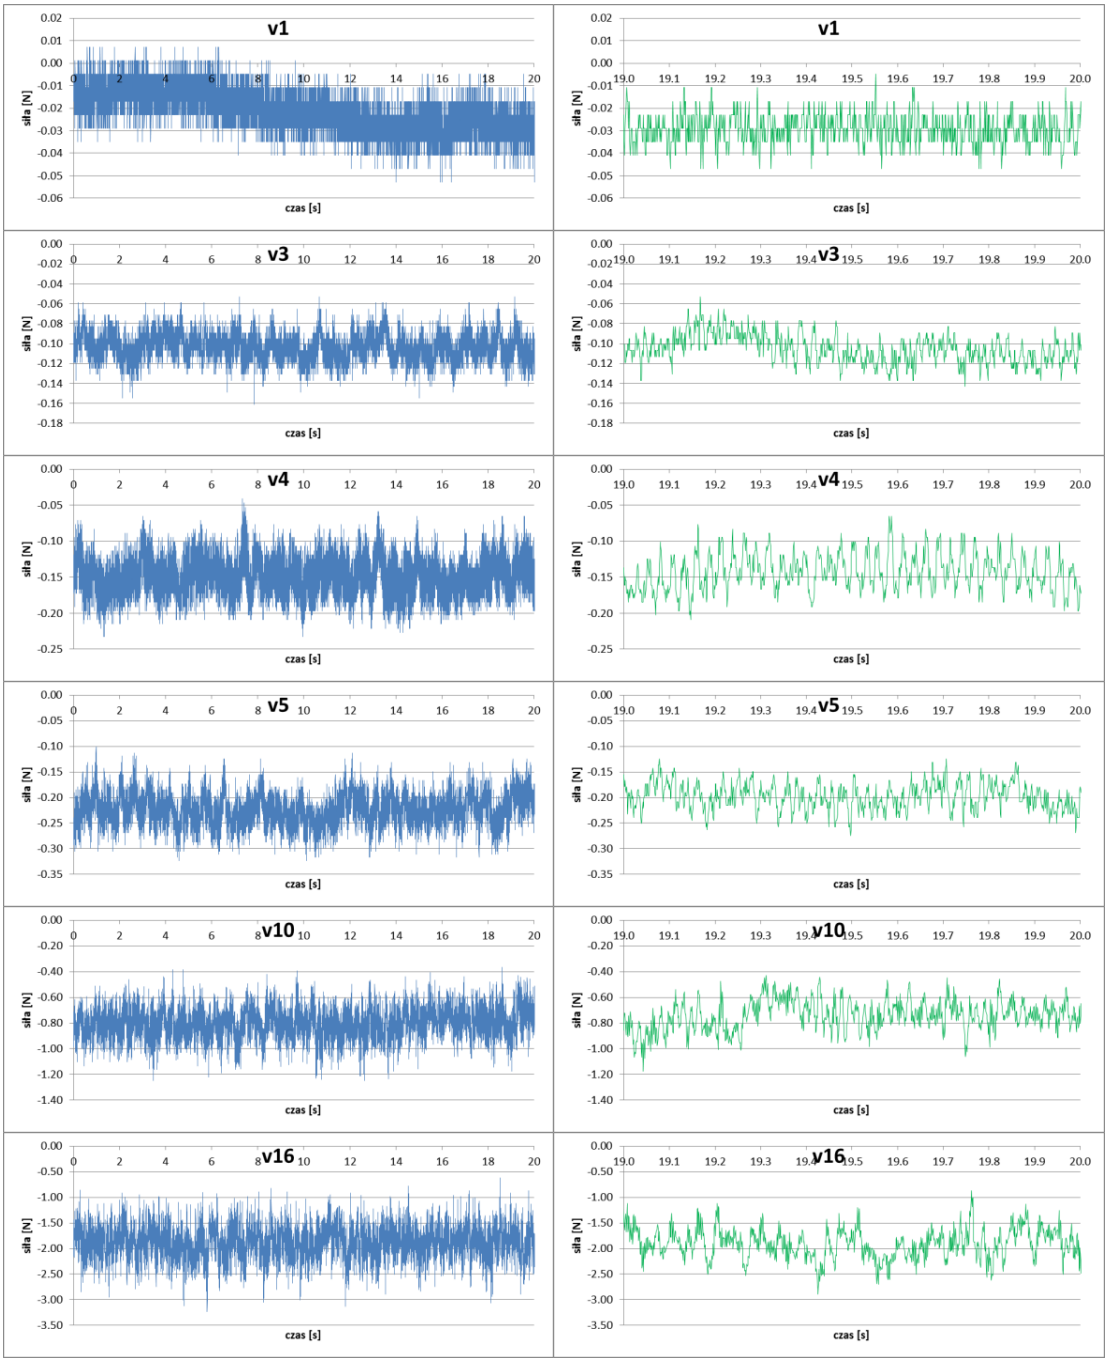

Figure 9. Time series of forces in lower windward guy of triangular shaft model (*od_m_tr_2x2_circ-bz2kl0*).

Spectral analysis of the guy force variations has been made. Exemplary graphs of PSD functions, respective to the time series of force variations in guys, have been presented in Figure 10. The graphs of PSD functions are shown in the same manner as for accelerations.

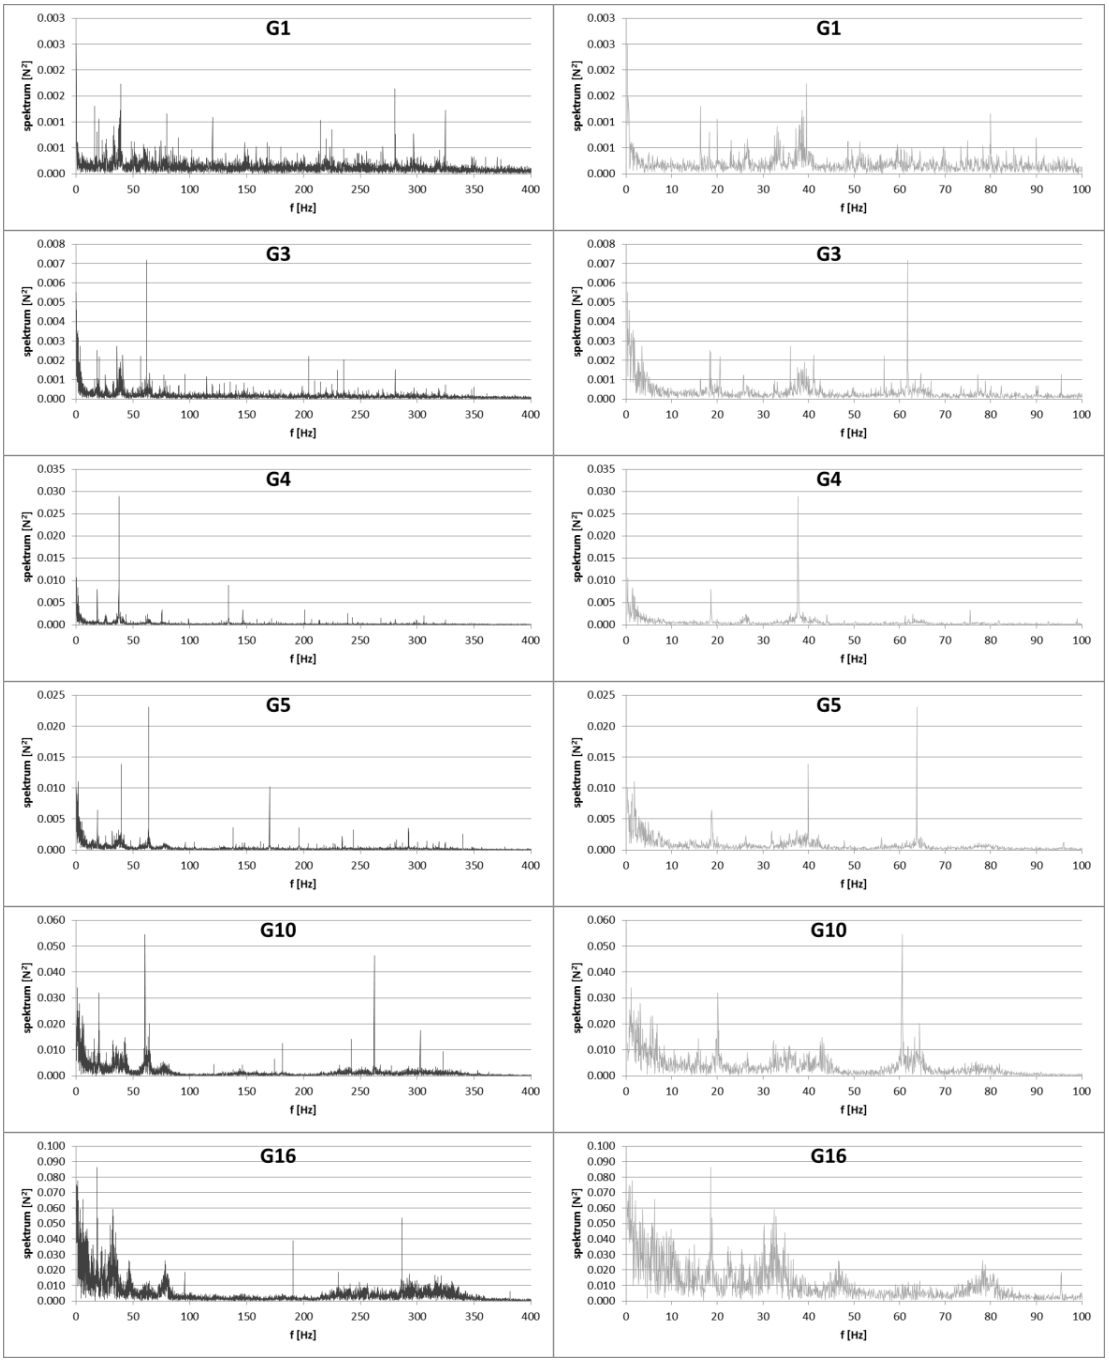

Figure 10. PSD functions for force variations of lower guy in triangular .

The results have been compared with the ones obtained with use of FEM calculations. Own software [3, 4] based on commercial system ALGOR has been used. The wind action has been modeled according to quasi-steady theory [5].

Displacements in selected points of mast structure have been obtained. Exemplary time series of displacements coming from calculations at the top of the mast model have been presented in Figure 11.

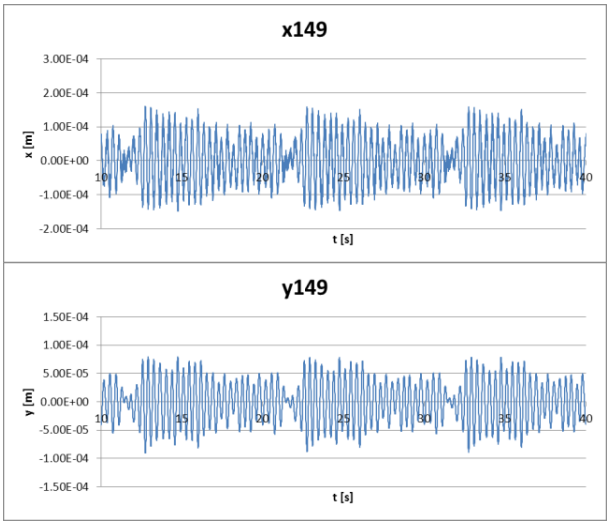

Figure 11. Exemplary time series of displacements of two perpendicular displacements on the top of the mast model.

Double differentiation has led to accelerations. Exemplary time series of along wind accelerations have been presented in Figure 12.

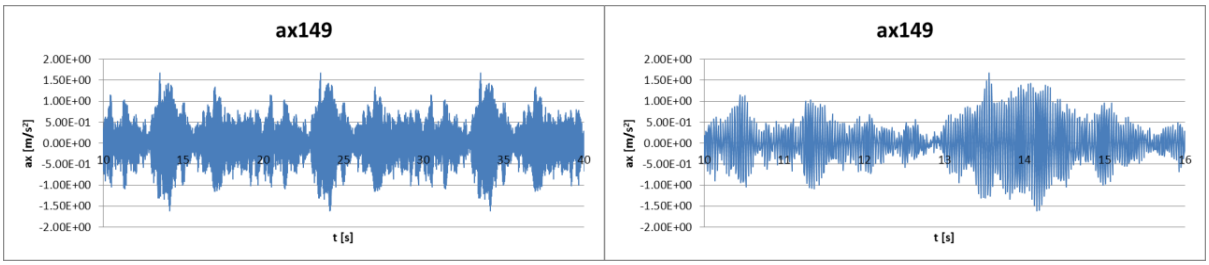

Figure 12. Exemplary time series of along wind accelerations: 30 s long time series (left), 6 s zoom (right).

Amplitudes of accelerations and their standard deviations have been compared with results obtained with measurements at the 8th wind speed level from wind tunnel tests (Fig. 13). The wind speed in numerical analysis has been set approximately equal to the mean wind speed in measurements at this mean wind speed step (v≈10 m/s).

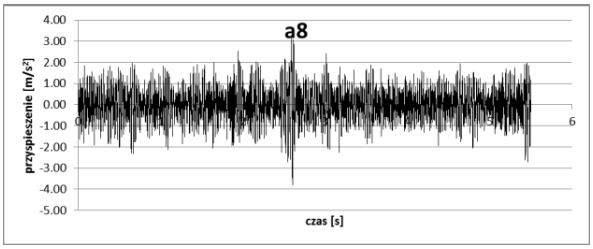

Figure 13. Exemplary time series of along wind accelerations from measurements at 8th mean wind speed step.

The obtained time series of accelerations from numerical analysis are in good accordance with the results from measurements in the wind tunnel. Amplitudes of accelerations in numerical analysis reach about 1.6 m/s^2. Similar values have been noticed in the wind tunnel tests. Amplitudes are usually only slightly higher in measurements than the ones obtained in numerical analy-

sis. There may be values of accelerations exceeding 3 m/s^2 coming from the stronger wind gust observed at short period of time. However, this is not changing the overall picture significantly, and the preliminary verification is proved for measurements versus numerical analysis.

4 CONCLUSIONS

The following conclusions can be drawn out of the presented results:

- Amplitudes of accelerations grow rapidly to about 2 m/s^2 in the case *a4*. Then they are getting smaller to about 1 m/s^2 and in the next steps they constantly grow with the wind speed increase.
- There is one dominating frequency in the case *a4* observed in the graphs of time series of accelerations. This frequency can also be observed in the PSD function graphs.
- The results of measurements allow us to mark the wind speed in this case as the critical one.
- The graphs of guy forces show both frequencies that have been observed in acceleration graphs for shafts and new frequencies that can be distinguished, as the ones referring to guys vibrations only, since they have not been observed before.

Wind parameters have significant influence on guyed masts response. Accelerations measurements allow recognition of mode shapes of vibrations. Different shapes of shaft cross-section of masts only slightly affect the wind field behind models in comparison to the flow without mast models placed in the wind tunnel. High slenderness of the shafts may be responsible for this result.

[a] *Department of Civil, Environmental and Architectural Engineering, University of Genoa, Via Montallegro 1, Genoa, Italy*

ABSTRACT: This paper presents the analytical and experimental studies of aeroelastic behavior of slender structures, particularly of lighting poles and antenna masts with distributed eccentricities. Critical conditions of coupled galloping and of generalized Den Hartog's criterion are derived in closed form. An application of the method on a real structure indicates the significance of the aerodynamic eccentricities, upper vibration modes, and coupling between the translational components of the motion. Additionally, in case of such a structure, it is pointed out that carrying out the classic simplified SDOF (single degree of freedom) stability analysis may lead to considerable errors in the prediction of instability conditions.

KEYWORDS: Aeroelasticity, steady-state theory, galloping, tubular poles, antenna masts, critical velocity, wind-tunnel test

1 INTRODUCTION

Tubular poles may appear as simple structures that can be modeled, very easily, by a cantilever beam with one or more concentrated masses usually at their top; unfortunately, this is often the concept that inspires the usual static engineering calculations. A deeper reflection on this structural type, however, points out totally different characteristics. The structures are built in such a large and growing number to represent a relevant economic problem in spite of a low single cost. They are characterized by an increasing height, lightness, slenderness and complicated shapes that make them extremely sensitive to complex wind-excited and aeroelastic responses and require refined analyses to capture their physical behavior (Fig.1). An impressive number of collapses that increasingly involve these constructions, frequently due to wind-excited fatigue [1], emphasize their susceptibility to wind actions and their potentially dangerous role in the anthropogenic territory.

A dominant property that joins engineering calculations and refined evaluations carried out in the literature on tubular poles is their idealization as polar symmetric structures. This is definitely not correct due to several peculiar features of these structures, such as stairs, cable bundles, or solar panels, usually applied to the shaft, lighting devices, top balcony, antennas and parabolas that are often put eccentrically with respect to the axis of the shaft, and cylinder hulls, which ever more frequently cover the transmission devices, endowed with non circular sections due to construction imperfections. One or the whole of these situations give rise to mass and shape eccentricities, which make these structures complex, both in mechanical and in aerodynamic terms, and sensitive to potential instabilities due to aeroelastic critical phenomena.

Review in literature shows that there are few studies on this issue, both in theoretical and experimental aspects. Solari and Pagnini [2] analyzed the wind-excited response and the galloping of lighting poles and antenna masts with distributed concentrated masses, upper modes and coupling between alongwind and crosswind vibrations, without considering eccentricities. Cara-

coglia and Jones [3] studied the galloping and buffeting responses of poles with a luminaire at the top; the effect of eccentric aerodynamic loads at the level of the luminaire is taken into account, but the main pole is considered as polar symmetric structure.

(a) (b) (c) (d)

Figure 1. Typical lighting poles and antennas masts

To clarify the role and the importance of the above remarks, this paper introduces a theoretical framework to evaluate the aeroelastic performance of slender structures with distributed eccentricities, particularly of lighting poles and antenna masts. A quasi-steady theory is first developed that takes into account the variations of mass, width of cross section, aerodynamic coefficients, eccentricity, and wind velocity along the structure; besides, upper modes of vibration and coupling effects among such modes are considered; aeroelastic instability conditions are determined in the state space. Starting from this formulation, and introducing suitable conditions, analytical solutions for the critical velocity of coupled and uncoupled systems are then derived.

As an example, this formulation is applied to a real telecommunication antenna mast, in which typical distributed eccentricities, such as stairs, cable bundles and masts are considered. This structure reveals the occurrence of unusual aeroelastic instabilities that emphasize the role of the upper modes, of the coupling between crosswind and alongwind vibrations, of the distribution of the eccentricities along the structural height.

2 GENERAL FORMULATIONS

Let us consider a vertical tubular pole idealized as a vertical cantilever beam with longitudinal axis z passing through the stiffness center of the cross section. The structural motion at height z is defined by two horizontal displacements x and y and a torsional rotation θ. The structure has height L, mass per unit length $m(z)$, width of cross section $b(z)$. The wind direction is horizontal and makes an angle α with axis x (Fig.2).

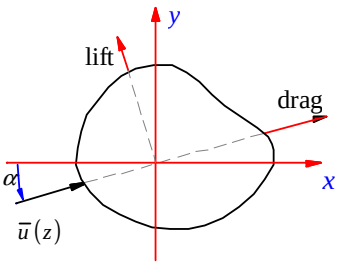

Figure 2. Wind action on a structural body.

To perform the stability analysis, the forces given rise from the mean wind velocity, atmospheric turbulence and vortex shedding are ignored. Then, the equations of motion can be expressed in principal coordinates as follows [4]:

$$\tilde{\mathbf{M}}\ddot{\mathbf{P}}(t)+\tilde{\mathbf{C}}\dot{\mathbf{P}}(t)+\tilde{\mathbf{K}}\mathbf{P}(t)=\tilde{\mathbf{F}}_a(t) \tag{1}$$

where $\mathbf{P}(t)$ is the generalized displacements vector; $\tilde{\mathbf{M}}$=diag($\tilde{m}_i$), $\tilde{\mathbf{C}}$ = diag($2\tilde{m}_i\xi_i\omega_i$), and $\tilde{\mathbf{K}}$=diag($\tilde{m}_i\omega^2{}_i$) are respectively the generalized mass, structural damping, stiffness matrices, in which $\tilde{m}_i$, ξ_i, ω_i are correspondingly the generalized mass, structural damping coefficient, and natural frequency associated with i-th mode (i=1,2…); whereas $\tilde{\mathbf{F}}_a(t)$ is the vector of generalized aeroelastic wind actions:

$$\tilde{\mathbf{F}}_a(t)=\int_0^L \mathbf{\Psi}^T(z)\mathbf{f}_a(z,t)\,dz \tag{2}$$

in which $\mathbf{\Psi}(z)$=[$\boldsymbol{\psi}_1(z)$ $\boldsymbol{\psi}_2(z)$ …] is the modal matrix where $\boldsymbol{\psi}_k(z)$ = [$\psi_{kx}(z)$ $\psi_{ky}(z)$ $\psi_{k\theta}(z)$]^T ; $\mathbf{f}_a(z,t)$=[$f_{ax}(z)$ $f_{ay}(z)$ $f_{a\theta}(z)$]^T is the vector of aeroelastic wind actions. By adopting the quasi-steady theory, it follows that:

$$\mathbf{f}_a(z,t)=-\frac{1}{2}\rho\bar{u}^2(z)b(z)\mathbf{R}^T\mathbf{c}_a(z)\mathbf{R}\mathbf{\Psi}(z)\dot{\mathbf{P}}(t) \tag{3}$$

where ρ is the air density, $\bar{u}(z)$ is the mean wind velocity profile ; $\mathbf{c}_a(z)$ and $\mathbf{R}$ are the aerodynamic coefficient and rotation matrices, respectively:

$$\mathbf{c}_a(z)=\begin{bmatrix} 2c_d(z) & c_d'(z)-c_l(z) & -R_0(z)\left(c_d'(z)-c_l(z)\right) \\ 2c_l(z) & c_d(z)+c_l'(z) & -R_0(z)\left(c_d(z)+c_l'(z)\right) \\ 2b(z)c_m(z) & b(z)c_m'(z) & R_0(z)b(z)c_m'(z) \end{bmatrix};\quad \mathbf{R}=\begin{bmatrix} \cos\alpha & \sin\alpha & 0 \\ -\sin\alpha & \cos\alpha & 0 \\ 0 & 0 & 1 \end{bmatrix} \tag{4}$$

in which $c_d(z)$, $c_l(z)$, and $c_m(z)$ are the mean drag, lift, and torsional moment coefficients, respectively, estimated through static tests in wind tunnel ; $R_0(z)$ is the characteristic radius of the cross section; dealing with a compact section, it is reasonably assumed as equal to zero [5-6].

Substituting Eq.(3) into Eq.(2), then Eq.(2) into Eq.(1) and rearranging in state space form, it leads to:

$$\dot{\mathbf{p}}=\tilde{\mathbf{A}}\mathbf{p} \tag{5}$$

where

$$\mathbf{p}=\begin{bmatrix}\mathbf{P}\\ \dot{\mathbf{P}}\end{bmatrix};\quad \tilde{\mathbf{A}}=\begin{bmatrix}\mathbf{0} & \mathbf{I}\\ -\tilde{\mathbf{M}}^{-1}\mathbf{K} & -\tilde{\mathbf{M}}^{-1}\left(\tilde{\mathbf{C}}+\tilde{\mathbf{C}}_a\right)\end{bmatrix} \tag{6}$$

in which $\tilde{\mathbf{C}}_a$ is the generalized aerodynamic damping matrix:

$$\tilde{\mathbf{C}}_a=\frac{1}{2}\rho\int_0^L \bar{u}(z)b(z)\mathbf{\Psi}^T(z)\mathbf{R}^T(z)\mathbf{c}_a(z)\mathbf{R}\mathbf{\Psi}(z)dz \tag{7}$$

The dynamical system represented by Eq.(5) is asymptotically stable if and only if all the real part of the eigenvalues of matrix $\tilde{\mathbf{A}}$ are negative [7]. Such an eigenvalue problem to find the con-

dition for the instability occurrence is normally solved through a numerical procedure. Particularly, neglecting the torsional rotation component and assuming that the resultant 2 DOFs coupled system is endowed with a set of couples of orthogonal modes having the same frequencies, i.e. $\omega_{2k-1}= \omega_{2k}$ (k = 1,2,…), this problem can be solved in closed form and the eigenvalues of the matrix $\tilde{\mathbf{A}}$ are given by [4, 8]:

$$\begin{aligned}\lambda_{1,2} &= i-\xi_{2k}+\frac{\rho b(z_e)\bar{u}(z_e)}{8\tilde{m}_{2k,eq}\omega_{2k}}\left(-\operatorname{tr}\tilde{\mathbf{C}}_{a,2k,eq}\pm\sqrt{\operatorname{tr}^2\tilde{\mathbf{C}}_{a,2k,eq}-4\det\tilde{\mathbf{C}}_{a,2k,eq}}\right)\\ \lambda_{3,4} &= -i-\xi_{2k}+\frac{\rho b(z_e)\bar{u}(z_e)}{8\tilde{m}_{2k,eq}\omega_{2k}}\left(-\operatorname{tr}\tilde{\mathbf{C}}_{a,2k,eq}\pm\sqrt{\operatorname{tr}^2\tilde{\mathbf{C}}_{a,2k,eq}-4\det\tilde{\mathbf{C}}_{a,2k,eq}}\right)\end{aligned} \tag{8}$$

where i is the imaginary unit; z_e is a reference height; $\tilde{m}_{2k,eq}$ and $\tilde{\mathbf{C}}_{a,2k,eq}$ are the equivalent mass and aerodynamic matrix related to mode 2k-th, respectively:

$$\tilde{m}_{2k,eq}=\frac{\int_0^L m(z)\left\|\boldsymbol{\Psi}_{2k}(z)\right\|^2 dz}{\int_0^L\left\|\boldsymbol{\Psi}_{2k}(z)\right\|^2 dz}\ ;\ \tilde{\mathbf{C}}_{a,2k,eq}=\int_0^L \boldsymbol{\Pi}_{2k}^T(z)\mathbf{c}_a(z)\boldsymbol{\Pi}_{2k}(z)dz \tag{9}$$

in which $\mathbf{c}_a$ is the aerodynamic matrix achieved by dropping the third column and row in the aerodynamic matrix $\mathbf{c}_a(z)$ given in Eq.(4), and $\boldsymbol{\Pi}_{2k}(z)$ is a functional matrix associated with the 2k-th mode given by:

$$\boldsymbol{\Pi}_{2k}(z)=\sqrt{\frac{\bar{\mu}(z)b(z)}{\bar{\mu}(z_e)b(z_e)\int_0^L\left\|\boldsymbol{\Psi}_{2k}(z)\right\|^2 dz}}\mathbf{R}\boldsymbol{\Psi}_{2k}(z) \tag{10}$$

where $\|\boldsymbol{\Psi}_{2k}(z)\|$ denotes the norm of the mode shape $\boldsymbol{\Psi}_{2k}(z)$ and $\bar{\mu}(z)$ is a suitable non-dimensional function expressing the shape of the mean wind velocity profile, e.g. a power or logarithm law:

$$\bar{u}(z)=\bar{u}(z_e)\frac{\bar{\mu}(z)}{\bar{\mu}(z_e)} \tag{11}$$

As a result, the necessary condition for instability is represented by the simultaneous satisfaction of the following two equations:

i) $\operatorname{tr}\tilde{\mathbf{C}}_{a,2k,eq}<0$ (12)

ii) $\operatorname{tr}\tilde{\mathbf{C}}_{a,2k,eq}\geq 0>\det\tilde{\mathbf{C}}_{a,2k,eq}$ (13)

The critical velocity at the reference height z_e associated with such two conditions is given by:

i) $$\bar{u}_{cr,2k}(z_e)=\begin{cases}-\dfrac{8\omega_{2k}\xi_{2k}\tilde{m}_{2k,eq}}{\rho b(z_e)\,\mathrm{tr}\,\tilde{\mathbf{C}}_{a,2k,eq}} & for\ \ \mathrm{tr}^2\,\tilde{\mathbf{C}}_{a,2k,eq}-4\det\tilde{\mathbf{C}}_{a,2k,eq}\le 0\\ -\dfrac{8\omega_{2k}\xi_{2k}\tilde{m}_{2k,eq}}{\rho b(z_e)\left[\mathrm{tr}\,\tilde{\mathbf{C}}_{a,2k,eq}-\sqrt{\mathrm{tr}^2\,\tilde{\mathbf{C}}_{a,2k,eq}-4\det\tilde{\mathbf{C}}_{a,2k,eq}}\right]} & for\ \ \mathrm{tr}^2\,\tilde{\mathbf{C}}_{a,2k,eq}-4\det\tilde{\mathbf{C}}_{a,2k,eq}>0\end{cases} \tag{14}$$

ii) $$\bar{u}_{cr,2k}(z_e)=-\frac{8\omega_{2k}\xi_{2k}\tilde{m}_{2k,eq}}{\rho b(z_e)\left[\mathrm{tr}\,\tilde{\mathbf{C}}_{a,2k,eq}-\sqrt{\mathrm{tr}^2\,\tilde{\mathbf{C}}_{a,2k,eq}-4\det\tilde{\mathbf{C}}_{a,2k,eq}}\right]} \tag{15}$$

It is worth noting that the eigenvalues derived in Eq.(8) and the instability conditions given in Eq. (12)-(15) take into account the variation along the whole structures of the width of cross section $b(z)$, mass per unit length $m(z)$, aerodynamic coefficients $\mathbf{c}_a(z)$, and mean wind velocity $\bar{u}(z)$. So, they constitute the generalization of the solutions given in literature, e.g. in [8], in which those structural and aerodynamic parameters were assumed to be constant. Moreover, focusing on the sole oscillation corresponding to crosswind modes, the galloping analysis of a SDOF system can be derived as a particular case of Eqs.(12) and (13). This can be done by setting α=0 and by considering only the element (2,2) of matrix $\tilde{\mathbf{C}}_{a,2k,eq}$. Consequently, the necessary condition for galloping occurrence it the k-th mode in the crosswind direction results:

$$\left(c_d+c_l'\right)_{k,eq}<0 \tag{16}$$

where $(c_d+c'_l)_{k,eq}$ is the equivalent galloping coefficient in the k-th mode obtained from the second equation of Eq.(9):

$$\left(c_d+c_l'\right)_{k,eq}=\int_0^L\left[c_d(z)+c_l'(z)\right]\Pi_k(z)\,dz \tag{17}$$

in which $\Pi_k(z)$ is a function related to the k-th mode:

$$\Pi_k(z)=\frac{\bar{\mu}(z)b(z)\psi_k^2(z)}{\bar{\mu}(z_e)b(z_e)\int_0^L\psi_k^2(z)\,dz} \tag{18}$$

The critical velocity corresponding to k-th mode at the reference height z_e is provided by:

$$\bar{u}_{cr,k}(z_e)=-\frac{4\omega_k\xi_k\tilde{m}_{k,eq}}{\rho b(z_e)\left(c_d+c_l'\right)_{k,eq}} \tag{19}$$

For a particular case in which $m(z)$, $b(z)$, $c_d(z)$, $c'_l(z)$, and $\bar{u}(z)$ are constant, then $(c_d+c'_l)_{k,eq}$ is equal to $(c_d+c'_l)$; furthermore, the critical velocity related to the first crosswind mode is resulted in:

$$\bar{u}_{cr,1}=-\frac{4\omega_1\xi_1 m}{\rho b\left(c_d+c_l'\right)} \tag{20}$$

which is the one given by Den Hartog.

Consequently, Eq.(16) and Eq.(19) are the generalizations of the classical galloping analysis.

It is worth noting that once the critical wind velocity at the reference height z_e is determined, thanks to Eq.(11), a critical wind profile is established.

3 CASE STUDY

An infinite series of different lighting poles and antennas masts exists in reality. The theoretical framework described above is applied herein to study the aeroelastic behavior of a particular type of real structure. This structure is an antenna mast whose total height is h = 30 m and it is composed by two steel shafts with circular sections (Fig.3). The first shaft, which is referred to as main shaft, is 24 m long. The outer diameter of its section, whose thickness is 5 mm, varies from 950 mm at the bottom to 350 mm at the top. The cables attached along this shaft have a distributed mass per unit length 5 kg/m. The second shaft, put above the first one, is 6 m long, and it carries 6 antennas; the total weight of this shaft is 540 kg. Its section has constant outer diameter 193.7 mm, and it is 7.1 mm thick. A stair is placed along the whole structure and has a unit mass per length 7 kg/m. The structural damping for each mode is assumed as 0.5%. The additional stuffs such as the stair, cables, and antennas give rise to a distributed mass eccentricity; instead, they are assumed to be ineffective to the structural stiffness. Besides, the pole is located at a terrain characterized by a roughness length z_0=0.3 m, and the mean wind velocity is assumed to follow the logarithm law.

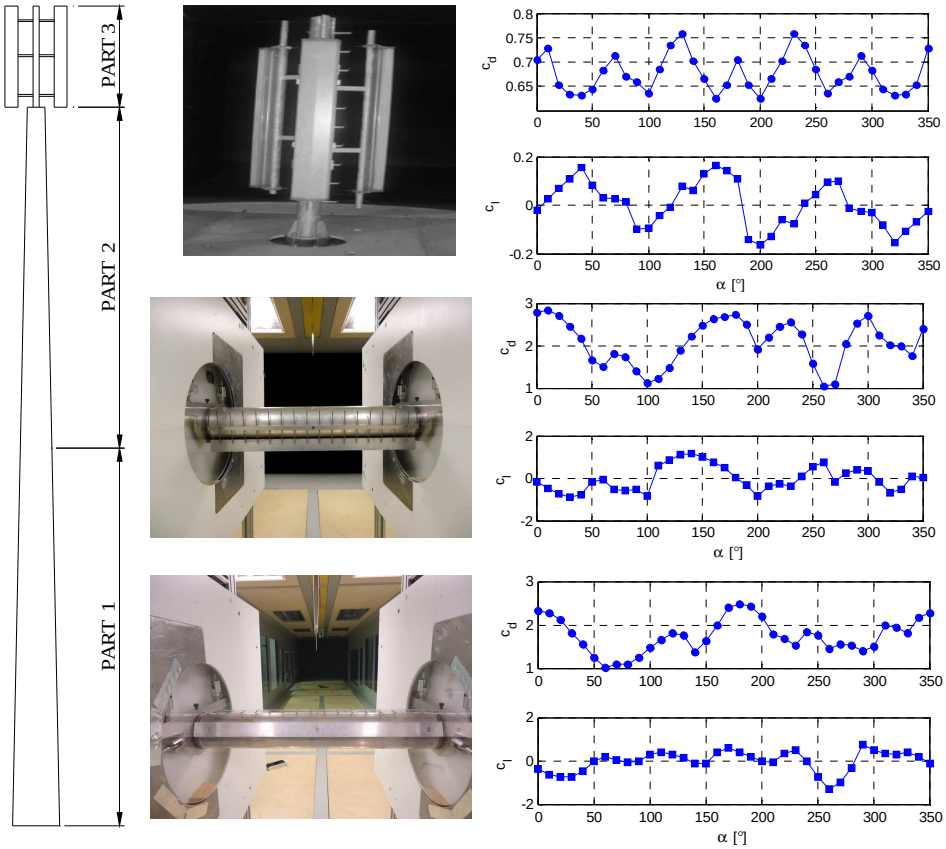

Figure 3. Sectional models of wind tunnel test and aerodynamic coefficients.

The static aerodynamic coefficients have been determined by wind tunnel tests. The tests on the main shaft have been conducted in the wind tunnel of the Faculty of Engineering of the University of Genoa. Since the outer diameter of the main shaft varies significantly from 950 mm to 350 mm, measurements have been carried out by dividing this shaft into two uniform parts with geometric scales 1:5 and 1:10. The angle of attack has been varied with 10° steps. For the top shaft, the results achieved from previous experiments performed in the wind tunnel of Milan Polytechnic have been used. All results pointed out that the Reynolds numbers do not affect considerably the aerodynamic coefficients. Fig.3 shows the drag and lift coefficients for each part of the pole.

4 NUMERICAL RESULTS AND DISCUSSIONS

The modal analysis provides the first four natural frequencies: $n_{1,2}$=0.774 Hz, $n_{3,4}$=3.628 Hz. The corresponding mode shapes are plotted in Fig.4. The eccentricity does not change the substantial similarity between couples of natural frequencies in translational directions, but it couples the corresponding mode shapes.

In the stability analysis, the Den Hartog's criterion is preliminarily utilized for each of three parts of the pole. Next, the instability conditions presented in the previous section for the SDOF and the 2DOF systems, i.e. uncoupled and coupled vibrations, are applied.

The analysis is carried out by taking into account the variation along the whole structure of the mass, width, mean wind velocity and aerodynamic coefficients. Two cases are considered, namely the shaft without eccentricity and with an eccentricity varying along its height. By employing Eq.(9), it results in that $\mathrm{tr}\tilde{\mathbf{C}}_{a,2k,eq}$ is always positive. Then Eqs.(13), (15), (16), and (19) are applied to determine the instability conditions and the critical velocities for both SDOF and 2DOF systems. The critical velocity is evaluated at the reference height fixed z_e=10 m. Any critical velocity larger than 200 m/s is disregarded. It is found that, on one hand, the presence of the distributed eccentricity, which is small as compared with the pole diameter, does not influence the aeroelastic response. On the other hand, the following remarks are highlighted.

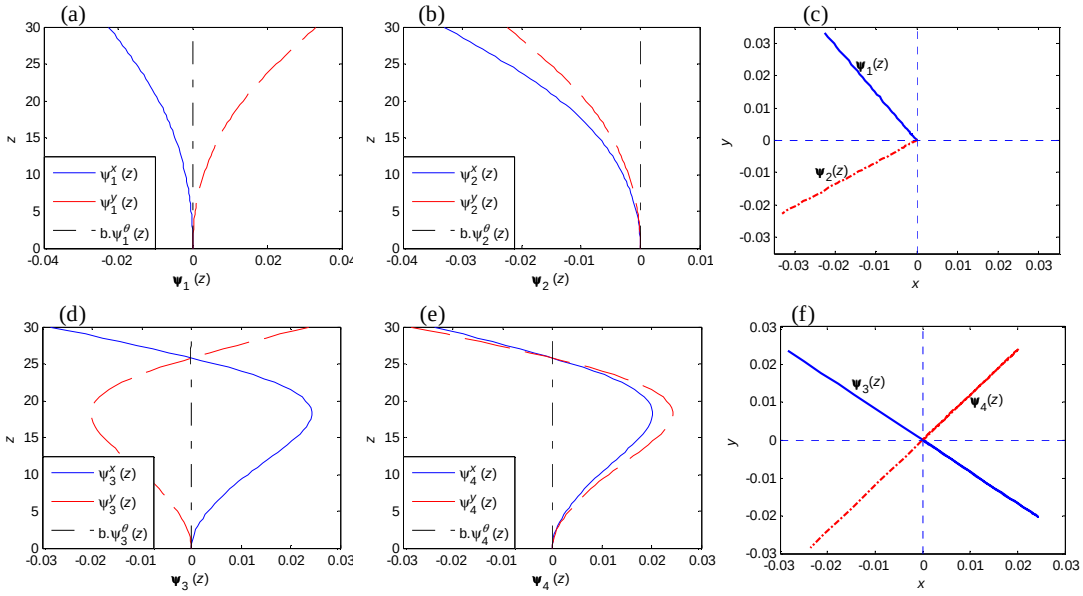

Figure 4. First four mode shapes : (a) first mode; (b) second mode; (c) first and second modes top view; (d) third mode; (e) fourth mode; (f) third and fourth modes top view

Firstly, Fig.5a shows the values of $(c_d+c'_l)$ for each of the three parts of the pole; Fig. 5b shows the values of $(c_d+c'_l)_{k,eq}$ provided in Eq.(17) for the first two crosswind modes. It can be seen that, according to the Den Hartog's criterion for each of three single parts, part 1 can gallop at wind attack angles 240° and 250°; part 2 at 0°, 100°, 120°, and 240° ; part 3 at 180° and 190°. However, applying the generalized Den Hartog's criterion given by Eq.(16), in which the shaft is considered in its whole, the structure can gallop at only 3 wind attack angles 180°, 190° and 240°. Moreover, the structure can be unstable not only in the first crosswind mode (mode 2 in Fig.2) but also in the second crosswind mode (mode 4 in Fig. 2). This latter case occurs for the angle of attack 240° where it cannot gallop in the first crosswind mode. Therefore, carrying out the galloping analysis only for first crosswind mode of a SDOF system can be unsafe.

Secondly, Fig.6a shows the necessary condition for instability of a 2DOF system, i.e. $\det\tilde{\mathbf{C}}_{a,2k,eq} < 0$, and Fig.6b presents the critical velocities for the 2DOF coupled system (Eq.(15)) in comparison with those for the SDOF uncoupled one (Eq.(19)). That the instability can occur in the third and fourth coupled modes reconfirms the importance of the higher modes in the stability analysis. Moreover, at the angle 180°, the SDOF model provides the critical velocity 37.03 m/s, while the 2DOF model gives a higher value, 40.52 m/s; in this case, carrying out a SDOF galloping analysis, as in the common practice, provides a result on the safe side. The situation changes at the angle 190°, where the critical velocity of a 2DOF system is 23.87 m/s, considerably lower than the value 36.12 m/s provided by a SDOF galloping analysis. This huge error (34%) stresses the significance of coupling the crosswind component of the motion with the alongwind one. In other words, neglecting such coupling as usual may give rise to unsafe evaluations. The difference between the above two critical velocities may result from the internal resonance due to the equality of two translational modes.

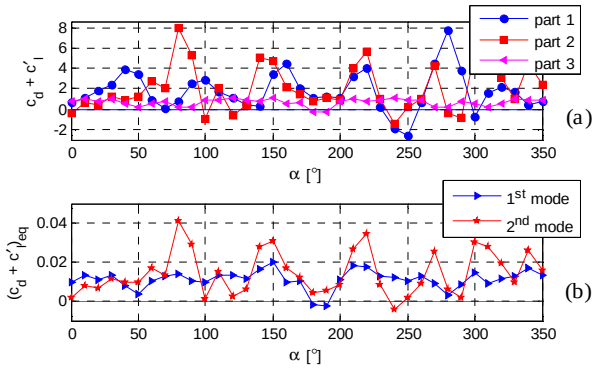

Figure 5: Galloping condition for SDOF system: Den Hartog'creterion (a); generalized Den Hartog's criterion (b)

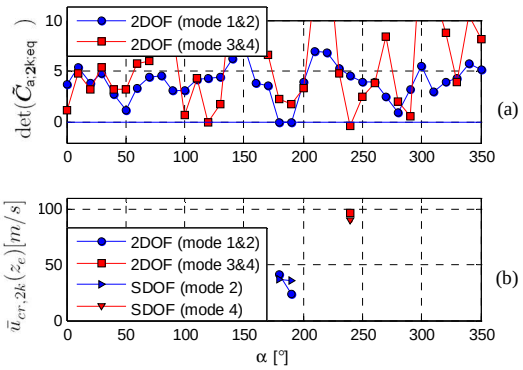

Figure 6. (a) Necessary conditions for 2DOF galloping; (b) Critical velocities.

Thirdly, in the first crosswind mode of a SDOF system, and in the first two modes of a 2DOF system, the galloping occurs only at the angles 180° and 190°, at which the top antennas part (part 3) is potentially unstable. This emphasizes the role of the antennas in the instability of the whole structure. To investigate deeper this role, the analysis is replicated by rotating the top part with an angle θ varying from 0° to 350°, with respect to the main pole, with an increment of 10°. Fig.7a shows, for each the angles of attack α, the minimum critical velocity corresponding to all the rotation angles θ. It can be witnessed that the structure is potentially unstable with different critical velocities for different position of the antennas part. In the meanwhile, for each angle θ, Fig.7b plots the minimum critical velocity corresponding to all the attack angles α. From this, the worst position of the top part respect to the main shaft that the critical velocity is smallest corresponds to θ=310°. This means that the antennas should not be put in such a position during the construction. In addition, due to the resonant coupling between the first two translational modes, the critical velocities of a 2DOF system are not always close to those of a SDOF system; even more, in some cases, e.g. at θ=0°, 140°, 150°, they are seriously lower than those of a SDOF system. Besides, the structure is unstable in the 4th uncoupled mode and in the 3rd and 4th coupled modes at all rotating angles θ while it is still stable in the lower modes at θ equal to 30°, 40°, 100°, 110°, 200°, 230°, 240°, and 330°. In summary, this study points out that, on one hand, the effect of the top antennas part on the stability of whole pole is noteworthy. On the other hand, it is confirmed that neglecting the alongwind component of the response, i.e. considering only the crosswind SDOF instability with different modes may lead to remarkable errors being fatal to the structure.

Lastly, to understand deeper the influence of the antennas part on the structural stability, the analysis is repeated by covering the antennas with a cylinder, as it is shown in Fig.1d. For this cylinder, c_d=0.74, and c_l=c'_d=c'_l=0. Fig.8a plots the necessary instability conditions (tr$\tilde{\mathbf{C}}_{\boldsymbol{a},2k,eq}$ is absent in this figure since it is positive for every k) while Fig.8b shows the critical velocities for the 2DOF coupled system in comparison with those for the SDOF uncoupled one. It can be seen that the instability phenomenon occurs only at 240° for the second crosswind mode in the case of a SDOF system and in the second two modes in the case of a 2DOF system. This phenomenon disappears at the lower modes. Furthermore, the critical velocities given by the SDOF and 2DOF models are coincident with the value 64.3 m/s. It can be concluded that the cover cylinder does not only create a positive aerodynamic damping that makes the structure more stable, but it can also decouple the aeroelastic motions in translational directions. It should be observed, however, that these considerations apply to perfectly circular cylinders. Recent experiences showed that this situation is definitely not guaranteed. In some limit cases values of the lift coefficient in the order of 0.4 have been detected. This creates a further sort of complexity that can modify also the stability conditions of the pole.

5 CONCUSIONS AND PERSPECTIVES

This paper establishes a general theoretical framework to study the aeroelastic instability of slender structures with distributed eccentricities. Neglecting torsion and focusing on the internal resonance of translational oscillations, an analytical solution for coupled instability conditions is formulated, which generalizes some previous results available in literature. The classic galloping condition for a SDOF system vibrating in the crosswind direction is obtained as a particular case.

An application of presented method to a real telecommunication antenna mast points out the importance of the aerodynamic eccentricities, of the upper modes of oscillation, and of the coupling between the crosswind and alongwind components of the motion. A comparison between the results provided herein and the classical engineering approaches emphasizes that relevant errors may occur, especially for particular sets of parameters and specific configurations. In such conditions the structure may exhibit very low critical galloping velocity able to produce unexpected damages and collapses. This might explains a lot of damages and collapses that these structures often suffer without clear and suitable explanations.

Showing the potentiality for the occurrence of critical situations unpredictable by means of classic models, this paper can be regarded as a preliminary step towards more refined analyses that may confirm the results provided herein.

The first and most important point is to study the reliability of the proposed theory by carrying out suitable aeroelastic wind tunnel tests and comparing the results obtained with monitored structures and the engineering evidence. Such study cannot avoid the investigation of the role of the turbulence, neglected herein by considering only smooth flows.

A second point to be inspected is a generalization of this study from the aeroelastic instability conditions to the wind-excited response [9, 10] and fatigue [11, 12]. Even far from unstable behavior, slender structures with distributed eccentricities are traditionally calculated without considering such eccentricities, crosswind response and upper modes. The results provided in this paper point out that all these aspects might strongly increase design wind loads, making the current design approaches for these structures seriously unsafe.

Design wind loads of wire mesh claddings and their fatigue behavior considering structural non-linearities

Frank H. Kemper[1], Markus Feldmann[2]

[1,2]*RWTH Aachen University, Institute for Steel Structures, Aachen, Germany*

ABSTRACT: Cladding elements made of prestressed, permeable wire meshes are for different reasons challenging with respect to their aerodynamic load-response behavior. On the one hand, the aerodynamic admittance is dominated by the flow resistance of the mesh and its individual location on the buildings surface. On the other hand, the wind excited stress range spectra may lead to structural failures caused by fatigue, therefore a proper determination of the expected gust induced vibrations and a subsequent stress analysis of the geometric non-linear structure is necessary. By means of wind tunnel tests and a sophisticated analytical model of the non-linear dynamic structure, a realistic design concept has been derived to allow a closed form structural dimensioning.

KEYWORDS: Permeable Structures, Gust Response, Geometric non-linearity, Fatigue Design

1 INTRODUCTION

Permeable cladding structures are part of modern architectural concepts. In most cases only simplest static load assumptions are considered for their design, i.e. a consideration as a free standing element. However, the complexity of the actual installation position and the thereby caused interaction with a closed inner façade lead to a significantly modified aerodynamic impact. Especially for permeable elements with high porosity, general rules are rare.

Wind affected structures generally have to withstand fluctuating load cycles. For an appraisement whether the resulting stress range spectra may lead to structural failures during the designed lifetime, standard methods are still rare because the influencing parameter are manifold. A realistic determination of structural stress range spectra provoked by the natural wind, needs profound knowledge about the statistical properties of the wind flow at the considered site, as well as about the dynamic structural behavior. Eventually, the interpretation of the resulting structural responses in terms of stress amplitudes $\Delta\sigma$ and associated frequencies of occurrence $N(\Delta\sigma)_{Life}$ over the expected lifetime are the main task to allow fatigue verifications. The complexity of the topic increases significantly, when the usual linearized considerations are not sufficient anymore. In the present paper the fatigue behavior of geometrically non-linear elements under gusty wind loads is considered.

2 WIRE MESH CLADDINGS

Cladding structures made of wire mesh are part of modern architectural concepts and they are used both as an amendment of conventional closed façades and as sole building closure (e.g. for car parks). In Figure 1 an innovative cladding concept is shown, thereby the permeable wire mesh webs are installed in front of the glazed façade.

2.1 Static Wind Force Description

2.1.1 Simplified Load Considerations

For the calculation of the static wind forces, the aerodynamic characteristics of the used meshes and the influence of the installation position at the building have to be known. In case of multi-layered cladding systems, where the outer skin is made of a permeable mesh structure and the inner one is impermeable, the distance between both is an important additional parameter for the load determination.

Approximative values for the design of mesh elements, a simple accumulation of the flow resistances leads to conservative results. Taking the example of the multi-layered cladding, the flow resistance consists of the mesh resistance and the resistance of the inner barrier. The first effect can be approximated by the Bernoulli Equation under consideration of the pressure loss coefficient of the mesh (1). Hence, the acting local wind speed u_i can be determined to:

$$\frac{\rho}{2} \cdot u_\infty^2 = (1 + \zeta_{Mesh}) \cdot \frac{\rho}{2} \cdot u_i^2 \rightarrow u_i = u_\infty \cdot \sqrt{\frac{1}{1 + \zeta_{Mesh}}} \tag{1}$$

The computation of local loads can be performed based on the mesh force coefficient and the local flow velocity v_i. Due to the second resistance effect (closed inner wall), generally an additional reduction of the local flow speed can be expected.

Figure 3. Illustration of the Wind Tunnel Model and Definition of Measurement Parameters, Angles and Measuring Positions

2.1.2 BLWT Investigations

More detailed information about the directional wind load components (due to the mesh resistance as well as due to the inner blockage) can be achieved based on experiments in the boundary layer wind tunnel. With this aim, a model of a building with multi-layered cladding system and variable distance between the cladding layers has been build in a scale of M1:250 (s. Fig. 4). For the measurements, a circular mesh cut-out has been connected to a high precision force balance ($F_{max} = 0.5$N). The position of the force balance was variable in 9 positions.

In order to allow a statistic analysis of the extreme wind induced forces, for each wind direction 30 independent runs have been performed. For a unique formulation of the location dependent wind load effects but independent of the mesh resistance, a flow parameter α_{local} is introduced, which represents the flow resistance caused by the impermeable inner wall. Generally, the wind load effect is formulated as:

$$\alpha_{local} \cdot c_{f,Mesh} = \frac{1+\zeta_{Mesh}}{q} \cdot \frac{F_{local}}{A} = \frac{F_{local}}{q_{local} \cdot A} \tag{2}$$

Under consideration of an Extreme Value distribution Type I, the peak values for the locational flow parameter α_{local} can be computed based on the well-known *Cook-Mayne* [3] method, whereat the force coefficient c_f refers to the mean wind load admittance of the mesh. Altogether,

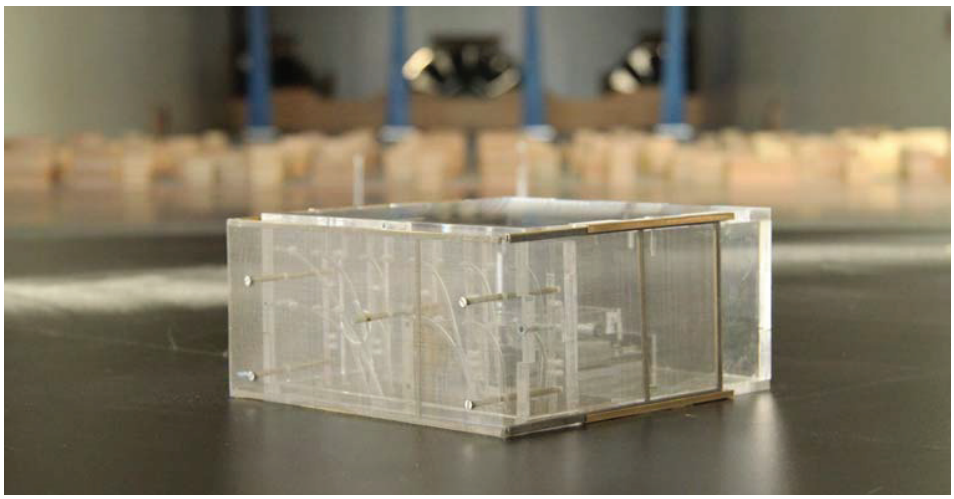

Figure 4. Windtunnel Model of a closed Building with permeable outer Cladding in a scale of 1:250

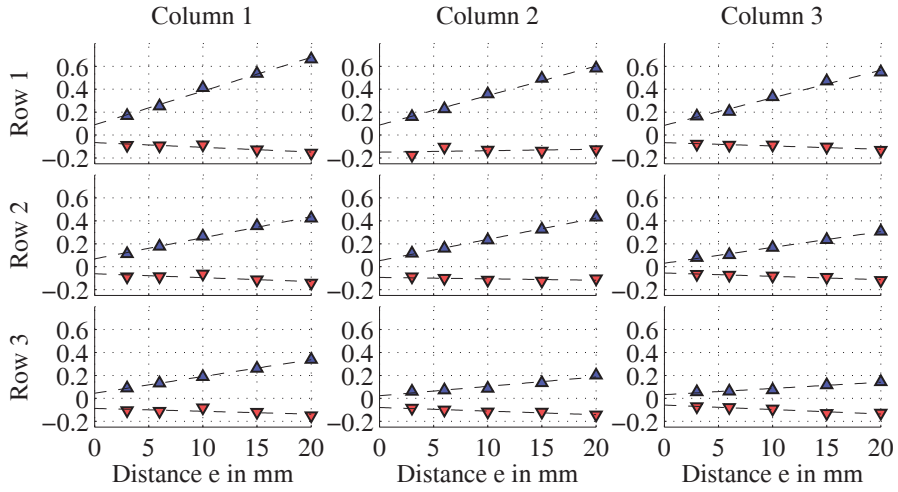

Figure 5. Characteristic Values $\hat{\alpha}$ and $\check{\alpha}$ for a mesh with a Pressure Loss Coefficient $\zeta_{Mesh} = 1.3$ for different Cladding Positions, dependent on the Distance e between Mesh and inner Cladding

the following formulas have been used for the analysis:

$$\hat{\alpha}_{local} = (1+\zeta_{Mesh}) \cdot \frac{mean(\hat{F}_i) + 0.636 \cdot std(\hat{F}_i)}{q_p(z = H_{OK}) \cdot c_f \cdot A} \tag{3}$$

$$\check{\alpha}_{local} = (1+\zeta_{Mesh}) \cdot \frac{mean(\check{F}_i) - 0.636 \cdot std(\check{F}_i)}{q_p(z = H_{OK}) \cdot c_f \cdot A} \tag{4}$$

In Figure 6 the results for $\hat{\alpha}$ are plotted, dependent on the wind direction and the distance between the cladding layers in model scale. Obviously, the perpendicular and nearly perpendicular flow towards the mesh ($\Theta \approx 0° - 20°$) is most unfavorable for the positive force in wind direction. With increasing distance between mesh and closed inner façade, as well as with increasing

wind direction, the wind positive wind force decreases. Appreciable negative wind forces only occur for wind angles above $\Theta \approx 45$, but the amplitude is commonly not decisive.

3 GEOMETRIC NONLINEAR STRUCTURAL BEHAVIOUR

The dynamic behavior of prestressed line-like elements can be described by a nonlinear single degree of freedom oscillator. As the resisting force is a polynomial with first and third order terms in r, this kind of oscillator is denoted as *Duffing-Oscillator* (s. Fig. 7). According to the geometric nonlinear kinematic, the deflection r of a Duffing-Oscillator leads to an elastic (additional) strain:

$$\varepsilon = \frac{\left(a^2+r^2\right)^{1/2}-a}{a} = \left[1+\left(\frac{r}{a}\right)^2\right]^{1/2} - 1 \tag{5}$$

Due to the increment of strain, the inner force N growths, compared to the prestressing force N_0:

$$N = N_0 + \varepsilon EA = N_0 + EA\left\{\left[1+\left(\frac{r}{a}\right)^2\right]^{1/2} - 1\right\} \tag{6}$$

The associated restoring force F_R of the Duffing-Oscillator can be determined by [1]:

$$\begin{aligned} F_R(r) &= 2\cdot N sin\phi = 2\cdot N\frac{r}{\left(a^2+r^2\right)^{1/2}} \\ &= 2\cdot N_0\cdot\frac{r}{a}\left[1+\left(\frac{r}{a}\right)^2\right]^{-1/2} + 2EA\cdot\frac{r}{a}\left\{1-\left[1+\left(\frac{r}{a}\right)^2\right]^{-1/2}\right\} \end{aligned} \tag{7}$$

Obviously, the response behavior from *Duffing-Oscillators* is dominated by the initial force N_0, the longitudinal elasticity EA and the span-width $2\cdot a$. The decisive parameter which combines the mentioned values is the degree of nonlinearity δ. It can be expressed as [5]:

$$\delta \approx \frac{EA}{2a^2N_0} \tag{8}$$

For fatigue verifications, not only the extreme values are relevant, but also the distribution of amplitudes has to be considered. For this aim, it is suggested to make use of advanced stochastic methods. Classical stochastic linearization approaches utilize an optimization of the expected value between the nonlinear and the linear stiffness to minimize the divergence of an equivalent linear system to the original system, in a least-square sense [8]. As a results a single equivalent structural frequency ω_{eq} can be found. This approach generally leads to a correct representation of the spectral energy and the increased structural frequencies, but underestimates the spectral

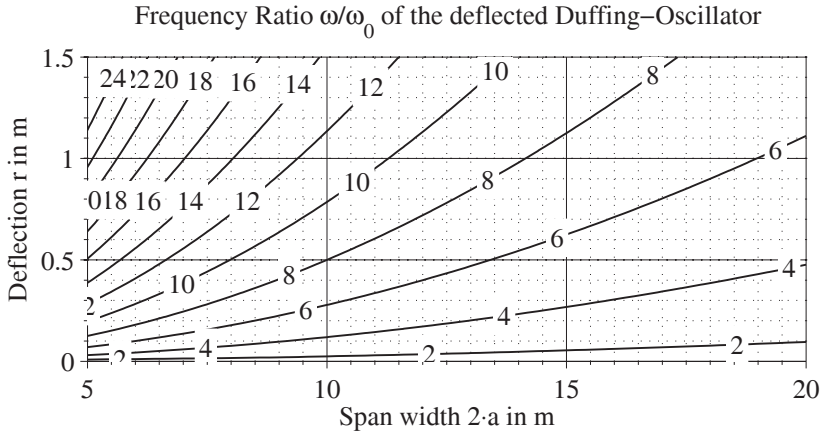

Figure 8. Increase of structural frequency of a Duffing-Oscillator dependent on span-width $2 \cdot a$ and applied deflection r

bandwidth (especially for slightly damped systems) [2]. Therefore *Miles* [7] and *Spanos* [9] used a concept, based on a linear differential equation of motion with a random expression for the amplitude dependent structural frequency (Equivalent Linear System, ELS). Transferring these concepts and extending them to stochastic wind loads with non-zero means leads to good approximations of the spectral system response, as well. Due to the analytic approach, they are advantageous compared to transient methods in case of structures which can be reduced to a single degree of freedom system.

In this paper, the ELS method is presented. The amplitude related structural frequency $\omega(A)$ can be obtained from:

$$\ddot{r} + 2\zeta\omega_0\dot{r} + \omega^2(A) \cdot r = f(t) \tag{9}$$

Hence, the differential equation of motion (9) represents a system of linear single degree of freedom oscillators. The Eigenfrequency ω is dependent on the deflective amplitude A and the expected frequency of its occurrence $P_n(A)$. According to [7], [9],[6] probability distribution can be expressed for a clear white noise excitation as:

$$P(A) = \frac{2\pi\omega_0^2\,(A + \delta \cdot A)}{\omega(A)} \cdot e^{-\frac{A^2\left(\delta \cdot A^2 + 2\right)}{4 \cdot \sigma_0^2}} \quad \text{and} \quad P_n(A) = \frac{P(A)}{\int_0^\infty P(a)da} \tag{10}$$

A dynamically excited Duffing-Oscillator changes its frequency continuously, the amplitude related detuning can be expressed analytically [1]:

$$\frac{\omega(A)}{\omega_0} = \sqrt{1 + \frac{3}{4}\delta A^2} \tag{11}$$

In Figure 8 exemplarily the increase factors of the structural frequency $\omega(A)/\omega$ are plotted over the system span width and the applied deflection.
The approximate PSD of the structural deflective response $S_{aa}(\omega)$ can now be computed according to:

$$S_{aa}(\omega) = \int_0^\infty \frac{S_{ff}(\omega)}{\left(\omega^2\,(A) - \omega^2\right)^2 + \left(2\zeta\omega_0\omega\right)^2} \cdot P_n(A)dA \tag{12}$$

Although equation 10 is only exact for a white noise excitation with zero expectation, it has been used as an approximation here, whereat the variance σ_0^2 of the process has been derived by a

linear spectral computation with the actual force spectrum (based on a *Kaimal* PSD of the wind velocity).

Wind gust effects generally come along with a significant mean load component. The structural vibrations then take place around the resulting average deflection. To incorporate those effects alternatively in the before described computation algorithm, firstly the static displacement r_{stat} has to be computed based on the associated load situation:

$$F_{stat} = 2 \cdot N_0 \cdot \frac{r_{stat}}{a} + (EA - N_0) \cdot \left(\frac{r_{stat}}{a}\right)^3 \tag{13}$$

Due to the static deflection, the structural stiffness increases. Subsequently, all dynamic computations acc. to Equations (11) to (12), may be used with the associated structural characteristics of the modified system (denoted by the index "1"), i.e. the Eigenfrequency ω_1 and the variance σ_1^2. Consistently, in Equation 12 the varying structural frequency is to be computed for $A_1 = A + r_{stat}$.

4 DETERMINATION OF NONLINEAR RESPONSES WITH STOCHASTIC METHODS

The geometric non-linear behavior can be considered analytically based on the findings of section 3. Typical prestressed cladding constructions show degrees of non-linearity between $\delta = 50$ and $\delta = 100$. In this section, the presented ELS method has been performed for structures with different degrees of non-linearity under varying load cases. As a load scenario, a 10 min gust impact has been considered, whereat for the aerodynamic admittance, different local flow coefficients have been taken into account. All associated properties are listed in Table 1.

As a first result, the power spectral densities of the structural deflections are plotted in Figure 10, as a comparison between the ELS method to conventional time based methods. The spectral results reveal the accuracy of the analytic method with respect to the predicted response behavior. In section 5, the consequence of the method, related to the fatigue prediction is investigated.

5 FATIGUE BEHAVIOUR AND STRUCTURAL INFLUENCE ON THE LIFETIME

Making use of a PSD based cycle count algorithm which is able to interpreted processes with arbitrary bandwidth, namely the *Dirlik*-algorithm [4], the rain-flow cycle count succeeds with frequency based responses. Even in case of nonlinear structures, the Rainflow classification can be performed based on the (with the prior described methods) computed power spectral density $S_{uu}(\omega)$.

The applicability of the presented methodology is illustrated by exemplary computations of flexible cladding elements (membrane structures) with different, realistic mechanical parameters. By means of these results, it is demonstrated how the different parameters influence the expectable damage and the fatigue life respectively.

So far, only the impact of a short-termed extreme wind on the stress range distribution has been considered. For the computation of the expected design life-time under fatigue aspects, the prevalent wind events during the foreseen lifetime have to be taken into account as well.

Table 1. Overview of Aerodynamic and Mechanic Properties of the Exemplary Computations

System	α_{local}	δ	System	α_{local}	δ	System	α_{local}	δ
S01-LC1	0.05	0.4	S02-LC1	0.05	4.0	S03-LC1	0.05	40
S01-LC2	0.5	0.4	S02-LC2	0.5	4.0	S03-LC2	0.5	40
S01-LC3	2.0	0.4	S02-LC3	2.0	4.0	S03-LC3	2.0	40

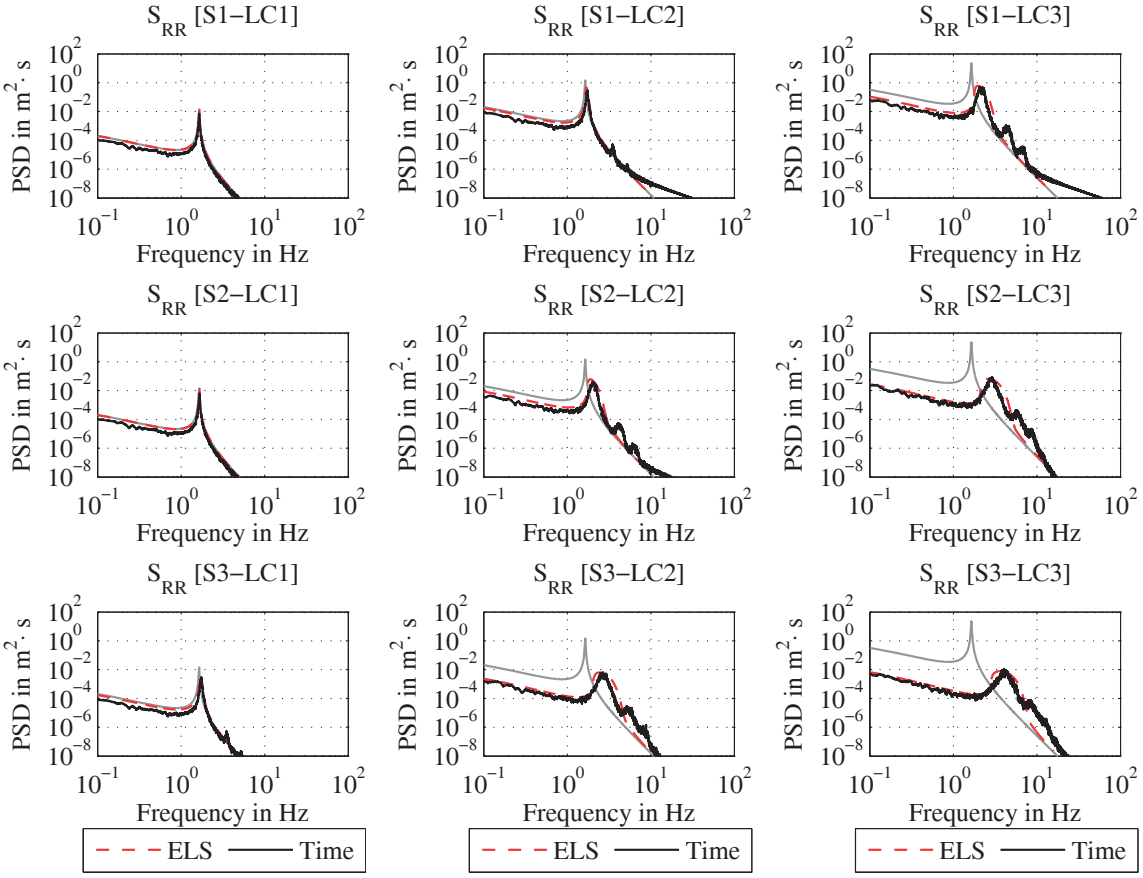

Figure 9. PSD of deflective Response for different Structures with ELS and transient Computation

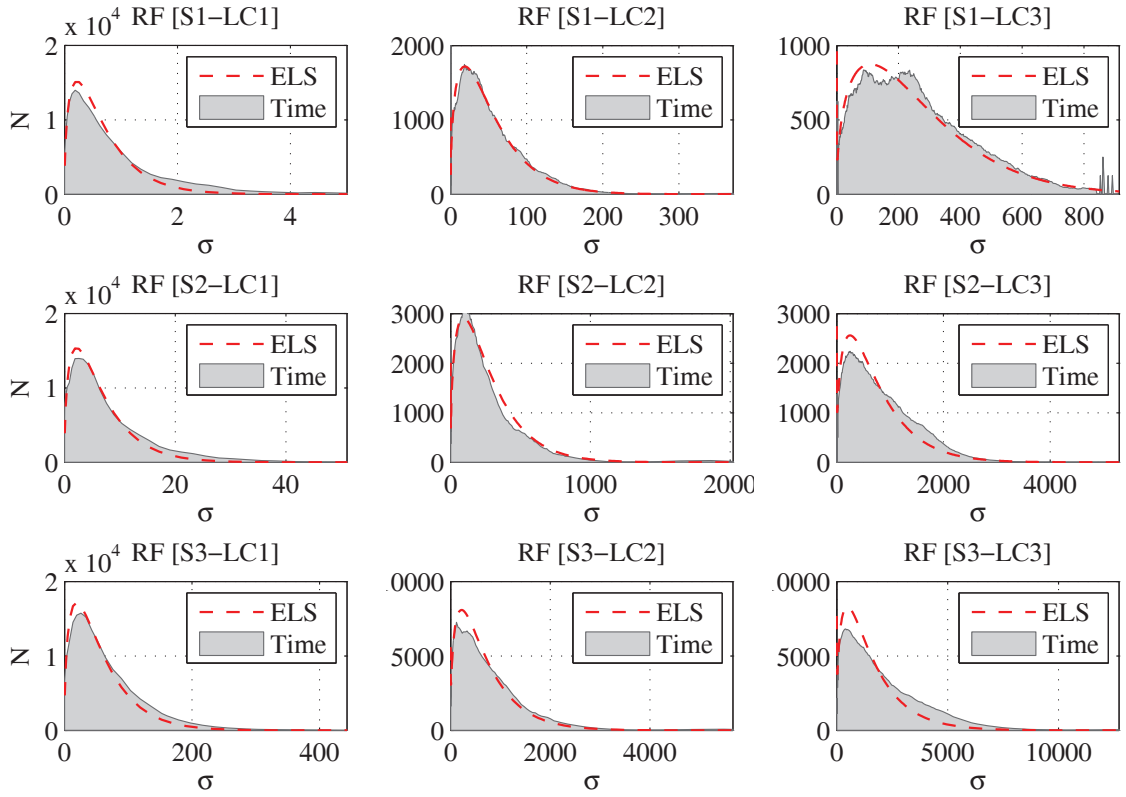

Figure 10. Stress Range Spectra (Rainflow Method) of ELS and transient computed Responses

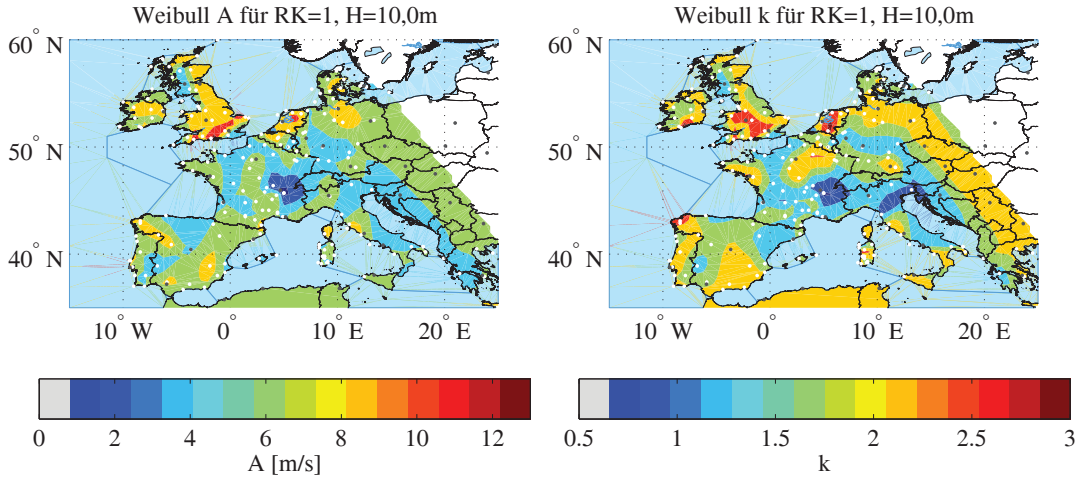

Figure 11. Weibull Parameter for Europe, Roughness Category 1 (Data Source: European Wind Atlas [10])

Merging all before described influence parameters, the stress range spectra can be computed by the following expression:

$$N(\Delta\sigma)_{Life} = \int_0^{\overline{u}} \frac{T_{Life}}{T_{ref}} \cdot f(u) \cdot N(\Delta\sigma, u) du \tag{14}$$

where: T_{Life} is the designed Lifetime, T_{ref} is the average time of the mean wind speed, $f(u)$ is the probability density function of the wind velocity and $N(\Delta\sigma, u)$ is the stress range spectra for a given mean wind speed within the average time period.

The probability density function for the frequency of occurrence of mean wind speeds can be derived based on the *Weibull*-Distribution:

$$f(\overline{u}) = \frac{k}{A}\left(\frac{\overline{u}}{A}\right)^{k-1} exp\left[-\left(\frac{\overline{u}}{A}\right)^{k}\right] \tag{15}$$

where: A is the scale and k is the form parameter of the distribution. Site dependent values for these parameters can be taken from e.g. the European Wind Atlas [10]. In Fig. 11, exemplarily the parameters A and k (cumulated over all directions) are plotted in the map of Europe for the roughness category 1 ($z_0 = 0.05m$), for a height of 10m and for an average period of $T = 1$ hour.

Based on the appropriate assumptions for the site dependent extreme wind impact and the probability of exceedance of the prevalent wind speeds, a realistic consideration of fatigue impact is possible. Using the direction related Weibull Parameter, even a directional design is possible.

The fatigue verification now succeeds with common methods, like *Miner*-Rule for a linear damage cumulation with an appropriate s-N-Curve. In most cases the s-N-Curve should be obtained from dynamic fatigue tests, as general notch cases are not classified for crimped wires.

6 CONCLUSIONS

Static wind load assumptions have been derived for permeable cladding structures, installed as an outer skin in front on conventional, closed façades. Based on simplified models of the total pressure drop and the extended Bernoulli equation, conservative loads can be determined. Additional wind tunnel results show a good concordance of the local flow parameter α_{local}.
With respect to the structural investigations, it has been shown, that reliable fatigue verifications based on cumulative damage predictions are possible by means of closed form spectral methods,

even for highly nonlinear structures. The chosen method, the equivalent linearization approach, leads to appropriate estimations of the increased structural frequencies of geometrical nonlinear systems under loading, as well as of the obtained damage prognoses. The presented examples emphasize the complexity of the topic and the effects of the various structural and aerodynamic parameters with respect to the expected fatigue life.

ABSTRACT: In order to reveal the status of typhoon landfall in China coastal areas, the coastal areas and frequency of typhoon landing were compared with the statistical analysis in the paper for nearly 50 years; combined with the wind pressure of low-rise buildings under typhoon in China's coastal, structures damage of low-rise buildings were investigated. The results show that, the southwest coast of Guangdong landfall the largest number of typhoon landing, while the coastal areas of Fujian and Zhejiang have larger number of strong typhoons; turbulence great impact on surface air pressure; It was also found that the high suction pressure zones occurred around the windward roof edges at a wind azimuth of 45^0,and wind pressure along the roof corner just behind the roof ridge. The results of the present study are expected to be useful for the future development of a simple approximate formula for the low-rise buildings of the coastal area for design use.

KEYWORDS: Typhoon ;Low-rise buildings; Hurricane; wind pressure; failure mechanism.

1 INTRODUCTION

A full-length paper should have a short introduction. This should state the reasons for the work, with brief reference to previous work on the subject.

Typhoon (tropical storms and strong tropical storm) is an extreme climate which originated in tropical ocean between latitudes 5^0 ~20^0 and have great destructive, belonging to one of the severe natural disasters. The intensity of typhoon is one of the largest sea area in the Western Pacific, typhoon frequently attacks in China's coastal areas, China is also one of the few countries most severely affected by the Typhoon [1].

Wind resistance capacity of 0oastal residential wall in China is 12-level design, the strength design value of the walls are about 327kg/m^2, and negative pressure of roof about 43kg/m^2. Positive wind pressure of super- typhoon “SaoMai” reached 510~900kg/m^2, roof negative pressure up to 67~118kg/m^2, which greatly exceeded the design limit value of the low-rise buildings at china coastal, Typhoon “SaoMai” caused heavy casualties, which collapsed 39,000 houses and killed 144 people in Zhejiang Province [2~3]. Previous wind statistics show that the damage of low-rise buildings caused losses were more than half of the total losses .Therefore, researching of low-rise building on wind resistance possesses important practical significance [4~7].

2 NEARLY 60 YEARS LANDED IN COASTAL AREAS OF CHINA TYPHOON

Fujian ,Guangdong and Zhejiang Provinces ,suffered most landing typhoons during the past 60 years from 1950 to 2011.Most of the landing typhoons originated from northwest Pacific at east of Philippine, with northwest path as the main track. On the average, 5 typhoons every year landed or impacted china coast areas during the past 60 years, with a relatively big inter annual change and slight upward trend. Most of the impacting typhoons mainly occurred in July to September, showing a normal distribution with August as the centre.

we can see the following conclusions:

(1) Number of landing Typhoon from 1949-2006 in coastal marine areas of Guangdong were a total of 211 typhoons, each year average 3.64, followed by Hainan Province, 135 typhoons, the average was 2.33.But in the 5 years, total of 46 of Landfalling typhoons from 2007 to 2011, the average annual number of 9.2 typhoons.
(2) Compared to 1949-2006 strong typhoon data for more than 50 years, number and frequency of strong typhoons nearly 5 years landing and affecting along the coast appear Increasing trends in china.

Extensive disaster investigation shows that:

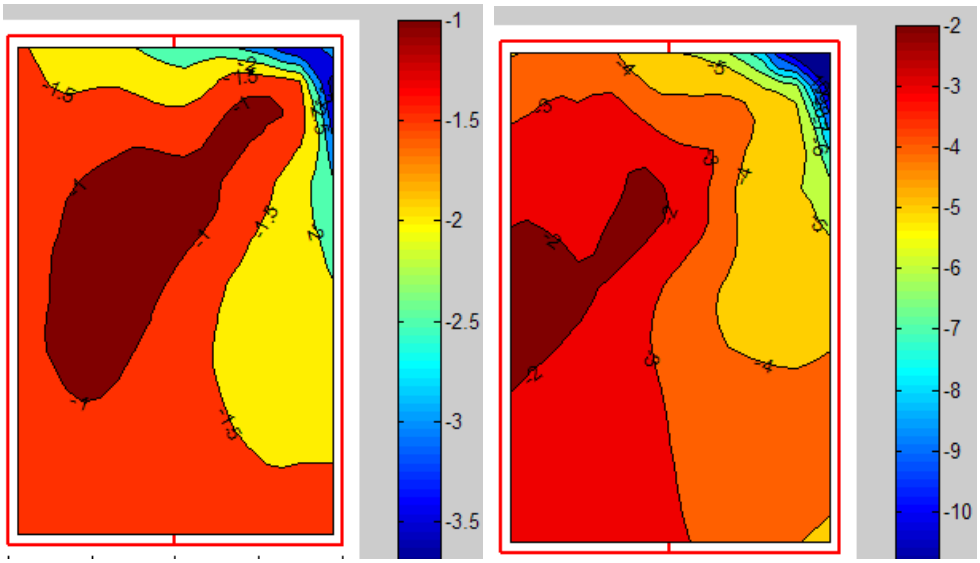
(1) Improper location: many houses built in the Typhoon-prone landed in empty fields, the region of villages and towns, offshore marine and upwind or higher ground, when the Typhoon landed, the geographical landform withstand wind loads of very large, very easily lead to collapse or damage of low-rise buildings.
(2) Improper design: wind damage of low-rise buildings of 1 or 2 independent houses account for a large proportion.
(3) Improper construction: construction of residences is not code for building construction, without structural design basic concepts of security, poor construction program, construction technology and construction techniques ,which led to the current poor quality of residential houses in coastal areas, and cause poor wind resistance capacity.

3 STUDY ON THE FAILURE MECHANISM OF COASTAL RESIDENTIAL WIND

According to the damage investigations,most damage to houses was restricted to the envelope of building, in particular to roof sheathing.which indicate that an improvement in wind resistance of the building's envelope will result in a significant reduction in overall economic losses.Failure mechanism of houses along the coast storms due to the Typhoon-prone area residential dwellings along the coast a large number of broad, each time the storms as a result of the economic problems, and also the essential problem facing social and political stability, so there is a need for low-rise buildings in storms damage mechanism of further scientific research.

Fig.1 Hurricane of a low-rise building in China coastal areas

Figure 2 show that[11], most damage to houses was restricted to the envelope of building, suggesting that coastal dwellings destroyed upwind wind-related, and roof more easily damaged than the walls.



a) Cp_{mean} b) Cp_{min}

Fig.2 Hurricane of a low-rise building in China coastal areas[11]

The results [8~11]show that, The entire roofs of the full-scale low rise building experience negative mean and minimum pressures regardless of the incident wind direction. The angular position of highest (mean and peak) suction do follow the vortex core position closely. It was found that the high suction pressure zones occur round the windward roof edges.The roof corner just at the windward end of the roof exhibit the highest minimumu pressure coefficients.The regions are expected to be the most vulnerable for wind induced roof damage in severe windstorms.strong suction and high pressure regions on the the leading edges and roof-corner regions were induced by the updrafts and downdrafts of wind flows near the eye of the typhoon. The highest negative mean pressure coefficients observed was -3.34.It occurred at a wind azimuth of 45^0,and the corresponding minimum pressure coefficients was -10.64.

CONCLUSIONS

(1) Some practical cosiderations and tasks in the development for wind- resistance design of low-rise buildings have been examined in this paper, author suggest that we should increase wind resistance design standard of coastal low-rise buildings in China.

(2) Strong suction and high pressure regions on the the leading edges and roof-corner regions were induced by the updrafts and downdrafts of wind flows near the eye of the typhoon.

(3) This article analyzes the main problems in practical construction of the coastal buildings in China, and puts forward improving measures for the improvement of current design of low rise buildings in China coast.

ABSTRACT: A full-scale moveable instrumented low-rise building has been constructed and implemented to monitor wind velocity field and associated building surface pressures during typhoons. The major objective of the field study is to further understand typhoon-generated wind characteristics and wind effects on the low-rise building under extreme wind conditions during typhoon landfalls. This paper presents a combined study of field measurements and wind tunnel tests. Detailed analysis of the mean, standard deviation and negative peak pressures measured on a roof corner zone of this building is conducted to investigate the pressure distribution characteristics in conical vortex region under oblique approaching wind directions. The field measurement results reveal that the windward leading edges on the corner area are consistently subjected to the most severe suction pressures for quartering winds. The measured extreme peak pressures are compared with those stipulated by ASCE 7-10 Standard. It is found that the measured extreme peak pressures at the windward leading edge area on the corner are significantly larger in absolute value than those determined by ASCE 7-10. Moreover, the effect of spatial and time average on the peak pressures on the corner zone is discussed. On the other hand, wind tunnel tests are performed to assess the wind effects on the experimental building. Comparison of the full-scale measurements and the model test results of negative peak and fluctuating pressure coefficients near the roof corner, roof ridges and leading edges shows distinct discrepancies. In general, the wind tunnel tests underestimate the real negative peak and fluctuating pressure coefficients on the roof corner zone for quartering winds. The outputs of this comprehensive study are expected to provide useful information for the wind-resistant design of low-rise buildings in typhoon-prone regions.

KEYWORDS: low rise building, typhoon, field measurement, wind tunnel test, wind-induced pressure, flat roof.

1 INTRODUCTION

Full-scale measurement is considered to be the most reliable method for evaluating wind effects on buildings and structures. There have been a number of field studies of wind effects on low-rise buildings conducted in the past several decades, including Aylesbury building field experiment (Eaton and Mayne,1975), the Silsoe structure building field experiment (Richardson et al.1990) and the Texas Tech University (TTU) Building filed experiment (Levitan and Mehta 1992a,1992b). The collected wind pressures on full-scale low-rise buildings were also used to validate the accuracy of wind tunnel test results, as reviewed by Uematsu and Isyumov (1999).

For example, the Aylesbury building measurement program provided wind pressure data for validation of wind tunnel experimental results (IAWE Aylesbury comparative experiment) using 1:100 models at 17 laboratories worldwide (Sill et al., 1992). The Silsoe structure building experiment provided the wind loads on a steel, gable-roof, and portal framed structure for verifying model test data (Richardson et al., 1994, 1995, 1997). In particular, several wind tunnel studies (e.g., Cocharan and Cermark, 1992; Okada and Ha, 1992; Endo et al., 2006) for the TTU Building have been conducted, and detailed comparisons with the full-scale measurements have been made. However, there are distinct discrepancies between the full-scale measurements and the wind tunnel test results of negative peak and fluctuating pressure coefficients near roof corners and roof leading edges.

More recently, field measurements on the Kern P. Pitts Centre provided valuable information of external pressure distributions and characteristics recorded during the passage of three cyclones in the proximity of the building (Caracoglia and Jones, 2009). In particular, the extensive Florida Coastal Monitoring Program currently being undertaken by three institutions in the USA focuses on monitoring of near-surface hurricane wind characteristics and wind pressures on residential low-rise buildings (Aponte, 2006). However, full-scale measurements of wind loads on low-rise buildings have rarely been conducted under strong windstorm conditions such as in eye-walls of hurricanes or typhoons. Consequently, there is lack of wind-induced pressure data on low-rise buildings under extreme wind conditions during typhoon landfalls. Obviously, there is an urgent need to enhance our understanding of turbulence structure of typhoons and the mechanisms for generations of extreme suctions in the region of flow separation or conical vortex. In this connection, a full-scale moveable instrumented low-rise building has been constructed and implemented to monitor wind velocity field and associated building surface pressures during typhoons. The major objective of the field study is to further understand typhoon-generated wind characteristics and wind effects on the low-rise building under extreme wind conditions during typhoon landfalls.

This paper is organized into four sections. Section 2 briefly describes the full-scale and wind tunnel measurement program for obtaining wind pressures on the instrumented low-rise building. Section 3 presents the measurement results from the instrumented building during the passage of several typhoons. Detailed analysis of the mean, standard deviation and negative peak pressures measured on a roof corner zone are conducted to investigate the pressure distribution characteristics in conical vortex region under oblique approaching wind directions. The measured extreme peak pressures are compared with those stipulated by ASCE 7-05 Standard. Furthermore, the effect of spatial and time average on the peak pressures on the corner zone is discussed. Moreover, wind tunnel tests are performed to assess the wind pressure distributions on the experimental building. The model test results are then compared with the field measurements to evaluate the accuracy of the model test results. Section 4 summarizes the major findings and conclusions from this combined full-scale measurement and wind tunnel test study.

2 FULL-SCALE AND WIND TUNNEL MEASUREMENT PROGRAMS

2.1 Full scale measurement

The monitoring station of the moveable instrumented building consists of a 6.0×4.0×4.0m flat-roof low-rise building and a 10m high meteorological tower located seven meters away from the building, as shown in Figure 1. Eighty differential pressure transducers (Setra model 264 or 265) with three types of measurement ranges of ±1250 Pa, ±2500 Pa and ±6250 Pa were used to measure the surface pressures on the building. A CR-5 PC based central recording monitoring

system which can simultaneously record data from 60 channels was used to measure wind speed, wind direction and pressure data. The pressure transducers and anemometers were sampled at 20 Hz. A more detailed description of the measurement system can be found in Li et al. (2009). The field measurements of wind speeds and wind pressures on the buildings were conducted under strong windstorm conditions such as in the eye-walls of Typhoons Hagupit and Chanthu. The information on the tracks of these typhoons and the building site is shown in Figure 2. This paper presents the selected results of the pressure data measured from nine taps on a roof corner and six taps at mid span of the experimental building, as shown in Figure 3. These corner taps are distributed in grids of 3 columns and 3 rows in two orthogonal directions. The tap locations nearest the roof edges are 0.12m from the edges. Tap12 indicates a tap located at row 1 and column 2 on the corner, as illustrated in Figure 3. Pressure coefficient is defined as follows:

$$C_p(t) = \frac{p(t) - p_s}{1/2\rho U_{ref}{}^2} \tag{1}$$

where $p(t)$ is the external pressure at a point of interest, p_s is the free stream static pressure or reference static pressure, ρ and U_{ref} are the air density and 10-minute mean wind speed at 10m height (reference height), respectively. The mean, standard deviation and peak pressure coefficients were calculated based on the measured pressure data. The pressure data presented in this paper were measured when the 10-min average wind speed at 10m height was larger than 8m/s (i.e., for dynamic pressure >40.2Pa).

Figure 1. The moveable instrumented building

Figure 2. Track of typhoons and location of the instrumented building

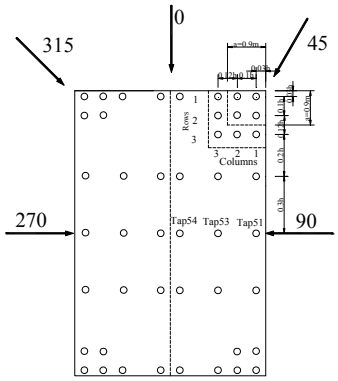

Figure 3.The locations of pressure taps and definition of incident wind direction

2.2 Wind tunnel test

The wind tunnel test was conducted at the Wind Tunnel Laboratory of Building and Environment of Hunan University. The wind tunnel is an open circuit tunnel with a working section of 3 meters wide and 2.5 meters high. With consideration of the size of the full-scale building, a geometric scale of 1:20 of the low-rise building was selected for the wind tunnel study.

For the critical wind directions (0°-90°) where the building roof was subjected to the most severe suctions, the terrain exposures at the building site can be categorized as coastal terrain and open land terrain, respectively. Therefore, the boundary layer wind flows for coastal terrain and open land terrain in the wind tunnel test were simulated based on the recorded profiles during typhoons and the terrain conditions around the instrument building site. The mean longitudinal wind speed and turbulence intensity profiles for the coastal terrain and the open land terrain, including the field measured profiles and those simulated for the wind tunnel test, are shown in

Figure 4 and Figure 5, respectively, for comparison purposes. The model scale mean wind speed profile was normalized by the mean wind speed at 0.5 meter height which corresponds to 10 meter full-scale height in order to compare the profile with the field measured profile. It can be seen from these figures that the mean wind speed profiles simulated for the model test are in good agreement with the field measured profiles. The mean wind speed profiles for the coastal terrain are well matched by a simple logarithmic profile with a roughness length z_0 ranged from 0.0027-0.0033m. A power-law exponent (α**)** 0.12 represents a mean value for the profiles over the coastal terrain. The simulated turbulence intensities for the coastal terrain were slightly larger than the measured ones. The mean value of the surface roughness length for the wind tunnel test was 0.03m which was close to the field measured mean value of 0.02m for the open land terrain. The power law exponent (α**)** was found to be 0.16 for this terrain. The model scale Jensen Number ranged from 133 to 1200 which was in accordance with the full-scale Jensen Number. The Reynolds Number based on the full-scale building height is 10^6 while it is 10^5 in the wind tunnel test.

Model and full-scale normalized longitudinal velocity spectra at 10m height are presented in Figure 6 for comparison purposes. Figure 6 shows that the full-scale velocity spectrum measured within the eye-wall region of Typhoon Chanthu follows a Karman-type spectrum in the main frequency range. Meanwhile, the model scale spectra are in good agreement with the full-scale spectrum in the main frequency range, implying that the spectral characteristics of a strong typhoon can be reproduced in the wind tunnel test. There are three interdependent scaling factors; length, velocity and time. The length scaling was fixed by the 1:20 scale model. The mean longitudinal mean wind speed at the reference height of the model test for the coastal terrain and the open land terrain were 7.93m/s and 8.45m/s, respectively. The mean longitudinal wind speed at the reference height of 10m in full-scale was typically between 10 and 40m/s during the typhoons. Thus, the velocity scaling is about 1:5. This means that the sampling period of 6s in the model test is equivalent to a 10min period recording in full-scale.

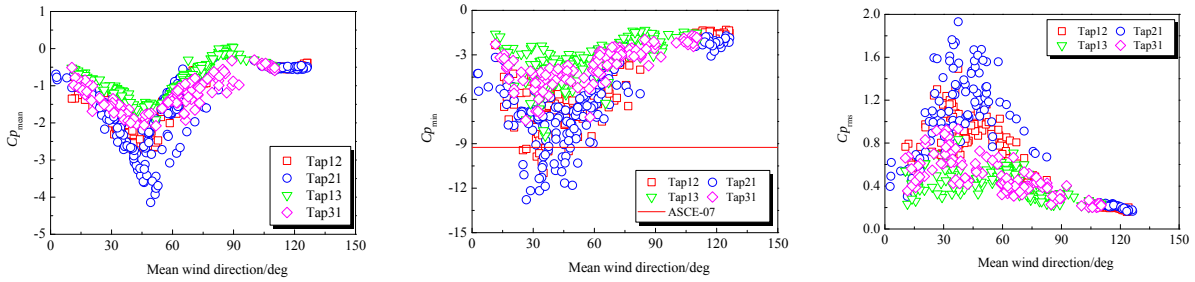
3 PRESSURE RESULTS AND DISCUSSIONS

3.1 *Wind pressures in conical vortex region*

Variations of the mean, negative peak and rms pressure coefficients at the windward leading edge on the corner (Tap12, Tap13 and Tap21, Tap31) with the mean incident wind direction are presented in Figure 7(a) through 7(c), respectively. The mean pressure coefficient distributions for all the taps were similar. The negative peak pressure coefficients and rms pressure

coefficients at Tap12 and Tap21 were consistently subjected to the most severe suction pressures around 20°-60°. The minimum negative peak pressure coefficient at Tap21 was found to be -13.5. Conical vortices were believed to form on the roof corner region, which produced the worst severe suctions on the corner for quartering winds. This observation is consistent with those obtained from other low-rise buildings (Tieleman et al. 1994; Kawai and Nishimura, 1996; Zhao, 1997; Banks et al., 2000; Wu et al., 2001; Blessing et al., 2009). Such extreme suctions occurring on roof corner zones and roof edges are the primary causes of roof damages of low-rise buildings during hurricanes and typhoons (Holmes, 2001).

The availability of the field measurements of wind pressure results from this experimental building provides an excellent opportunity for comparisons with the provisions of wind codes and standards to assess the suitability of the codes of practice. Comparisons between the measured pressures and those derived from ASCE 7-10 Standard (2010) are presented in Figure 7 (b). It should be noted that the pressure coefficients stipulated in the ASCE were determined based on 3 sec gust wind speed. Hence, appropriate transformations are necessary in order to make meaningful comparison with the field results which were determined based on 10 min mean wind speed data. The value determined from ASCE 7-10 Standard is -9.25 for the corner zone, which was converted from -2.8 stipulated in the Standard by consideration of a gust pressure factor of 1.51^2=2.28 (converting 3s gust speed to 10min mean wind speed) and the associated adjustment factor was 1.45 for the reference height and terrain exposure. The pressure coefficients measured at Tap12 and Tap21 on the corner are significantly larger in absolute value than that stipulated in ASCE 7-10 for the corner zone.



(a) Cp_{mean} (b) Cp_{min} (c) Cp_{rms}

Figure 7 Variations of pressure coefficients with mean wind direction for the taps on the roof corner

3.2 *Area-averaged pressure coefficients*

The design wind loads on roof member and cladding stipulated in current codes or standards are made up of the most critical area averaged pressure coefficients specified as functions of tributary area. Area-averaged pressure coefficients and the duration for determination of peak wind loads are key factors for evaluation of wind loads on roof members and claddings.

Firstly, the correlations of pressure coefficient in the corner zone were investigated. The correlations of pressure coefficient indicate how well the pressures are related in space under the conical vortex flow. The correlations between Tap 11, Tap 13, on the short-span leading edge of the roof, and Tap 31, on the long-span leading edge, with the other corner taps are shown in Figure 8. It can be seen from the figure that the pressures at Tap 11 are reasonably correlated with other taps in row 1 (above 0.85 for Taps 12, 13) and are also related to those in column 1 on the diagonally opposite edge (above 0.75 for Taps 21 and 31). In general, it appears that there are higher correlations at most locations in the corner area. These results indicate that both edges are affected by the generation of delta wing vortices. Therefore, the area-averaged pressures on the corner area can be obtained by adding up the pressures measured at all the taps, weighted by the respective tributary areas involved the taps. As an example, corner leading edge area I includes

Tap11, Tap 21 and Tap 31 and corner area II covers the cross-area of row 2 and column 2, while corner area III with 1.44m^2 includes the nine taps marked as the dotted square, as shown in Figure 3.

The variations of the negative peak pressure coefficient at the corner leading edge area I, corner area II and corner area III with the mean wind direction are presented in Figure 9. As expected, the largest peak coefficients in absolute value occurred at the windward leading edge on the corner area zone for wind attacking angles around 20°-45°. The minimum peak negative pressure coefficient on the corner leading edge area I was found to be -9.9 which was slightly larger in absolute value than that stipulated in ASCE 7-10 Standard (2010) for corner zones.

For investigation of the area and time averaged effects on peak pressures, the pressure data on the roof corner zone with 1h record duration under a quartering wind around 45° with mean wind speed 18.3m/s were selected herein as a case study. The effects of time and area average on the negative peak pressure coefficients on the corner zone are presented in Figure 10. The minimum peak pressure coefficients decreased generally with an increase in time average (T). But, the peak pressure coefficients stabilized around 3s average time. As expected, the area averaged peak negative pressure decreased considerably when the area increased.

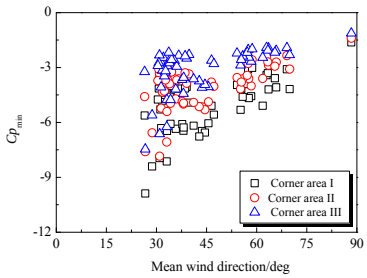

Figure 9. Variation of negative peak pressure coefficients on the corner area with mean wind direction

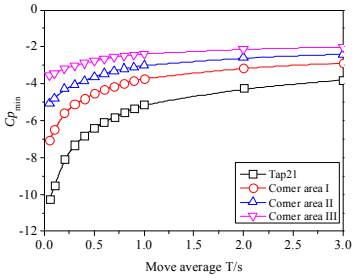

Figure 10. Effects of time and area averaging on negative peak pressure coefficients at Tap21 and in the corner area

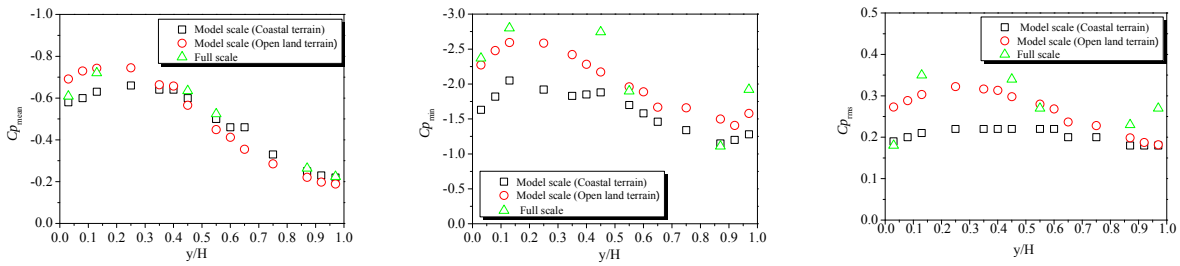
3.3 *Wind tunnel results and comparison with the full-scale measurements*

3.3.1 *Wind pressures coefficients on the roof*

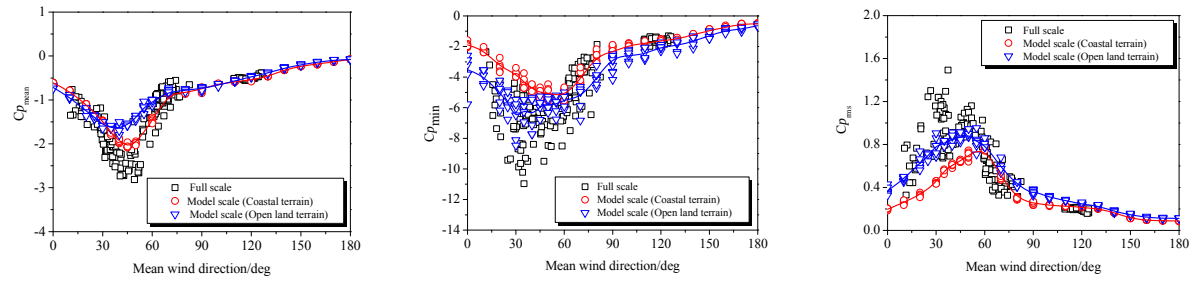
The comparisons of the mean, negative peak and rms pressure coefficient distributions along the mid-plane section across the roof between the full-scale and model-scale tests for an angle of approaching wind of 90° are shown in Figure.11 (a) through 11 (c), respectively. It can be seen from these figures that the model-scale mean pressure coefficients are in good agreement with the field measured values except for the mean pressures coefficients at the leading edge. Moreover, the field measured negative peak and rms pressure coefficients in magnitude at the leading edge are slightly higher than the wind tunnel results. It was found that the field measured peak suction pressure coefficient of -2.85 was observed near the leading edge area of the roof, while the peak suction pressure coefficients were -2.05 and -2.59 observed for the coastal terrain and the open land terrain, respectively. The discrepancies between the model-scale and full-scale negative peak and rms pressure coefficients at the leading edge of the roof may be caused by several factors, such as non-stationary wind characteristics during typhoons and Reynolds number effects etc. These results indicate that wind tunnel tests may underestimate the fluctuating and negative peak pressures at the leading edge of the flat roof under separation bubble.



(a)Cp_{mean} (b)Cp_{min} (c)Cp_{rms}

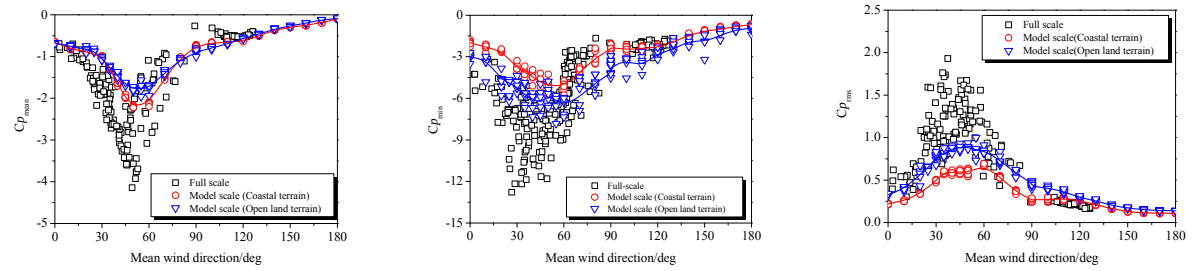
Figure 11. Comparison of pressure coefficients along the centerline on the roof between the field and wind tunnel measurements (at wind direction of 90 degree)

The comparisons between the full-scale and model-scale measurements of the mean, negative peak and rms pressure coefficients at Tap12 are shown in Figure.12 (a) through 12(c). For the mean pressure coefficients, the smoother (coastal) terrain model test results are closer to the full-scale data. High magnitudes of the mean pressure coefficients are observed for angles of attack from 30° to 60°, as shown in Figure 12(a). It is found that the wind tunnel test underestimated the negative peak and rms pressure coefficients in the roof corner region in comparison with the full-scale results for the critical wind angles, as depicted in Figure 12(b) and 12(c). Besides the critical wind direction range (from 0° to 90°), the negative peak and rms pressure coefficients measured in the wind tunnel test for the open terrain are higher in magnitude than the full-scale values. The similar observations were made for Tap21 as shown in Figure13 (a)-13(c). The results displayed in Figures 12 and 13 indicated that the wind tunnel test underestimated the highest fluctuating and peak pressure coefficients near the edges of the roof corner zone under conical vortices. The distinct discrepancies may be attributed that it is difficult to fully simulate the realistic wind characteristics during typhoons in a conventional wind tunnel.



(a) Cp_{mean} (b) Cp_{min} (c) Cp_{rms}

Figure 12. Comparison of the mean, peak and rms pressure coefficients at the roof corner tap12 between the field and wind tunnel measurements

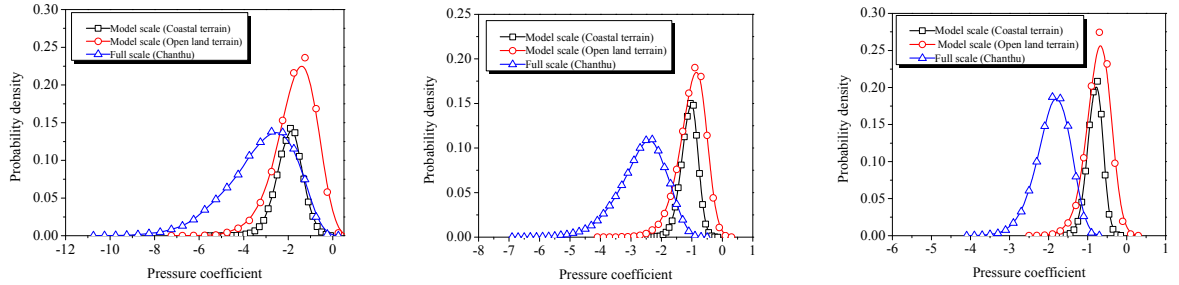


(a) Cp_{mean} (b) Cp_{min} (c) Cp_{rms}

Figure 13. Comparison of the mean, peak and rms pressure coefficients for the roof corner tap21 between the field and wind tunnel measurements

3.3.2 Probability density function

The probability density functions of pressure coefficient for Tap21, corner area I and corner area III obtained from the full-scale measurements and the wind tunnel test for approaching wind direction of 45° were estimated as shown in Figure.14 (a) through 14(c), respectively. It obviously appears that the probability distributions of the field measured pressures at the corner tap and on the corner areas are more highly skew than those of the wind tunnel test, corresponding to skewness to the left. The differences in the tail of the probability density functions indicate that the wind tunnel test underestimate the negative peak pressures. Meanwhile, the probability distributions of the field measured pressures significantly deviate from the Gaussian distribution, demonstrating that the probability distributions of the pressures in a conical vortex flow region are non-Gaussian.



(a)Tap 21 (b) Corner area I (c) Corner area III

Figure 14.Comparison of probability density of pressure coefficient for Tap21, areas I and II between the full-scale and wind tunnel measurements (for wind direction of 45 degree)

3.3.3 Spectral analysis

The representative spectra of fluctuating pressures for Tap21, corner area I and corner area III, which were obtained from the full-scale measurements and the wind tunnel test, are shown in Figure 15(a) through 15(c), respectively. The comparison shows that the field measured spectral amplitudes are higher than these of the model test results for Tap 21. The spectra measured from the open terrain are closer to the full-scale spectra than those obtained from the coastal terrain, implying that the real wind flows were more turbulent than those from the coastal terrain. The agreement of the spectra is better for corner area III than other two cases. This suggests that as the increase of the considered area for determination of wind loads on it, more accurate area-averaged wind pressures may be obtained.

4 CONCLUSIONS

A combined study of field measurement and wind tunnel test was conducted to investigate the wind loads on a low-rise building during typhoons. The major conclusions of this study are summarized as follows:

(1) The windward leading edges on the corner area were consistently subjected to the most severe suction pressures for quartering winds. The measured minimum peak pressure coefficient was -13.5 and the associated minimum peak pressure coefficient at the windward corner leading edge area was -9.9. The measured extreme peak pressures at the windward leading edge area on the corner were significantly larger in absolute value than those from ASCE 7-10 Standard. These findings imply that the peak uplift loads prescribed in ASCE 7-10 for components and cladding may be non-conservative for low-rise buildings during typhoons.

(2) Comparison of the full-scale measurements and wind tunnel test results of negative peak and fluctuating pressure coefficients near the roof corner, roof ridges and roof leading edges showed distinct discrepancies. This implied that the conventional wind tunnel techniques cannot reproduce the highest peak and fluctuating pressure coefficients on roof regions under conical vortices or separation bubbles for extreme wind conditions.

Field measurement of wind loads on low-rise building with adjustable roof pitch

Wang Xu, Huang Peng, Gu Ming

State Key Laboratory of Disaster Reduction in Civil Engineering, Tongji University, Shanghai, China

ABSTRACT: A low-rise building and a tower were constructed near Shanghai Pudong International Airport by East China Sea to study the characteristics of wind field and wind pressure on the roof of the building. The remarkable feature of the test building is that the roof pitch can be adjusted range from 0° to 30°, so that the wind pressure for different roof pitches can be analyzed. In this paper, the time-histories of three pieces of ten-minute wind pressures were analyzed with different roof pitches at 0°, 10° and 20° respectively, and then comparison was done with a wind tunnel test on a rigid model of 1:30 scale. It indicates that distributions of the mean and fluctuating pressure agree well with those of the wind tunnel test results. The non-Gaussian feature of the pressure is investigated. It is shown that there exists a linear relation between the skewness and kurtosis, and the fitting formulae are presented at 0, 10, and 20 pitches.

KEYWORDS: field measurement, test building with adjustable roof pitch, low-rise building, pressure coefficient, wind tunnel test, non-Gaussian.

1 INTRODUCTION

Wind is a part of our daily lives. While wind can be beneficial to humankind's enterprises, it can also be extremely destructive to buildings and other structures we build on the earth[1]. According to the survey of wind hazard, the main reason results in causalities and property losses is the damage and collapse of the low-rise buildings at villages and small towns, especially in China. So it is necessary to improve wind resistance capacity of low-rise buildings based on field measurement and thus reduce property losses attacked by severe wind.

The last three decades of the twentieth century were notable for a number of full-scale studies of wind loads on low-rise buildings. In these studies, advantage was taken of the considerable developments that had taken place in electronic instrumentation, and provided a vast body of data which challenged wind tunnel modeling techniques. In the early 1970s, the BRE(Building Research Establishment) in the UK commenced a program of full-scale measurements on a special constructed experimental building with two stories at Aylesbury, England[2]. The building had the unique feature of a roof pitch which was adjustable between 5°and 45°. In the late 1980s, another famous full-scale experiment on low-rise building was set up in Lubbock, Texas, USA[3,4]. The building had a small steel shed of height, 4.0m, and plan dimensions, 9.1and 13.7m and a near-flat roof. The building had the unique feature of being mounted on a turntable, thus enabling control of the building orientation relative to mean wind direction. Almost at the same time, a new full-scale experiment was commenced in Silsoe, UK[5,6]. The building was a larger steel portal-framed structure, 24m long, 12.9m span, and 4m to the eaves, with a 10 degrees roof pitch, located in open country. The building had unique capacity of being fitted with both curved and sharp eaves. At the beginning of twentieth century, a 6m cube has been constructed at Silsoe Research Institute in an open country exposed position in order to provide a facility for fundamental studies of the interactions between the wind and a structure[7,8]. The building had the feature of the changes in roof pressure brought about by pitching the cube for-

wards by 2.5° and 5°. At the late of 2000s, the researchers from Hunan University in China put forward the idea of removable building and successfully developed field measurement of wind loads on that building[9,10]. The main feature is that the building can be moved to the typhoon landed areas, which makes more opportunities to carry out field measurement during typhoon. The building for field measurement in this paper is built near Shanghai Pudong International Airport by East China Sea. The size of the plane of the building is 10m×6m and the height of the eave is 8m. The feature of this building is that the pitch of roof can be changed. The roof pitch can be adjusted between 0°and 30° by using the lifting device. The architectural appearance of the pitch-changed building is designed according to the common characteristics of the low-rise buildings at villages in Southern China. Therefore, the research results have important significances to the wind resistance study of low-rise buildings in China.

2 THE FULL-SCALE FACILITY

2.1 *Introduction of full-scale building*

Pudong district in Shanghai is the area where strong wind, especially strong typhoons, frequently occurs each year. So a field laboratory had been set up by State Key Laboratory of Disaster Reduction in Civil Engineering of Tongji University to study the turbulence characteristics near ground and wind effects on low-rise buildings in the field. The field laboratory is located on flat area close to the Yangtze river estuary, and in the vicinity of Shanghai Pudong International Airport(see Figure 1). It consists of a test building and a meteorological tower(see Figure 2).This laboratory features many capabilities not found in past full-scale experiments. The notable feature of the test building is that its roof pitch can adjust from 0° to 30°. Figure 3 shows the full-scale building respectively with 0° and 30° roof pitch.

Figure 4 shows the essentials of the design. The hinged design method was used for the connections of the roof and the girder of ridge. With the lifting of girder by two sets of worm and worm wheel, the roof pitch will change correspondingly.

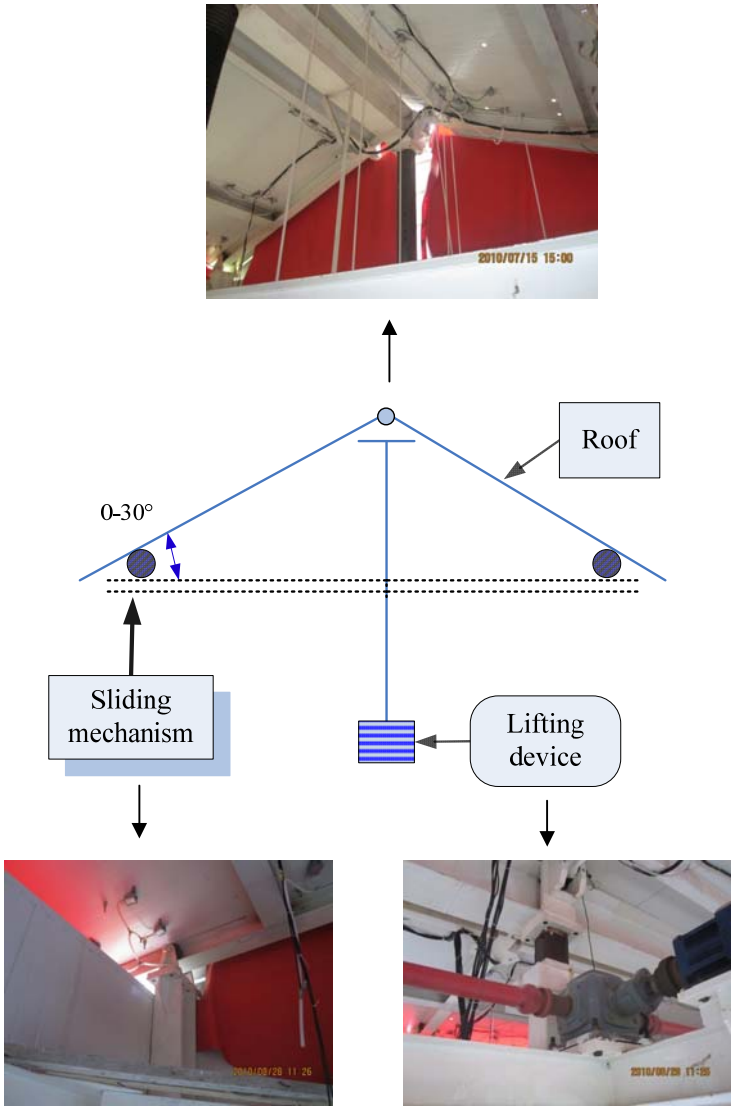

Figure 4. Elevating system

2.2 *Field instruments*

According to the demand of the field experiment, the anemometers type of R.M. Young 81000, R.M. Young 85106, R.M. Young 05305V are installed respectively at the level of 10m, 20m, 30m and 40m, see Figure 5. The sample frequency of R.M. Young 85106 is 1Hz, and those of the other two types are 20Hz. Micro differential pressure sensors supplied by Shuangqiao Sensor measurement and control technology Co. Ltd are installed on the roof of the test building to study local wind pressure in the field. Figure 6 shows the photo of the pressure sensors.

Figure 7 shows the pressure measurement system of field experiment in this paper. A valve is added to prevent rainwater from damaging the sensors.

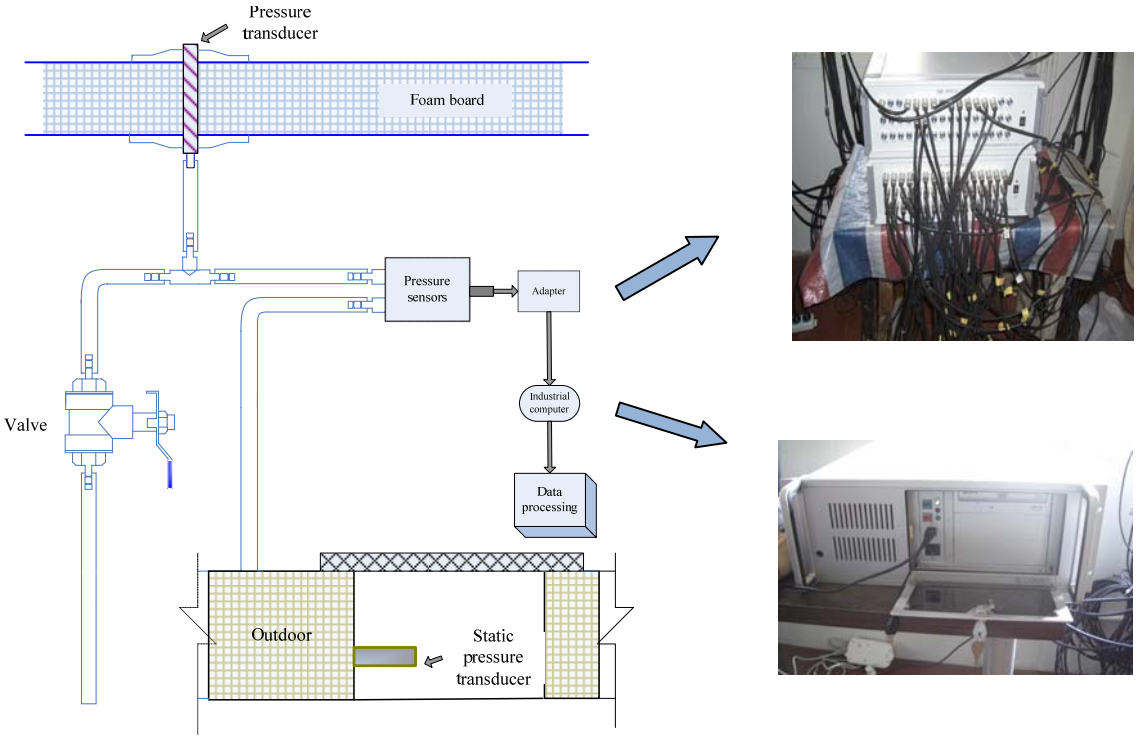

Figure 7. Pressure measurement system

2.3 *Layout of pressure measurements*

Figure 8 shows the positions of pressure transducers, there are ninety-four taps on the roof. There are more pressure transducers installed at north-east corner of the roof than other regions because of the frequently emerge of southeast wind in Shanghai.

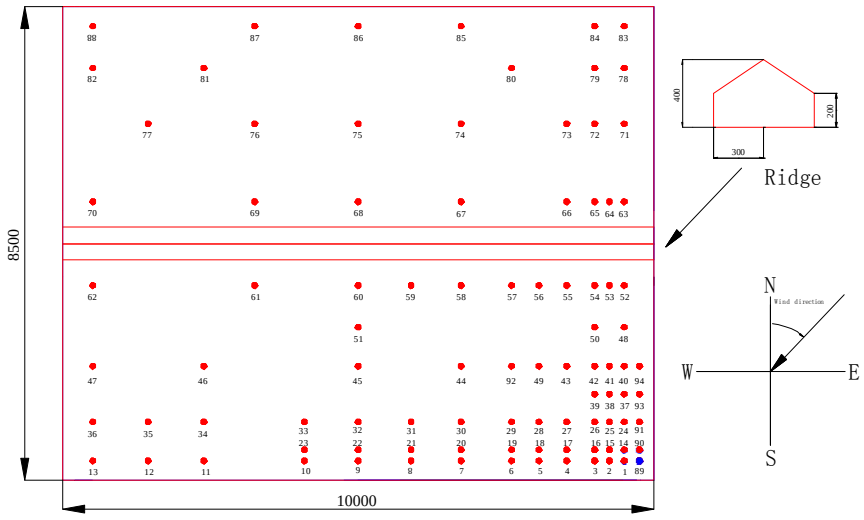

Figure 8. Layout of pressure measurements on test building

3 TEST RESULTS

In order to compare the wind pressure on the roof between full-scale experiment and wind tunnel test, wind tunnel test was made with a rigid model of 1:30 scale based on full-scale test building. The test is carried out in TJ-2 Boundary Layer Wind Tunnel in Tongji University, whose working section is 3m in width, 2.5m in height and 15m in length. Wind condition corresponding to roughness exposure B in the Chinese code [11] is simulated in the wind tunnel at a length scale of 1/50. Table 1 shows the parameters of field measurement and wind tunnel test.

Table 1. Cases of field measurement and wind tunnel test

Parameters	FS1	FS2	FS3	WT1	WT2	WT3
Test type	Full-scale	Full-scale	Full-scale	Wind tunnel	Wind tunnel	Wind tunnel
Scale proportion	1:1	1:1	1:1	1:30	1:30	1:30
Roof pitch	0°	10°	20°	0°	10°	20°
Mean wind speed at eave	8.58 m/s	9.95m/s	9.97m/s	9.02m/s	9.02m/s	9.02m/s
Mean wind direction	41°	34°	43°	40°	35°	45°
Turbulence intensity	0.233	0.158	0.221	0.247	0.245	0.241
Frequency（Hz）	20	20	20	312.5	312.5	312.5
Sample time and data length	10min 12000	10min 12000	10min 12000	38.4s 12000	38.4s 12000	38.4s 12000

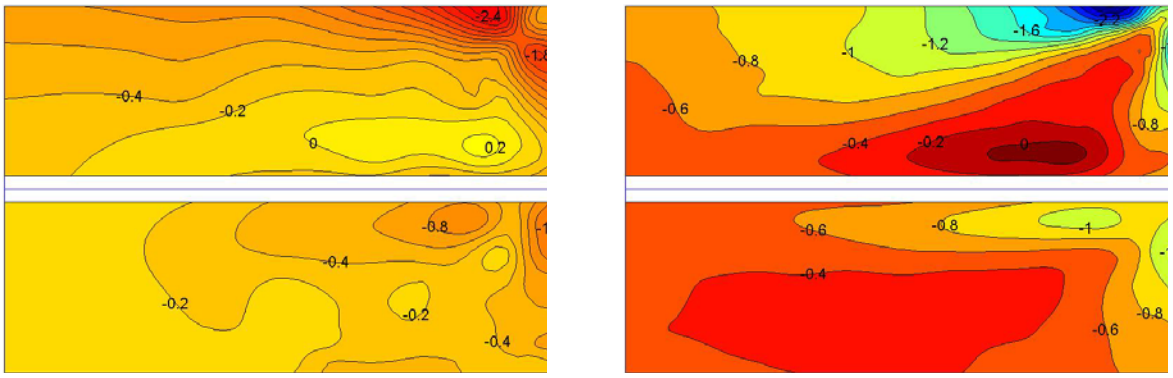
The surface pressure on the body is usually expressed in the form a non-dimensional pressure coefficient[12]. A general time-varying pressure coefficient C_{p_i} is as follows:

$$C_{p_i} = \frac{p_i - p_\infty}{p_0 - p_\infty} \tag{1}$$

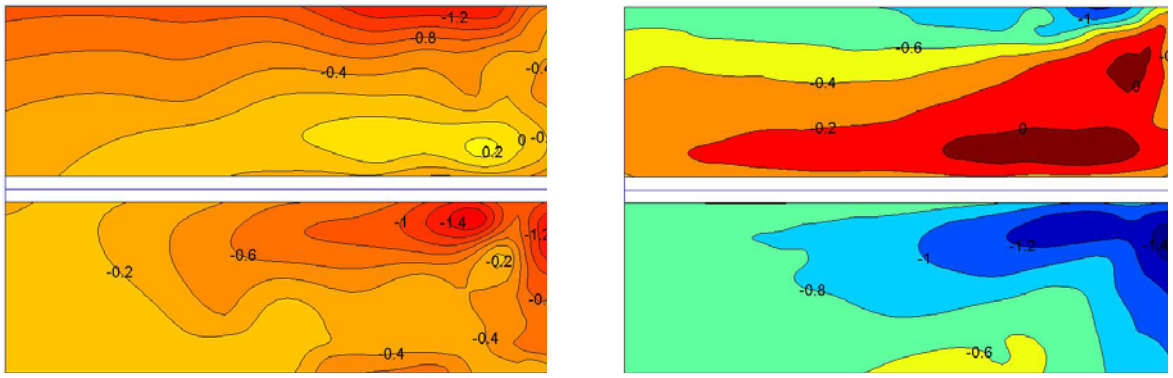
where p_i is the pressure of tap i; p_0 is a total reference pressure; p_∞ is a static reference pressure. In this paper, the mean wind speed was measured at height of the eave of test building.

3.1 *Pressure distribution on roof surface*

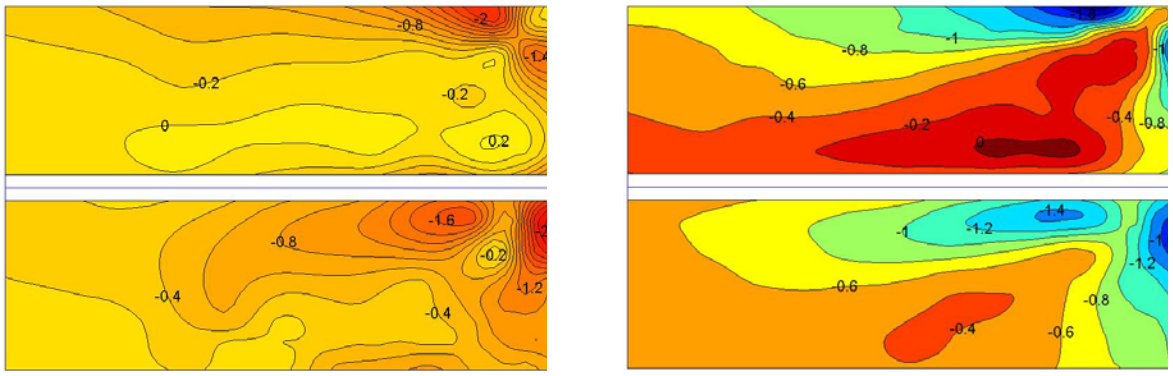
In order to compare the results, Figure 9 shows the contour graph of mean wind pressure on the roof based on two types of experiments, and Figure 10 shows the contour graph of fluctuating wind pressure. It indicates that the distributions of mean and fluctuating pressure agree well with those of the wind tunnel test results. No matter field or wind tunnel experiment, we can see there are two pairs of conical vortices occurred at the windward of roof as well as the backside of ridge. In these regions, negative pressure is larger than that in other regions.



FS1 WT1



FS2 WT2



FS3 WT3

Figure 9. Contours of mean wind pressure coefficients

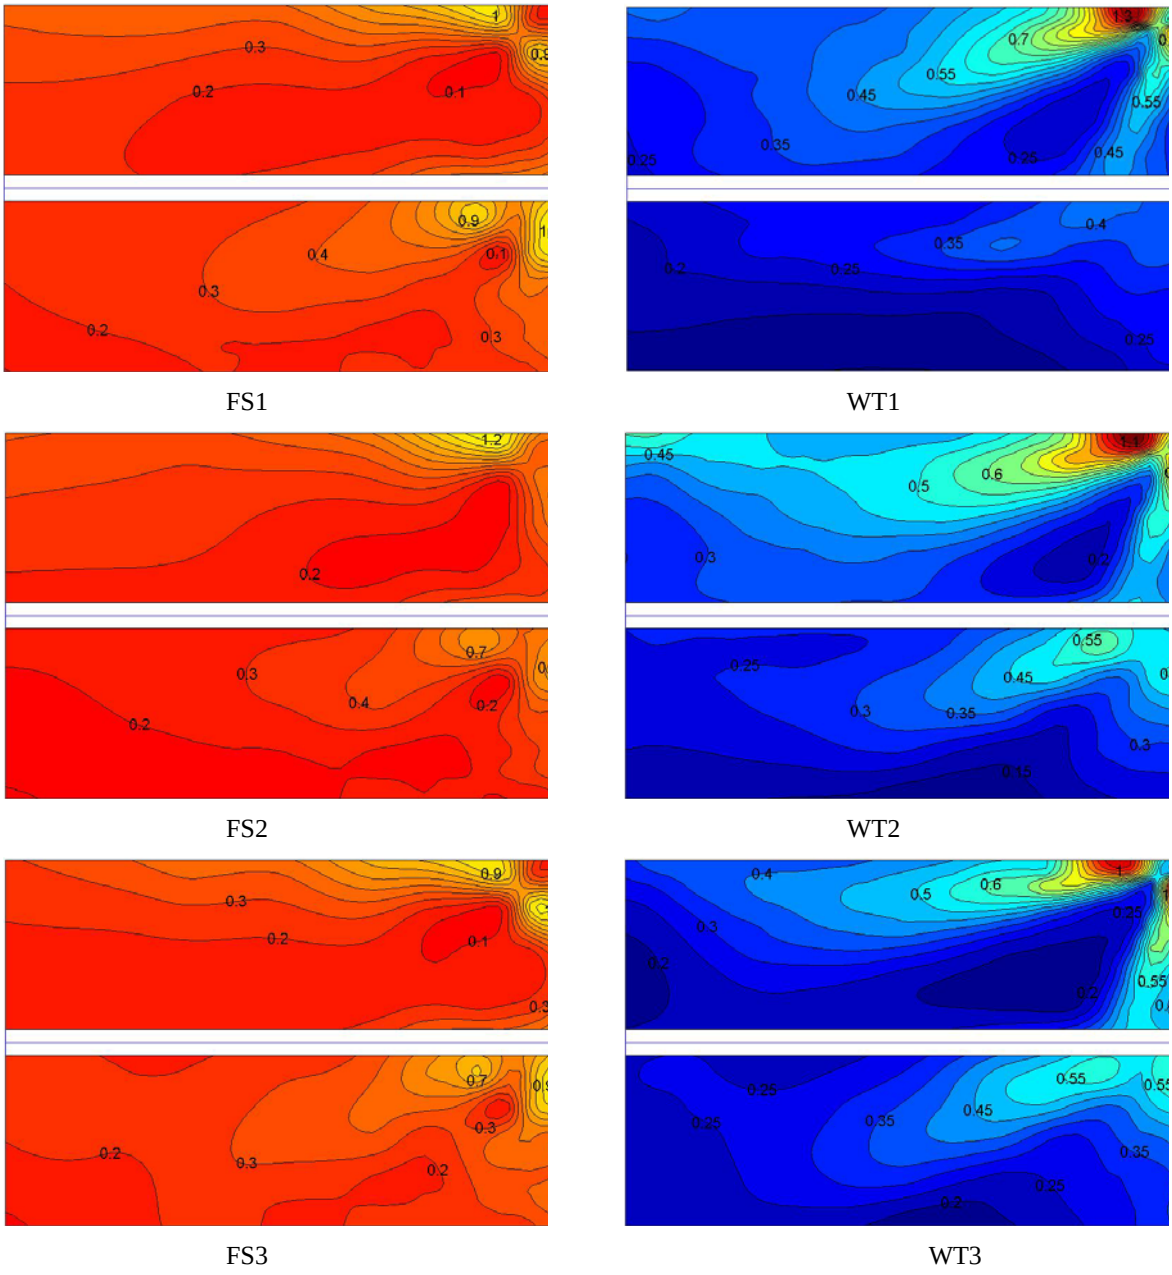


Figure 10. Contours of rms wind pressure coefficients

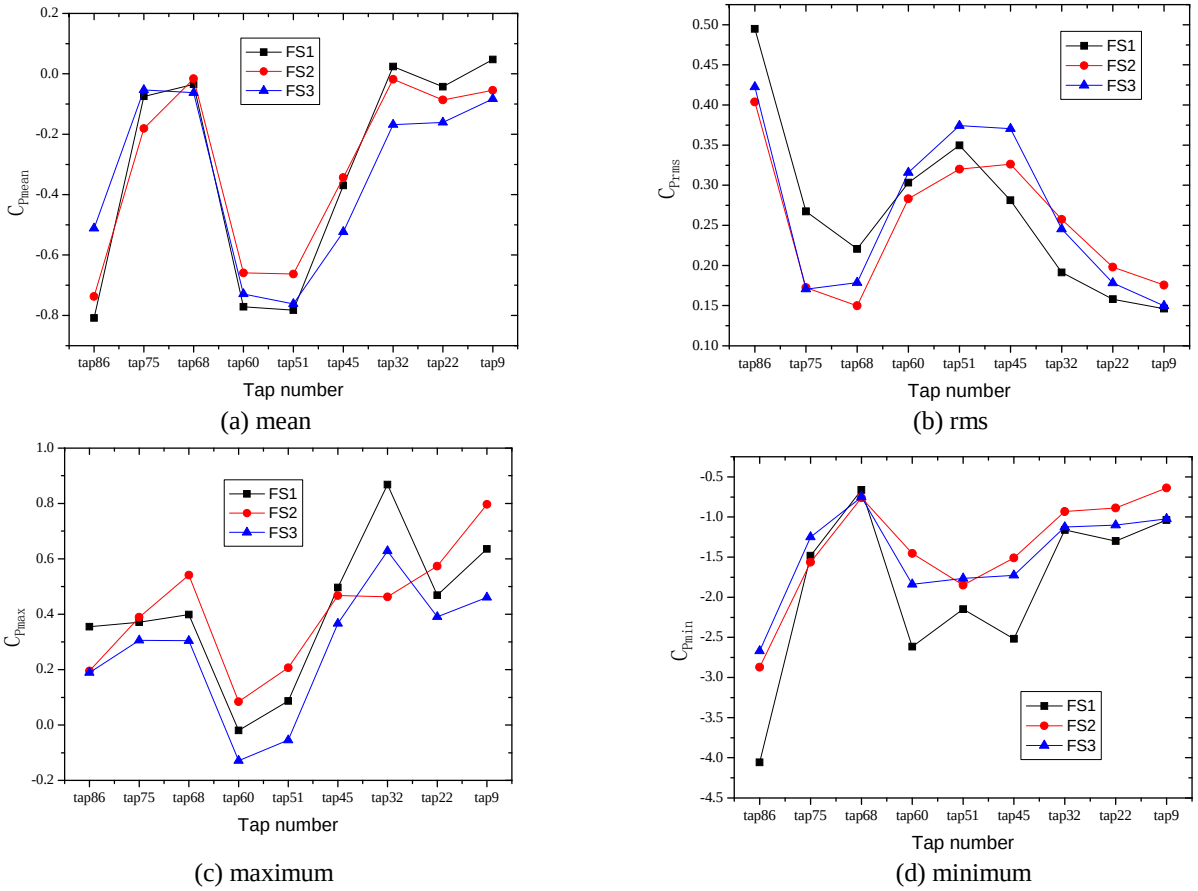
3.2 *Mean and peak wind pressure coefficients along middle line*

In order to study the influence of the roof pitch on the wind pressure, the pressure coefficients of the nine taps along the central line are analyzed, which are taken advantage of the field data FS1, FS2 and FS3 in Table 2. Figure 11 shows the mean, fluctuating and peak values of wind pressure along the middle line changing with the roof pitch. First of all, we can see from Figure 11(a), in the windward region, the mean negative pressure is maximum at the 0 ° and minimum at 20 °, but contrary to the leeward area. The results in Figure 11 (b) is the same as Figure 11 (a), fluctuating wind pressure increases with the roof pitch decreases in the windward region, in contrast to

the leeward regional conclusions. It can be seen obviously from Figure 11(c), the maximum wind pressure at 20° is significantly smaller than these at the other two roof pitch, while Figure 11(d) shows the minimum value is at 0 °. In summary, the roof pitch has a significant influence on the roof surface wind pressure, not only on the mean wind pressure, but also on the fluctuating and peak wind pressure. The wind pressure changes significantly because the air flow pattern and the internal structural properties of vortex on the roof surface vary with the roof pitch.



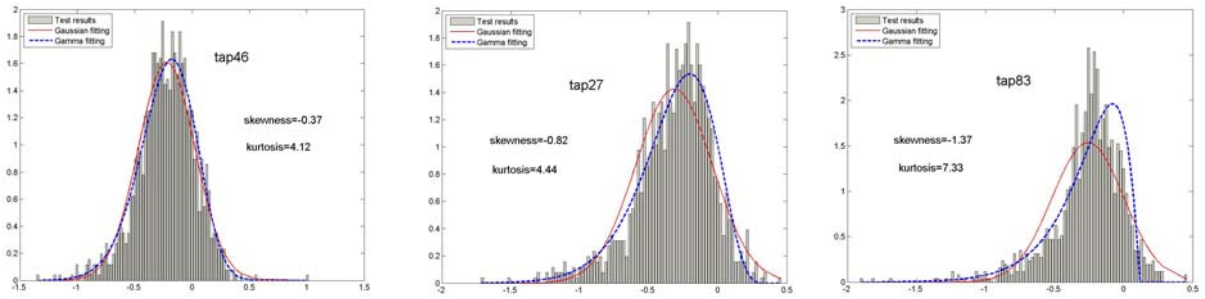
(a) mean (b) rms

(c) maximum (d) minimum

Figure 11. Mean and peak wind pressure coefficients along central line

3.3 *Non-Gaussian features of fluctuating wind pressure*

The assurance of safety and reliability of buildings requires estimation of the extremes of the applied load effects. If the statistical description in a system differs significantly from Gaussian, conventional methodologies with implicit assumption of Gaussian may no longer be valid requiring a non-Gaussian estimation framework. This is particularly important when considering the extremes, which are sensitive to the tail regions of the probabilistic description of non-Gaussian processes. For instance, the local pressure fluctuations measured at corners as well as other separation flow regions of roofs of low buildings are found to be highly non-Gaussian [13,14]. Thus, it is necessary to carry out the study on non-Gaussian features of fluctuating wind pressure.



(a) (b) (c)

Figure 12. Probability distribution of wind pressure

Due to space limitation, only the probability distribution of fluctuating pressure for typical measured taps under working condition of FS1 has been given in Figure 12. We can see the local fluctuating pressure measured at the windward of the roof as well as the backside of the ridge is found to be highly non-Gaussian. The absolute value of skewness and kurtosis in these regions are obviously larger than that in other regions. The probability distribution of fluctuating pressure agrees well with Gaussian processes when skewness is larger than -0.5, and has better agreement with Gamma distribution when the value of skewness is between -1 and -0.5, nevertheless neither of the distributions is in accordance with the measured data.

The value of skewness and kurtosis are sensitive to the tail regions of the probabilistic distribution of non-Gaussian processes, and the relation between skewness and kurtosis is very important for the study on the extremes of the applied load effects. Figure 13 shows the relation between the measured results. It shows that there is a linear relation between the skewness and kurtosis, and the fitting formulae are presented between skewness and kurtosis at 0°, 10°, and 30° pitches. To evaluate the precision of the fitting functions, the theoretically calculated and the fitted values of kurtosis in all work cases are also compared in Figure 13. It can be seen from Figure 13 that the fitted values can be reliably used for evaluating the theoretically calculated values.

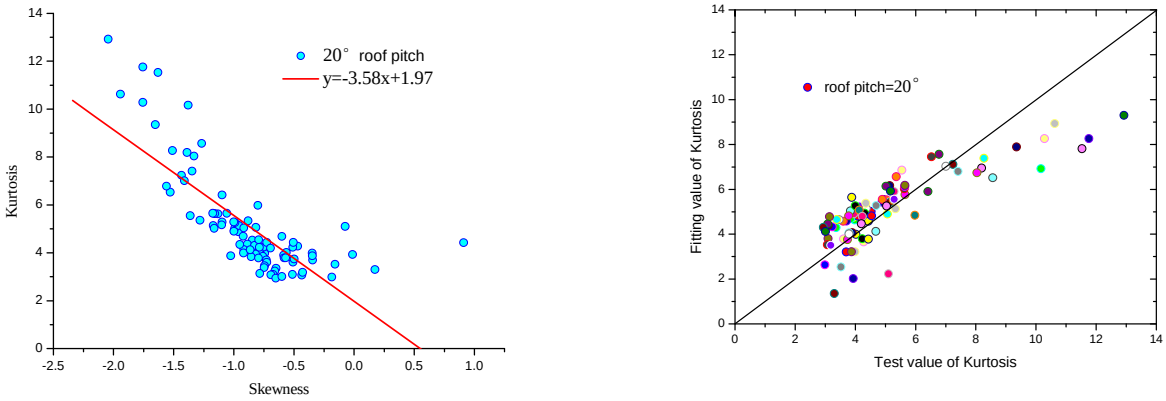
(b) roof pitch=10°



(c) roof pitch=20°

Figure 13. Variation of skewness with kurtosis

4 CONCLUSIONS

The characteristics of wind pressure on the roof of the test building are studied. The main results are as follows:

(1) The trend of average and fluctuating wind pressure distribution tested by the filed measurement is consistent with that by wind tunnel test.

(2) The probability distribution of fluctuating pressure agrees well with Gaussian processes when the skewness is larger than -0.5, while has better agreement with Gamma distribution when the value of skewness is between -1 and -0.5, nevertheless neither of the distributions are in accordance with the measured data.

(3) There exists a linear relation between the skewness and kurtosis, and the fitting formulae are presented between skewness and kurtosis with 0, 10, and 30 pitches, which will be helpful to the calculation of the extreme of wind pressure.

Wind-induced torsional aerodynamic loads on low and medium height buildings

M. Elsharawy, T. Stathopoulos and K. Galal

Faculty of Engineering and Computer Science, Concordia University, Montréal, QC, Canada

ABSTRACT: Since there is limited information about wind-induced torsional loads on buildings, wind tunnel tests were carried out on a series of buildings with low and medium heights. Four buildings (scale 1:400), having the same horizontal dimensions but different heights (6, 12, 25 and 50 m), were tested in a simulated open terrain exposure for different wind directions (i.e. from 0^o to 180^o every 15^o). The synchronized wind pressure measurements on the rigid building model allowed estimating the instantaneous shear forces and torsional moments. All results were normalized and presented in terms of mean and peak values of shear and torsional coefficients representing two load cases (torsion and shear load). Furthermore, the experimental results were compared with the existing torsion- and shear-related provisions in the National Building Code of Canada (NBCC 2010), the American Society of Civil Engineers Standard (ASCE/SEI 7-10) and the European Code (EN 1991-1-4). The results demonstrated significant discrepancies among the provisions of these wind standards from one side and the wind tunnel results from another in evaluating torsional wind loads on low and medium height buildings. The findings of this study could assist to improve the analytical methods to evaluate wind-induced torsional loads on low and medium height buildings.

KEYWORDS: Torsion, wind loads, codes, low buildings, medium height buildings, structural design

1 INTRODUCTION

The common characteristics of wind-induced loads on building envelopes continuously vary in temporal and spatial dimensions. The variation of local wind pressures on building claddings and the total effective wind forces (base shear/overturning moment) on the main structural building systems of low and medium rise buildings have been investigated extensively in the past few decades (Krishna, 1995, Stathopoulos and Dumitrescu, 1989, and Sanni et al, 1992). However, studies on wind-induced torsional loads on low and medium height buildings are very limited. Discrepancies have been found when wind-induced torsional load provisions for low and medium height buildings in three well known building codes and standards (American, Canadian, and Eurocode) were compared by Elsharawy et al. 2011. Wind-induced torsion has been measured in the wind tunnel for three low-rise buildings with different aspect ratios (length/width = 1, 2, and 3) in open terrain exposure by Isyumov and Case, 2000. The study suggested that applying partial wind loads, similar to those implemented for the design of tall buildings, would improve the design of low buildings until more pertinent data become available. Recently, three low rise buildings having the same horizontal dimensions but different roof angles (0^o, 18.4^o, and 45^o) located in open terrain exposure were tested by Elsharawy et al. 2012. The results were also compared to the current wind load provisions and it was found that the American standard introduces torsional moment in line with the experimental data, while the Canadian and Eurocode provisions underestimate the torsional moment on low buildings.

In the current study, wind-induced torsional loads on low and medium height buildings were examined in the boundary layer wind tunnel. Building model (scaled at 1:400) has been used to represent four actual buildings having the same horizontal dimensions but with different heights. All buildings were tested in open exposure for different wind directions. The synchronized wind tunnel measurements were presented in terms of shear, and torsional coefficients. Furthermore, the experimental results were compared with wind provisions in the NBCC 2010, ASCE/SEI 7-10 and EN 1991-1-4.

2 WIND TUNNEL STUDIES

All experiments were carried out in a boundary layer wind tunnel with a working section approximately 12.2 x 1.80 m and an a adjustable roof height ranging between 1.4 and 1.8 m. A turntable of 1.2 m diameter is located on the test section of the tunnel and allows testing of models for any wind direction. A new automated Traversing Gear system has been installed to give the capability of measuring wind characteristics at any spatial location around a building model inside the test section. A geometric scale of 1:400 has been recommended for the simulation of the most important variables of the atmospheric boundary layer under strong wind conditions.

2.1 Building models

The basic building model used for the experiments was fabricated from plexiglass and scaled at 1:400. Figure 1 shows the model and the location of 146 pressure taps on its side walls. The roof does not have any pressure taps, since the uplift force does not contribute to torsion or horizontal shear forces. The model was tested at different building heights representing four actual buildings with heights (6, 12, 25 and 50 m). Model dimensions and the tested building heights are given in Table 1.

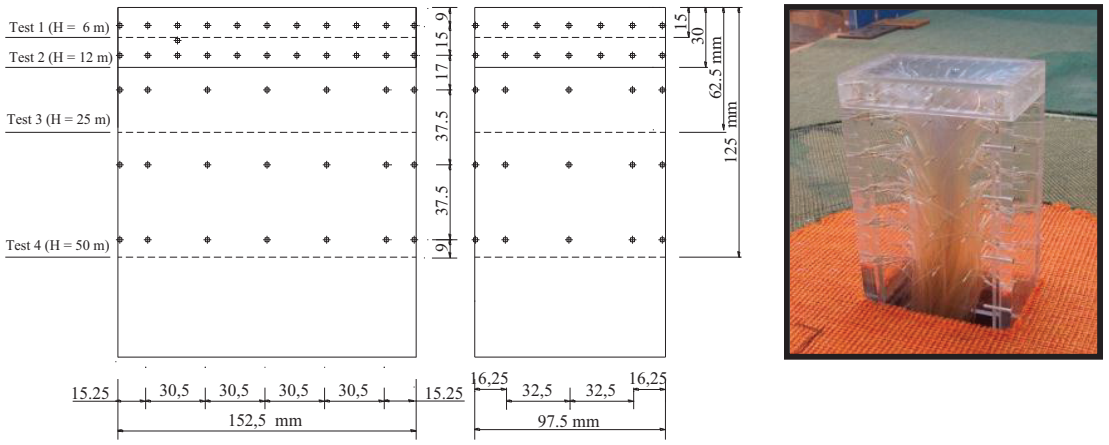

Figure 1. Building model and 146 pressure taps location.

Table 1. Model dimensions and Building heights tested

Building	Dimensions	
	Scaled (1:400, mm)	Actual (m)
Width (B)	97.5	39
Length (L)	152.5	61
Tested heights (h)	15, 30, 62.5, 125	6, 12, 25, 50

2.2 Terrain simulations

An open-country exposure was simulated in the wind tunnel. Figure 2 shows the flow approach profiles of mean wind velocity and turbulence intensity measured using a 4-hole Cobra probe (TFI) for the simulated terrain exposure. The gradient wind velocity is 13.6 m/s at a height of z_g=70 cm. The power law exponent for the wind velocity profiles simulated in these tests was 0.16. Although, it is not common for medium height buildings to be situated in open terrain, this exposure was used as a kind of conservatism since higher loads are expected to act on buildings. The pressure measurements on the models were conducted using a system of miniature pressure scanners from Scanivalve (ZOC33/64Px) and the digital service module DSM 3400. All measurements were synchronized with a sampling rate of 300Hz on each channel for a period of 27 sec (i.e. about 1 hour in full scale).

2.3 Analytical approach

Figure 3 shows a schematic representation of external pressure distributions on building envelope at a certain instant, the exerted shear forces (F_X, F_Y) and torsional moment (M_T). Pressure measurements are scanned simultaneously. The instantaneous wind force at each pressure tap is calculated according to

$$f_{i,t} = (p_{i,t} \times A_{effective}) \qquad f_{j,t} = (p_{j,t} \times A_{effective}) \qquad (1)$$

where $P_{i,t}$, and $P_{j,t}$ are instantaneous pressures measured at each pressure tap. The wind forces exerted at pressure tap locations in X- and Y-directions are noted by $f_{i,t}$ and $f_{j,t}$, respectively. For each wind direction, the horizontal force components in X- and Y-directions, and the total base shear, are evaluated according to

$$F_X = \sum_{i=1}^{N} f_{i,t} \qquad F_Y = \sum_{j=1}^{M} f_{j,t} \qquad V = \sqrt{F_X^2 + F_Y^2} \qquad (2)$$

where N and M are the numbers of the pressure taps on the longitudinal and transverse directions, respectively. All these forces are normalized with respect to the dynamic wind pressure at the mean roof height as follows:

$$C_{vx} = \frac{F_x}{q_h B\, h} \qquad C_{vy} = \frac{F_Y}{q_h B\, h} \qquad C_V = \frac{V}{q_h B\, h} \qquad (3)$$

Where q_h = dynamic wind pressure at mean roof height (kN/m^2), B = minimum horizontal building dimension (m), and h = mean roof building height (m). The torsional coefficients (C_T) and equivalent eccentricity (e) are evaluated based on

$$C_T = \frac{M_T}{q_h B\, h\, L} \qquad e(\%) = \frac{M_T}{L * V} \times 100 \qquad (4)$$

where L= building length

NBCC 2010 specifies wind loads on low buildings (mean roof height, h < 10 m, or h < width, B and h < 20 m) and medium-height rigid buildings (h < 60 m, h/B < 4, lowest natural frequency, f_n > 1 Hz). On the other hand, ASCE/SEI 7-10 identifies low buildings as (h < 18 m and h < B) and medium-height rigid buildings as having f_n > 1 Hz. In EN 1991-1-4, low buildings were defined as those with h < 15 m while buildings with frames, structural walls with h less than 100 m are introduced structurally as rigid buildings. In this study all tested buildings were assumed to be structurally rigid and follow the limitations stated in the three wind load standards.

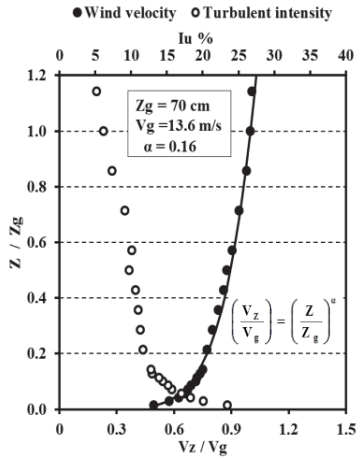

Figure 2. Wind velocity and turbulence intensity profiles for open terrain exposure.

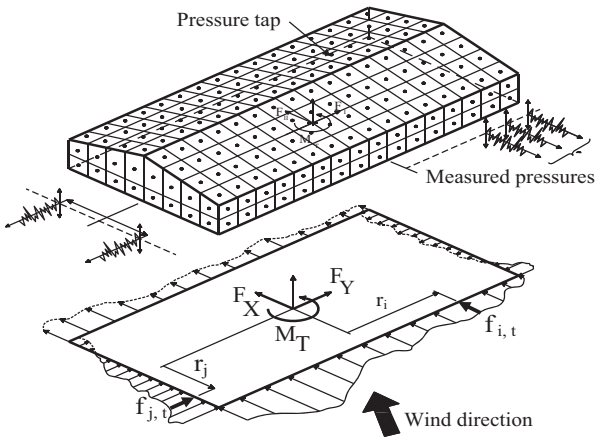

Figure 3. Instantaneous wind pressure distributions, generated wind forces (F_X, F_Y) and torsional moment (M_T).

3 COMPARISON WITH PREVIOUS STUDIES

A comparison with a previous study by Amin and Ahuja, 2012 for building (L = 37.5, B = 15, h = 90 m, scale 1:300, 140 pressure taps) was made using the wind tunnel measurements for building model (L = 61 m, B = 39 m, h = 50 m, scale 1:400, 146 pressure taps). Figure 3 shows the evaluated mean torsion for both buildings for different wind directions. The mean torsion coefficient was calculated based on the following formula

$$C_{T\,Mean} = \text{Mean Base Torsion} / (q_h BhL) = (\sum_{i=1}^{i=n} C_{P\,\text{Mean}}\ x\ A_{effective}\ x\ r_i) / BhL \qquad (5)$$

Where n=number of pressure taps, $C_{P\ Mean}$ = mean pressure coefficient, $A_{\ effective}$= presented area by the pressure tap, r_i = the distance between pressure tap and the building center.

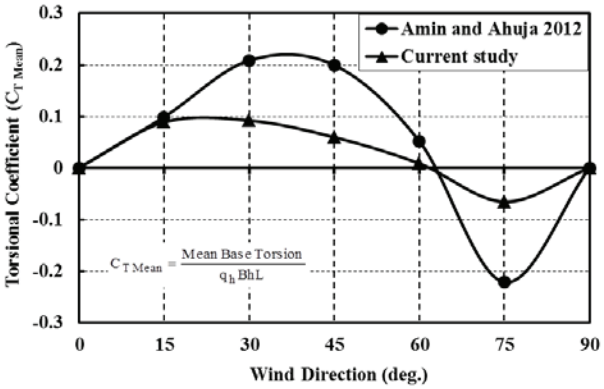

Figure 3. Mean torsional coefficient measured by Amin and Ahuja, 2012 and the current study

Data show relatively good agreement for the variation of the mean torsional coefficient measured in the two studies. The differences seen between the two studies for some wind directions may be attributed to the difference in building dimensions, the scale used, the number of pressure taps.

4 EXPERIMENTAL RESULTS

4.1. Variation of torsion and shear coefficients:

Figure 4 shows the variation of mean and peak shear coefficients (C_{vx}, C_{vy}) with wind direction for the two buildings (6 and 50 m) tested in simulated open-country exposure. The maximum shear forces in x-direction occur for wind directions from 0^o to 45^o; while in y-direction when wind is almost perpendicular to building face, i.e. 90^o. For the tested buildings, the peak shear coefficients have increased by about 50% with increasing building heights form 6 to 50 m.

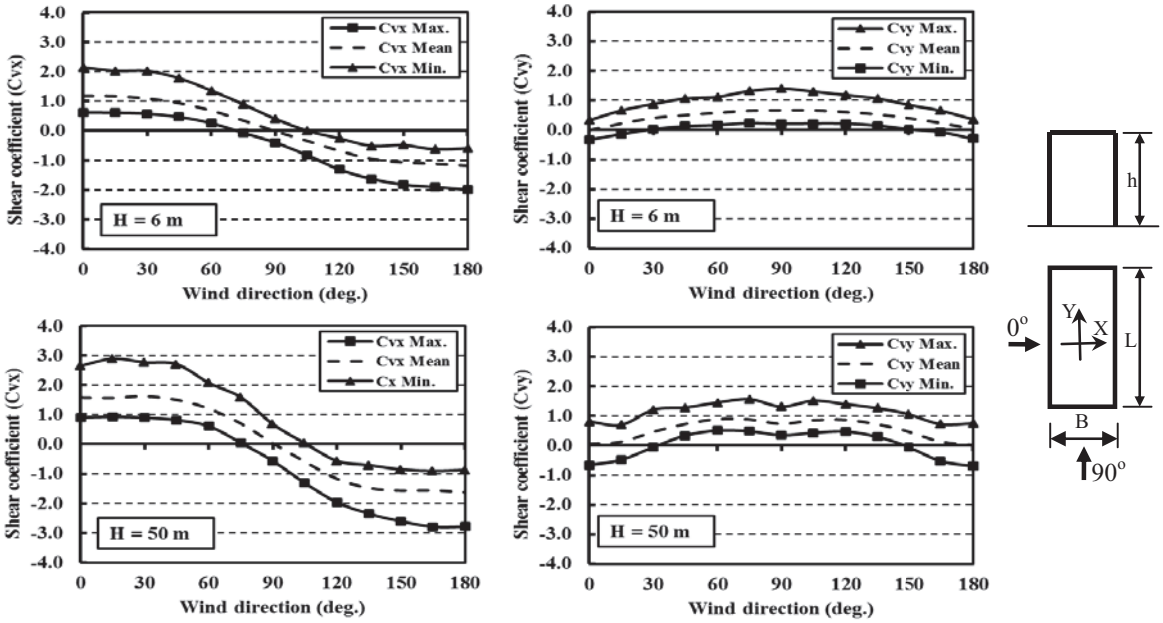

Figure 4. Variation of shear coefficients (C_{VX}, C_{VY}) with wind direction for building models corresponding to 6 and 50 m heights.

Although, the determination of the shear coefficient is important to propose equivalent wind loading, identification of horizontal distribution of these wind loads on building structural system still requires information about the torsional moment. The variation of mean and peak torsional coefficients with wind direction is presented in Figure 5 for buildings (6, 12, 25, and 50 m) in open-country terrain exposure. As a result of the building models having symmetric shapes, mean torsions are zero for wind directions perpendicular to building face, i.e. 0^o and 90^o. However, there are significant maximum and minimum torsional coefficients for these wind directions due to the lack of wind pressure correlation over the building envelope in the horizontal direction. The maximum torsional moment occurs for wind directions from 15^o to 45^o for the first three buildings (6, 12, 25 m) while for the 50 m building, two peaks appear at wind directions 30^o and 75^o. This may be attributed to different characteristics of wind flow interactions with buildings with height lower than 25 m compared to buildings with heights greater than 25 m. For better understanding in this regard, a flow visualization study is scheduled as a part of future tasks in the current research project.

4.2. Most critical torsion and shear coefficients

As it is very well known, the distribution and the magnitude of wind forces on building envelope are linked to the magnitude of torsional moment. Therefore and based on the wind tunnel measurements, two load cases are presented. Case A shows maximum torsion ($C_{T\ Max.}$) and corresponding shear ($C_{V\ Corr.}$) while Case B shows maximum shear ($C_{V\ Max.}$) and corresponding torsion ($C_{T\ Corr.}$). For simplicity, torsional loads can be treated analytically by introducing wind forces (V) with equivalent eccentricity (e) as shown in Figure 6. Tables 2

and 3, for Case A and Case B, show the evaluated coefficients for the critical wind directions for which the maximum torsion and shear were measured. For the 50 m building height, the most critical torsional moments have been measured for wind azimuths 30^o and 75^o. Thus, it quite significant for the wind provisions to cover these critical torsions for achieving the anticipated proper design for low and medium height buildings.

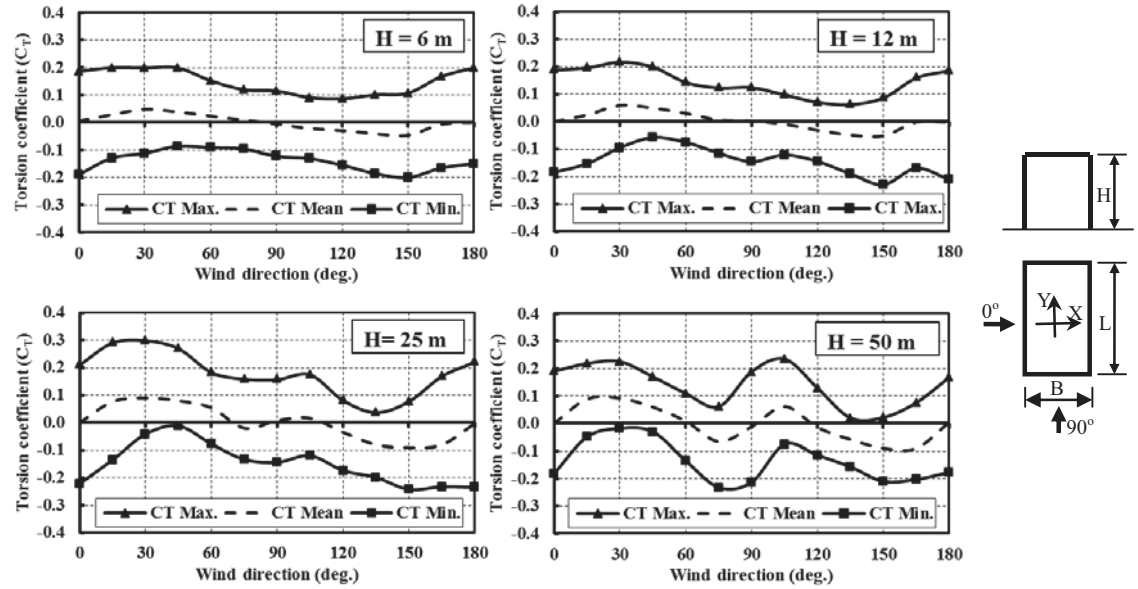

Figure 5. Variation of mean and peak torsion coefficients with wind direction for four different building heights (6, 12, 25 ,and 50m)

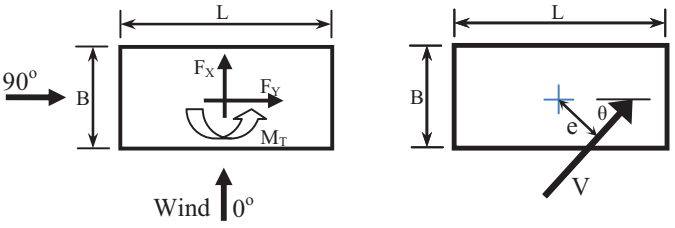

Figure 6. Horizontal wind force and torsional moment and its equivalent eccentric force.

The maximum equivalent eccentricity has been reported of about 16% of building largest horizontal dimension for building with height 50 m. The maximum ratio between the corresponding shear (associated to maximum torsion, Case A) to the maximum base shear (full load - Case B) was 74% for the 25 m high building. As indicated in many past wind tunnel studies, wind-induced torsion always exists even for wind direction for which the maximum full shear force occurs. The current study demonstrates that maximum shear is mostly associated with equivalent eccentricity about 5%. This is in line with the following statement given in ASCE/SEI 7-10, (Commentary part, C27.4.6),

> "*...wind tunnel studies often show an eccentricity of 5% or more under full (not reduced) base shear. The designer may wish to apply this level of eccentricity at full wind loading for certain more critical buildings even though it is not required by the standard. The present more moderate torsional load requirements can in part be*

justified by the fact that the design wind forces tend to be upper-bound for most common building shapes."

Table 2. Case A: Maximum torsion ($C_{T\,Max.}$) and corresponding Shear ($C_{V\,corr.}$)

Building height (m)	Wind tunnel measurements				
	Wind azimuth	$C_{T\,Max.}$	$C_{V\,Corr.}$	θ	*e (%)*
6	30^o	0.20	1.40	89.90^o	14.20

5 INSTANTANEOUS WIND FORCES ON BUILDING SURFACES

The wind flow characteristics (i.e. attached flow, separation, and reattachment) around buildings are critical for the determination of torsional moment (M_T). The non-uniform distribution of the generated wind loads in the horizontal directions is the main reason for generating torsional moment. Figure 7 shows measured integrated wind forces on building with height 25 m in X and Y axes for the critical wind directions, i.e. 0^o, 90^o, and 30^o as the peak torsional moment occurs.

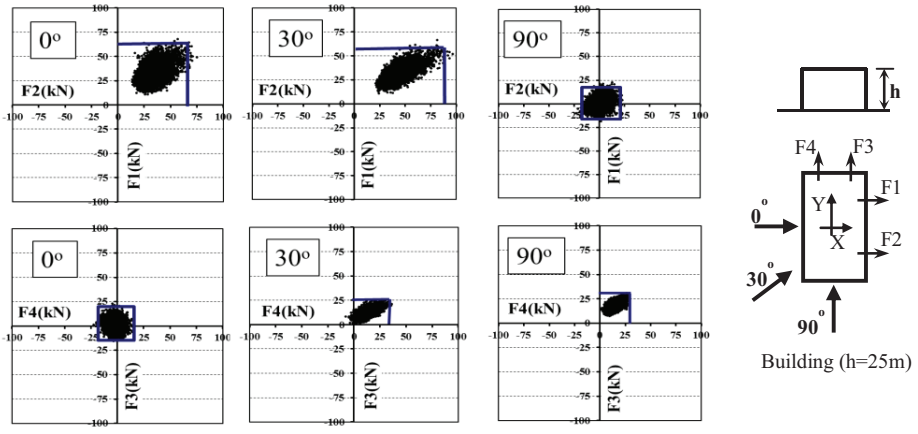

Figure 7. Horizontal forces in X and Y directions for azimuths 0^o, 30^o, and 90^o for which maximum torsions were measured for building with height = 25 m.

Since all buildings have symmetric shapes and structural systems, the center of rigidity is located at the middle of building plan. Identification of the wind forces (F1 to F4) around the vertical building axis may allow better understanding for the relation between the generated torsion and wind direction. In case of perpendicular wind (0^o and 90^o), the forces (F1 and F2) vary with the same magnitude ranges and the trend line for these values has almost slope 1:1, and the correlation coefficient is very small (0.003). Similarly, the F3 and F4 values vary in

the same manner for the same wind directions. This justifies the fact of the zero mean-torsion measured while having relatively maximum and minimum torsions for these wind directions. For wind direction 30^o, the magnitude range of (F_2) generated on the side close to wind is about double the force range of (F_1) generated on the far side. The trend line for the F1 and F2 values has slope equal to 2:3 while the correlation coefficient is 0.38. Accordingly, this could explain why the maximum torsion occurs for wind direction 30^o.

6 CODE PROVISION COMPARISONS WITH WIND TUNNEL RESULTS

The results of the wind tunnel tests (Case A and Case B) for the tested building heights were compared to the values for base shear force and torsional moment evaluated by NBCC 2010, ASCE/SEI 7-10 and EN 1991-1-4.

6.1. NBCC 2010

In NBCC 2010, the static method (called herein NBCC 2010-S1) is introduced for low buildings while the simplified method (called herein NBCC 2010-S2) is proposed for rigid buildings with intermediate height. The static method calculations for the torsional and shear coefficients were derived based on figure I-7 of NBCC 2010, Commentary I, where the external peak (gust) pressure coefficients (C_pC_g) are provided for low buildings. Likewise, for the simplified method, the external pressure is taken from Figure I-15, Commentary I. Partial and full load cases were considered to estimate maximum torsion and corresponding shear, as well as maximum shear and corresponding torsion. Calculations were carried out considering the open terrain exposure. Static method values were increased by 25% to eliminate the implicit reduction (0.8) due to directionality issue.

6.2. ASCE/SEI 7-10

The three analytical procedures stated in ASCE/SEI 7-10 to evaluate wind loads were applied for this comparison. The envelope method (ASCE 7-10-E) appropriate for low buildings ($h < 18$ m and $h < B$) where h and B are the mean roof height and the least horizontal dimension respectively, figure 28.4-1 is used to get the external pressure coefficients (GC_{pf}). The basic (transverse) and torsional load cases presented in ASCE 7-10, figure 28.4-1 are used to estimate the maximum torsional moment and the maximum base shear. Directional methods-Part 1 and Part 2 (called in this paper ASCE 7-10-D1 and ASCE 7-10-D2), proposed in ASCE/SEI 7-10 to be used for all building heights, are also considered in this comparison. External pressure coefficients were collected from figure 27.4-1. Pressure coefficients are provided in table 27.6-1 for buildings with height up to 48.8 m. ASCE 7-10 calculations were carried out considering the open terrain exposure C. Also, the directional factor was taken as 1.

6.3. EN 1991-1-4

The Eurocode defines one unified analytical method that can be used for predicting the wind forces on all building types regardless of height. Torsional effects are taken into account by applying non-uniform pressures and forces, as shown in EN 1991-1-4, Figure 7.1. A triangular wind load is applied on the windward surface with a rectangular load on the leeward face of the building. External pressure coefficients for vertical walls of rectangular plan buildings are calculated using Figure 7.5 and Table 7.1 available in section 7, while for the external pressure of duo-pitch roofs, values are provided in the same section (Figure 7.8 and Table 7.4a).

All ASCE/SEI 7-10 values were multiplied by 1.51^2 and EN 1991-1-4 values by 1.06^2 in order to consider the effect of the 3-sec and the 10-min wind speed respectively in comparison to the mean-hourly wind speed in NBCC 2010.

Figure 8 summarizes the results for Case A (see Table 2). Peak torsional coefficients, corresponding shear, and equivalent eccentricity are evaluated either by the wind tunnel study or by the provisions of standards considered. Case B (see Table 3) comparison results, maximum shear, corresponding torsion and equivalent eccentricity are presented in Figure 9.

In the first instance, European code shows very good agreement with torsions measured in the wind tunnel for low and intermediate height buildings, see Figure 8. However, the applied wind load (i.e. corresponding shear) and the corresponding equivalent eccentricity are different from the measured values, given that torsional coefficients are always products of force coefficients times eccentricities. For low buildings, the envelope method in ASCE/SEI 7-10 shows relatively good agreement with the measured torsion, although decreasing the eccentricity from about 18% to 15% will improve its performance. Also, the static method in NBCC 2010 underestimates torsion on low buildings significantly. On the other hand for medium height buildings, the wind load procedures in the NBCC 2010 and the ASCE/SEI 7-10 overestimate torsion in some case significantly. Regarding Case B, Figure 9 indicates clearly that the static and envelope methods for low buildings in NBCC 2010 and ASCE/SEI 7-10 respectively succeed to predict maximum shear forces. All other methods in the three provisions overestimate shear forces on low and medium height buildings, as shown in Figure 9. Based on the results presented in Figures 8 and 9, it could be recommended that applying 75% of the full wind loads (i.e. maximum shear measured in Case B) with equivalent eccentricity 15% will improve torsion evaluation for low and medium height buildings.

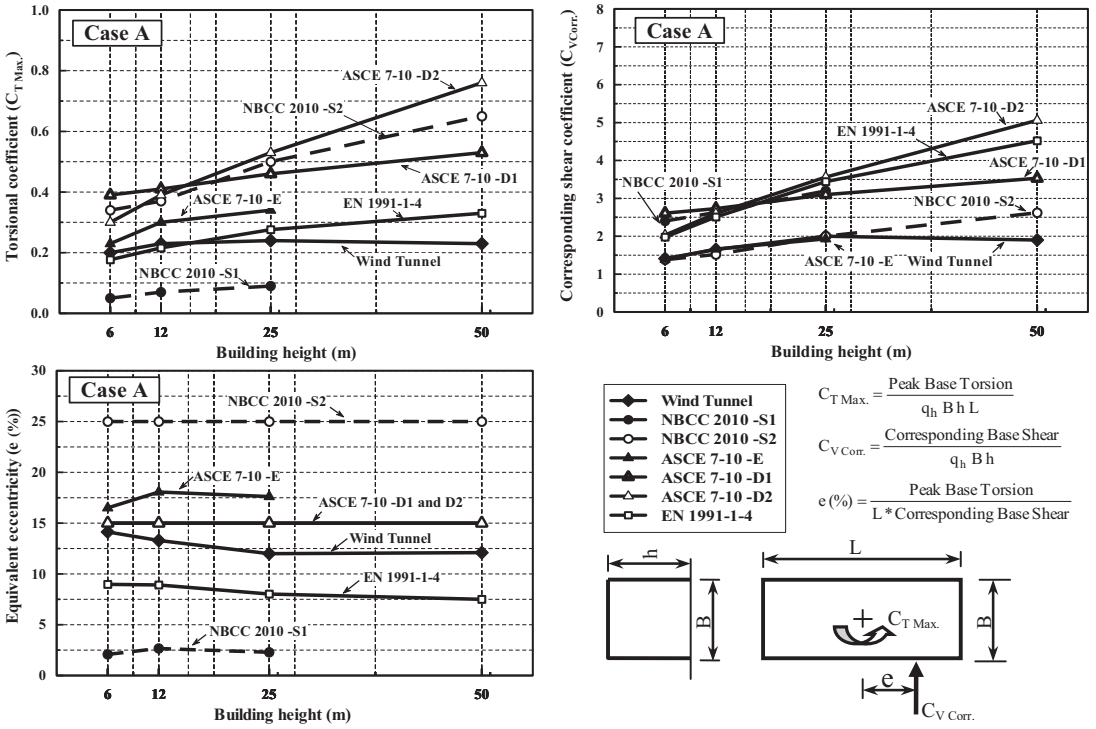

Figure 8. Comparison of torsional load case evaluated by NBCC 2010, ASCE/SEI 7-10, and wind tunnel tests (Case A: maximum torsion and corresponding shear)

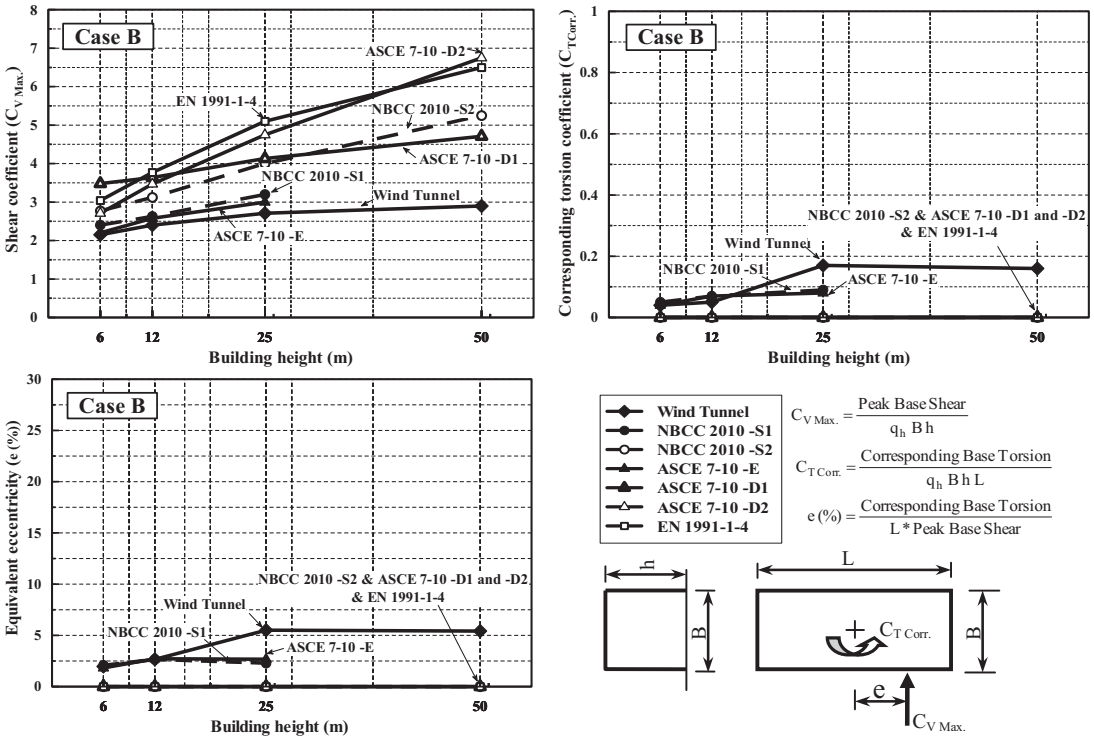

Figure 9. Comparison of shear load case evaluated by NBCC 2010, ASCE/SEI 7-10 and wind tunnel tests (Case B: maximum shear and corresponding torsion).

7 CONCLUSIONS

Wind-induced torsion was measured in the wind tunnel for four buildings having the same horizontal dimensions with different heights ranged from 6 m to 50 m. In addition, the experimental results were compared with wind provisions in NBCC 2010, ASCE/SEI 7-10 and EN 1991-1-4. The comparison results demonstrate the following:

a) For low buildings:
- The static method in NBCC 2010 underestimates torsion significantly.
- The envelope method in ASCE/SEI 7-10 shows relatively good agreement with the measured torsion.
- EN 1991-1-4 shows good agreement with the wind tunnel results.

b) For intermediate height buildings:
- Wind load procedures in NBCC 2010 and ASCE/SEI 7-10, overestimate torsion while EN 1991-1-4 shows good agreement with the wind tunnel results.

Until more experimental data become available, it could be recommended that applying 75% of the full wind loads with equivalent eccentricity 15% will improve torsion evaluation for low and medium height buildings.

ABSTRACT: The wind pressure distributions on flat roofed steel frame buildings with and without parapet are studied by wind tunnel tests. At first, the magnitudes and distributions of the mean, fluctuating and minimum wind pressure coefficients on the surface of the models are analyzed. Then, wind pressure distributions derived from wind tunnel test and main country codes are compared in transverse wind direction, not considering wind-induce internal pressure and gust effect factor due to such low-rise building with enough rigidity. Finally, the characteristics of the proper orthogonal decomposition results of the measured wind pressure field are analyzed. The investigation can provide some basic understanding and reference for clauses about wind loads.

KEYWORDS: Flat-roofed buildings; parapet; wind tunnel test; wind pressure distribution; shape coefficient; code; proper orthogonal decomposition

1 INTRODUCTION

Flat roofs with and without parapet are widely used for commercial and residential low-rise buildings with steel frames Their relatively light dead and flexibility make them susceptible to wind load. There have been relatively few studies on the effects of parapet on wind load for low-rise building, this is likely due to the conclusion in Ref [1] that the code provisions for buildings without parapet are equally applicable to buildings with parapet, which may lead to unnecessary cost waste in structural design. The current codes have no recommendations about considering the effects of parapet in wind-resistant design. The present study is first to examine the general distribution of wind loads on flat-roofed buildings with and without parapet, secondly to compare wind pressure distribution obtained from wind tunnel test and main country codes, and thirdly to analyze the characteristics of the proper orthogonal decomposition results of the measured wind pressure field.

2 EXPERIMENTAL PROCEDURE

The experiments were carried out in the Boundary Layer Wind Tunnel at State Key Laboratory for Disaster Reduction in Civil Engineering at Tongji University. The wind tunnel working section is 2.5m high, 3m wide and 15m long. The exposure category of the ground roughness can be regarded as Category B according to *Load code for the design of building structures* GB50009-2001 of china [2]. Model A without parapet and model B with 1.2m high parapet commonly used in China were made at a geometric scale of 1:40, and they have the same full scale dimensions. Figure 1 shows the prototype buildings. 235 taps were arranged on the roof and walls of the models to measure wind pressure simultaneously. Due to wind load on parapet is beyond the scope of this study, no tap was arranged on the parapet. Figure 2 shows the layout of pressure taps on the roof and walls. The wind attack angle is varied from 0^o to 360^o in 45^o in steps (Figure 2). Wind speed and corresponding velocity pressure at the eave heights of the models are taken as the reference wind speed and reference pressure in analyzing the wind pressure coefficients. The reference wind speed at the reference height is near to 8m/s.

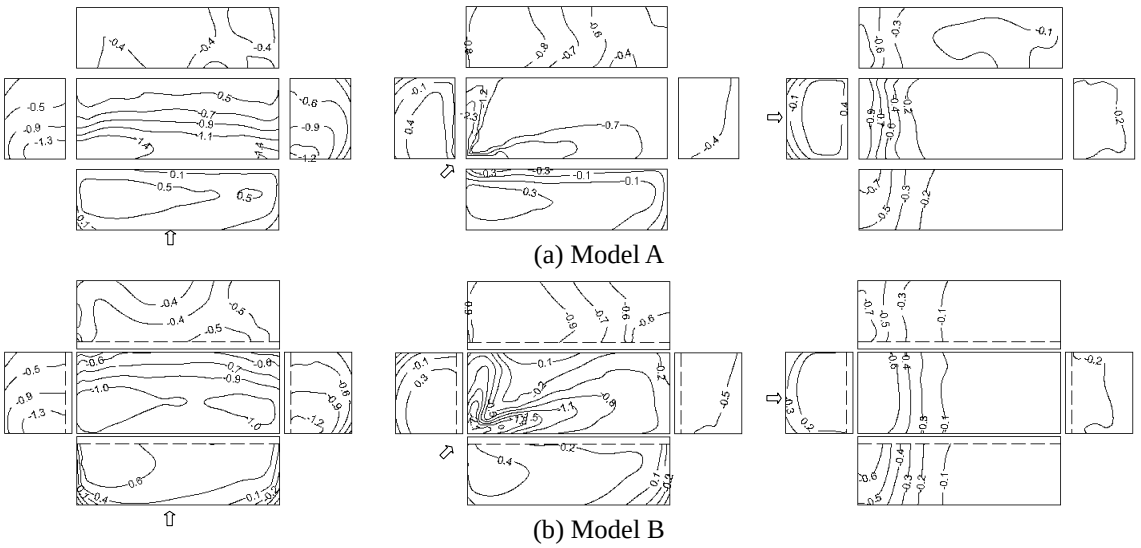
3 RESULTS AND DISCUSSION

3.1 *The characteristics of wind pressure*

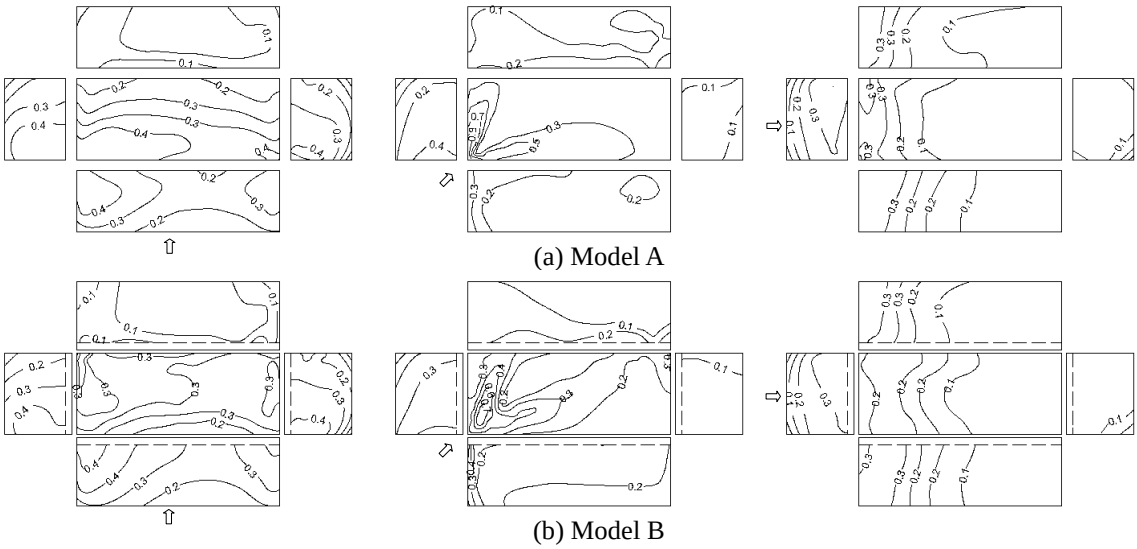
Figure 3 and figure 4 show the magnitudes and distributions of mean and fluctuating wind pressure coefficients on model A and model B with 0^0, 45^0, and 90^0 wind directions, respectively, in consideration of the symmetric conditions of the models. The distributions of mean wind pressure coefficient on the walls of model B are similar to those of model A, and the magnitudes of mean wind pressure coefficient on the walls of model B are close to those of model A in the same wind direction. Wind pressure on the walls is little affected by the presence of parapet. The distributions of mean wind pressure coefficient on the roofs of model A and model B are similar in the same wind direction; however a significant decrease in the magnitudes of wind pressure coefficient on the roof of model B, compared with those of model A, is observed due to the presence of 1.2m parapet. The effects of parapet on the roof and the walls are consistent with the findings in Ref [3]. The magnitudes and distributions of fluctuating wind pressure coefficients on model B are similar to those of model A in the same wind direction.



(a) Model A

(b) Model B

Figure 3. Mean wind pressure distributions



(a) Model A

(b) Model B

Figure 4. Fluctuating wind pressure distributions

The variations of the instantaneous pressure distribution on the roofs of the two models in 45^0 wind direction with time from $t= T_{max}-5\Delta t$ to $t= T_{max}+6\Delta t$ are shown in figure 5, where T_{max} represents the time when the maximum peak suction is observed at the reference height during the whole record. These results show that the pressure distribution, which causes very severe suctions in the leading edge and corner regions, last only 4-6 time steps, or 0.2-0.3s in very case that was tested. The pressure distributions on the roofs change significantly with time during such a short period around $T_{max.}$ The area of severe suctions at $t= T_{max}$ is small as up to 0.5m×1m, which covers the connections in self-drilling screws of profiled steel sheets commonly used in China. These results indicate that the time and/or spatial averages of wind fluctuations lead to a remarkable decrease in the peak suction.

(b) Roof with parapet

Figure 5. Variations of the instantaneous pressure distribution on the roofs in 45^0 wind direction

3.2 *Comparison with current codes*

The magnitude and distribution of wind pressure on model A in transverse wind direction, obtained from wind tunnel test is compared with those from current codes, including GB 50009-2001, *Architectural Institute of Japan Recommendations for Loads on Buildings* AIJ2004 [4], *Minimum Design Loads for Buildings and Other Structures* ASCE/SEI7-05 of American [5] and *Structural Design Actions* AS/NZS1170.2:2002 of Australian/New Zealand [6]. Not considering wind-induce internal pressure and gust effect factor due to such low-rise building with enough rigidity, design wind pressure from current codes can be estimated in uniform equation as:

$$w_d = 0.5\rho_{air} v_d^2 C_s C_h \tag{1}$$

where, w_d is design wind pressure; ρ_{air} is the air density, , which normally lies in the range 1.20 to 1.25 kg/m^3; v_d is design wind speed, determined by the height, exposure category, time duration and return period. C_s is the shape coefficient a modifying coefficient for the place of the point on the surface; C_h is the height coefficient, a modifying coefficient for the height of the point. In AIJ2004 and AS/NZS1170.2:2002, C_h is concluded in the calculation of v_d, which has little effect on wind pressure on such low-rise building.

The parameters of the estimation on design wind pressures from different country codes are given in table 1. Wind pressures in all codes are evaluated at an elevation of 10 m. Time duration of wind speed in GB 50009-2001 and AIJ2004 are 10 minutes; while 3 seconds in ASCE/SEI7-05 and AS/NZS1170.2:2002. Return period of wind speed in AIJ2004 is 100 years; while 50 years in other codes. Conversion coefficients of time duration and return year are used in determination of wind speed between different codes. The zone of the shape coefficient, C_s, in table 1 is shown in figure 6. H is the eave height of the building and a equals to 1.44 m according to ASCE/SEI7-05. For the flat-roofed building, the shape coefficient distributions from GB 50009-2001 are the same as those from AIJ2004. The roof end, windward wall end and leeward wall end suffered higher pressure are considered in

ASCE/SEI7-05. The shape coefficients decreasing along wind direction on the roof and side walls are considered in AS/NZS1170.2:2002, which is more consist with experimental results.

Table 1. The parameters of the estimation on design wind pressures from different country codes

Parameters			GB 50009-2001	AIJ2004	ASCE/SEI7-05	AS/NZS1170.2:2002
Wind speed at 10 m height (m/s)			23.71	26.08	35.09	35.09
C_h			1.022	1.009	1.017	1.008
v_d (m/s)			23.71	26.31	35.09	35.72
C_s	Windward wall	W	+0.80	0.60	+0.48	+0.80
		WE	+0.80	0.60	+0.72	+0.80
	Leeward wall	L	-0.50	-0.40	-0.34	-0.50
		LE	-0.50	-0.40	-0.51	-0.50
	Side wall	S1	-0.70	-0.70	-0.53	-0.65
		S2	-0.70	-0.70	-0.53	-0.50
	Roof	R1	-0.60	-0.87	-0.81	-1.10
		R2	-0.60	-0.87	-0.81	-0.80
		R3	-0.60	-0.87	-0.81	-0.50
		R1E	-0.60	-0.87	-1.26	-1.10
		R2E	-0.60	-0.87	-1.26	-0.80
		R3E	-0.60	-0.87	-1.26	-0.50

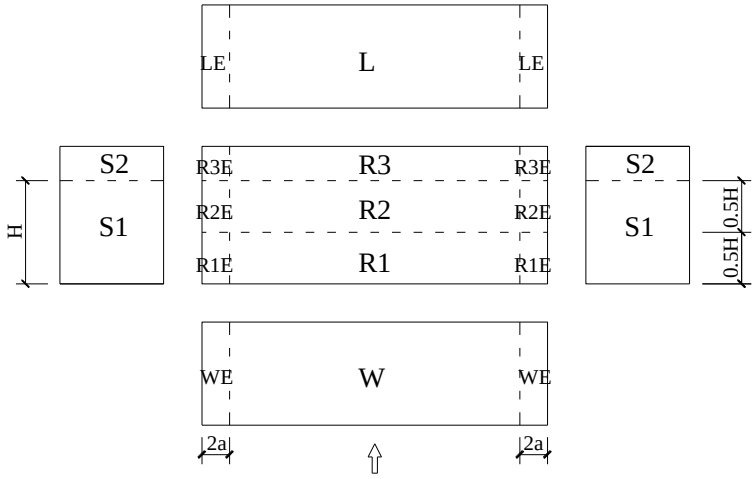

Figure 6. The zone of the shape coefficient according to the codes

The comparison of design wind pressure from different country codes with experimental results is shown in figure 7. Load combination coefficient, 1.4, is considered by GB 50009-2001 to compare with design wind pressure by other codes. Experimental results show that the wind pressures on the windward wall and the leeward wall are close to constant; while the wind pressures on the roof and the side walls decrease along wind direction. Wind pressures on the windward wall and the leeward wall obtained from GB 50009-2001, ASCE/SEI7-05 and AS/NZS1170.2:2002 are much larger than experimental results, which may result from two factors: (1) larger shape coefficient on the windward wall given by the codes; (2) 3-s wind speed, close to gust wind speed, used in ASCE/SEI7-05 and AS/NZS1170.2:2002. Wind pressures on the windward wall and the leeward wall obtained from AIJ2004 are relatively close to experimental results. Wind pressures on side walls and the roof obtained from GB 50009-2001 and AIJ2004 are somewhat smaller than experimental results, not considering higher suction on the windward end. Although wind pressure on the

roof obtained from ASCE/SEI7-05 is much larger than experimental result, it does not reflect actual wind pressure distribution. Wind pressure distributions on the roof and side walls given by AS/NZS1170.2:2002 are suitable to experimental results. The reason of larger wind pressure on the roof and side walls given by AS/NZS1170.2:2002 than experimental results is mainly 3-s wind speed in AS/NZS1170.2:2002.

3.3 *The characteristics of proper orthogonal decomposition*

Proper Orthogonal Decomposition (POD) is a method used to derive the most efficient coordinate system for observing individual phenomena [7]. It can be applied to the analysis of random phenomena. As an example, contribution proportion of each mode from proper orthogonal decomposition on model B is given in table 2. It can be seen that, when wind direction is 90^0, the contribution of the first mode, as well as the cumulative contribution of the first several modes is a little larger in comparison with the results corresponding to 0^0 or 45^0 wind direction. For an expected cumulated contribution approximate to 90%, at least

more than 50 modes should be considered. The first twelve eigenvectors of the measured wind pressure on model B in 90^0 wind direction are shown in figure 8. The contribution proportions of each mode to the global wind pressures field are given in the brackets under the contours of corresponding mode. Wind pressure on the model has good spatial correlation. The first several modes give a global description of wind pressure distribution on the model surface, while the other high-order modes just represent local distributions.

Table 2. Eigenvalues, proportions and cumulative proportions for the pressure field on model B

Mode	0^o			45^o			90^o		
	Eigen -value	Proport -ion(%)	Cumulative proportion (%)	Eigen -value	Proport -ion (%)	Cumulative proportion (%)	Eigen -value	Proport -ion (%)	Cumulative proportion (%)

4 CONCLUSIONS

Flat-roofed buildings with and without parapet have been tested in a wind tunnel to investigate the characteristics of wind pressure distribution. 1.2m high parapet, commonly

used in China, reduces mean suctions and extreme suctions by up to 50% on the roof edges, and wall loads remain unaffected by the presence of parapet. The variations of the instantaneous pressure distribution with time indicate that the time and/or spatial averages of wind fluctuations leads to a remarkable decrease in the peak suction. Wind pressure distributions on the flat roofed steel frame building without parapet in transverse wind direction given by AS/NZS1170.2:2002 are suitable to experimental results that wind pressures on the windward wall and the leeward wall are close to constant; while the wind pressures on the roof and the side walls decrease along wind direction. Wind pressure on the models has good spatial correlation. The first several modes give a global description of wind pressure distribution on the model surface, while the other high-order modes just represent local distributions.

Internal pressure in real flexible porous buildings: A design perspective

Guha T. K.[a], Sharma R. N. [a], Richards P. J. [a]

[a]*Department of Mechanical Engineering, The University of Auckland, New Zealand*

ABSTRACT: Analytical and associated numerical investigations of the fluctuating internal pressures induced through a dominant opening in real buildings with leaky and flexible envelopes are undertaken. The damping effect of these factors both separately and in combination are quantified using Root Mean Square (RMS) internal pressure coefficients and equivalent damping ratios for a range of envelope flexibilities and background porosities for the case of the Texas Tech University (TTU) test building. In particular, the equivalent damping ratio and the RMS internal pressure coefficient for the TTU building with a flexibility parameter of 2 and porosity ratio of 20% is found to be around 4 times higher and 27% lower than for a rigid non-porous TTU building. Simulated ratios of the RMS internal pressures and the peak spectral response of internal pressure for leaky and flexible buildings to that of rigid, nonporous envelopes are presented in non-dimensional format for a range of building volumes, opening areas and porosity ratios. Additionally non-dimensional charts of the RMS internal to external pressure ratios for real flexible and leaky envelopes are presented in a form suitable for design purposes.

KEYWORDS: Internal Pressures, Envelope Flexibility, Background Leakage.

1 INTRODUCTION

Buildings in real life, excepting special circumstances, have flexible and leaky envelopes. Flexibility and background leakage are known to act as dampers to internal pressure fluctuations induced through a dominant opening in the building. This has been demonstrated previously by wind tunnel [1,2] and full-scale studies [3] that dealt with these two factors separately. Theoretical models [2,4], in accordance with the experimental predictions, that take into account the effect of either of these factors in isolation have also been proposed.

Research, both theoretical and experimental, into the combined effect of leakage and flexibility, as occurs in most real buildings, has received comparatively little attention [5]. In fact, many studies of internal pressure in the past have tended to neglect their effects altogether. While theoretical studies have been limited by the lack of knowledge of the structural characteristics of the envelope (such as stiffness) and the distribution of the leakages arising out of normal construction tolerances, experimental research has suffered mainly from the difficulties in the similarity based modeling such as the lack of suitable materials to simultaneously satisfy the mass and stiffness scaling of such a realistic scenario. Even fewer, if at all any, has been the quantitative studies of the combined effect of these two factors in moderating the fluctuating and peak internal pressure response compared to that for a rigid, non-porous building; an issue this paper attempts to address from a design perspective.

While full-scale measurements of internal pressure in real flexible and leaky buildings for a range of internal volumes and opening sizes under strong wind conditions offer a promising alternative, they are expensive, time consuming and resource intensive. Additionally controlling

the different factors such as the extent of flexibility and leakage in the building envelope presents difficulties in full-scale. This paper thus uses analytical modeling and associated numerical simulation technique to quantify the damping effects of envelope porosity and flexibility on the fluctuating internal pressure response. The damping influence of flexibility and background leakage are exhibited separately and in combination for different envelope flexibilities and porosities for the case of the Texas Tech University (TTU) test building [6] with an opening in terms of the simulated Root Mean Square (RMS) internal pressure coefficients and equivalent damping ratios. Results of the RMS and peak spectral response of internal pressure for leaky and flexible buildings in comparison to that of rigid, nonporous envelopes (of the same nominal internal volume and opening size) are presented in non-dimensional format for realistic values of non-dimensional parameters S^*,Φ_5 [7] and porosity ratio (r) [2]. Design charts of the RMS internal to external pressure ratios are also presented for ranges of S^*, Φ_5 and r in a form suitable for design purposes.

2 GOVERNING EQUATIONS

Internal pressure induced in a building is described using an air slug/jet oscillating through the opening, being forced by the turbulent external pressures against an air-spring inside the building volume and damped by the irrecoverable loss of energy due to viscous and radiation effects. Further damping is imparted by flexibility and background leakage in the envelope of real buildings. Such buildings usually behave quasi-statically to fluctuations in the onset wind, meaning structural displacements are linearly proportionally to the applied load at all times. Hence they are considered as static structures. The leakages in the building envelope are found to behave quasi-steadily to onset turbulence, low pass filtering the external pressure fluctuations beyond a critical frequency [2] that is dependent on the mean internal-external pressure difference and the total leakage area in the surface.

Figure 1 provides a schematic representation of a real flexible and leaky building with an opening for which a general equation of the internal pressure response is provided.

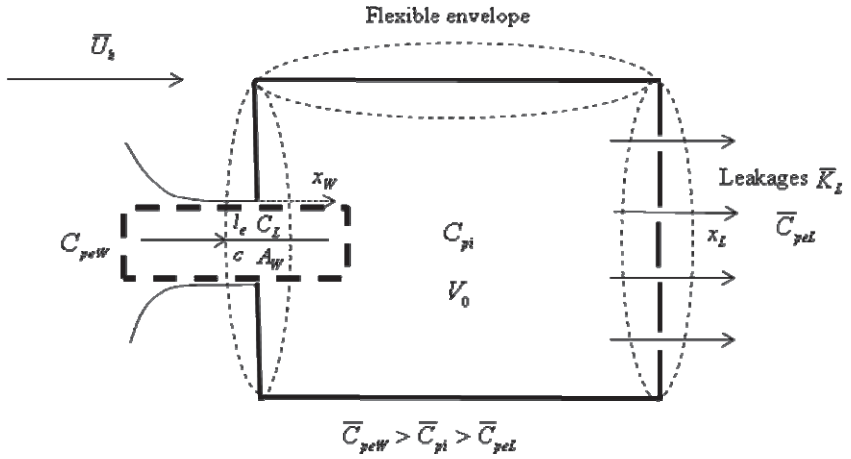

Figure 1. Schematic of a real flexible and leaky building with an opening

The unsteady equation of motion of the air-slug oscillating through the windward dominant opening under the fluctuating internal and external pressures (represented by the coefficients C_{pi} and C_{peW} respectively) and damped by energy losses through the opening, takes the form:

$$\rho_a l_e c A_W \ddot{x}_W + \frac{1}{2}\rho_a c A_W C_L |\dot{x}_W| \dot{x}_W = c A_W q\left(C_{peW} - C_{pi}\right) \tag{1}$$

where ρ_a, l_e, c and A_W are the density of air, effective length of the air slug, flow contraction coefficient and area of the opening respectively, C_L is the loss coefficient of flow through the opening, q is the ridge height dynamic pressure derived from the ridge height wind velocity $\overline{U}_h$ and $\dot{x}_W$, $\ddot{x}_W$ are the velocity and acceleration of the oscillating air-slug respectively.

The quasi-static response (i.e. displacement and its temporal derivatives) of the building envelope to fluctuating internal pressures in terms of the non-dimensional volume change (υ) can be written as

$$\upsilon = \frac{qC_{pi}}{K_B} + 1; \dot{\upsilon} = \frac{q}{K_B}\dot{C}_{pi}; \ddot{\upsilon} = \frac{q}{K_B}\ddot{C}_{pi} \tag{2}$$

where K_B is the bulk modulus of the building envelope. The quantity υ can be defined as V/V_0 where V is the instantaneous volume and V_0 is the nominal volume of the building.

The quasi-steady equation of motion through the leakages lumped together with predominant damping is given by

$$\frac{\rho_a}{2} A_L \overline{K}_L \dot{x}_L |\dot{x}_L| = q A_L \left(C_{pi} - \overline{C}_{peL}\right) \tag{3}$$

where $\overline{K}_L \approx 1/c^2$ and A_L and are the steady-state loss coefficient and area of the lumped leakage and $\dot{x}_L$ is the flow velocity through it for a mean leeward external pressure coefficient $\overline{C}_{peL}$.

Conservation of mass inside the building volume determined by the continuity equation with an isentropic pressure-volume relationship is given by

$$C_{pi} = \frac{\gamma P_a}{qV_0}\left[c A_W x_W - A_L x_L - V_0(\upsilon - 1)\right] \tag{4}$$

where γ =1.4 is the ratio of specific heat capacities for an isentropic process and P_a is the atmospheric pressure.

The governing equation of internal pressure in a quasi-static flexible and leaky building with an opening can be deduced from Equations 1-4 as

$$\begin{aligned} &\frac{\rho_a l_e V_e}{\gamma c A_W P_a}\ddot{C}_{pi} + C_L \frac{\rho_a q V_e^2}{2\left(\gamma A_W P_a\right)^2}\left|\dot{C}_{pi} + \frac{A_L \gamma P_a \overline{U}_h}{qV_e}\sqrt{\frac{C_{pi} - \overline{C}_{peL}}{\overline{K}_L}}\right|\left(\dot{C}_{pi} + \frac{A_L \gamma P_a \overline{U}_h}{qV_e}\sqrt{\frac{C_{pi} - \overline{C}_{peL}}{\overline{K}_L}}\right) \\ &+ \frac{\rho_a \overline{U}_h l_e}{2qc\sqrt{\overline{K}_L\left(C_{pi} - \overline{C}_{peL}\right)}}\left(\frac{A_L}{A_W}\right)\dot{C}_{pi} + C_{pi} = C_{pe} \end{aligned} \tag{5}$$

where V_e is the effective volume of the cavity and equal to V_0 (the nominal cavity volume) for a building with rigid envelope and equal to $V_0(1+b)$ for a flexible envelope, where $b = \gamma P_a / K_B$ is the ratio of the bulk modulus of air to that of the building envelope.

The Helmholtz frequency (f_{HH}) of internal pressure oscillations is given by

$$f_{HH} = \frac{\omega_{HH}}{2\pi} = \frac{1}{2\pi}\sqrt{\frac{\gamma c A_W P_a}{\rho_a l_e V_e}} \tag{6}$$

where ω_{HH} is the corresponding angular frequency. It can be noted from Equation 6 that the effect of envelope flexibility is associated with a corresponding reduction in the Helmholtz frequency of the system (due to increase in the value of parameter b and hence effective volume V_e).

Putting b = 0 and A_L = 0 in Equation 5 leads to Sharma & Richards' [8] form of the well known dynamic equation of internal pressure for a rigid non-porous envelope originally proposed by Holmes [7].

A non-dimensional form of Equation 5 based on the parameters S^* [$=\left(A_W^{3/2}/V_e\right)\left(a_s/\overline{U}_h\right)^2$], Φ_5 [$=\lambda_U/\sqrt{A_W}$], porosity ratio r [$=A_L/A_W$] and a non-dimensional time t^* [$=t\overline{U}_h/\lambda_U$] is given by

$$\frac{C_I}{cS^*\phi_5^2}\frac{d^2C_{pi}}{dt_*^2} + \frac{C_L}{4\left(S^*\phi_5\right)^2}\left|\frac{dC_{pi}}{dt_*} + 2\left(\frac{A_L}{A_W}\right)S^*\phi_5\sqrt{\frac{C_{pi}-\overline{C}_{peL}}{\overline{K}_L}}\right|\left(\frac{dC_{pi}}{dt_*} + 2\left(\frac{A_L}{A_W}\right)S^*\phi_5\sqrt{\frac{C_{pi}-\overline{C}_{peL}}{\overline{K}_L}}\right)$$
$$+\left(\frac{A_L}{A_W}\right)\frac{C_I}{\phi_5 c\sqrt{\overline{K}_L\left(C_{pi}-\overline{C}_{peL}\right)}}\frac{dC_{pi}}{dt_*} + C_{pi} = C_{pe} \tag{7}$$

where C_I = $\sqrt{\pi/4}$ is the inertia coefficient of flow through the opening, a_s is the speed of sound and λ_U is the longitudinal integral length scale of turbulence at the building ridge height. It should be noted that S^*, as defined here, intrinsically incorporates the effect of envelope flexibility through usage of an effective volume (V_e) instead of the nominal building volume (V_0). For given values of C_I, c, C_L and $\overline{K}_L$, Equation 7 can be solved to yield the response of internal pressure as a function of S^*, Φ_5 and r.

3 QUANTIFICATION OF THE EQUIVALENT DAMPING RATIO (ζ_{eq})

It is a common practice to quantify all the damping effects of internal pressure fluctuations using the loss coefficient C_L. Attempts have been made in the past to match the predicted resonant response to the measured value by altering the value of C_L until a match is obtained. A review of such investigations and the values of C_L thus obtained are discussed by Holmes and Ginger [9]. A wide scatter of values ranging from 1.2 to 100 is observed in these studies. This brings forth the question as to whether C_L is being overloaded with the damping effects of other factors when it is solely meant to quantify the energy losses at the opening. While some of the values reported in literature, such as C_L=1.2, have been supported by CFD studies [8] of internal pressure involving rigid non-porous buildings with effects of other dampers eliminated, the particularly high values such as 44 and 100 used for spectral matching in some studies [3,10] seems unrealistic. The possibility of damping due to envelope compliance and leakage in the model and/or full-scale buildings seems to have been intrinsically included in C_L leading to such unrealistically high values.

It is therefore physically more realistic to quantify the effect of the different dampers operating separately or in combination using as equivalent damping ratio (ζ_{eq}). This can be done by re-

writing the governing equation of internal pressure (Equation 5) in the standard single degree-of-freedom dynamic system

$$\frac{1}{\omega_{HH}^2}\ddot{C}_{pi}+\frac{c_j}{k}\dot{C}_{pi}+C_{pi}=C_{pe} \tag{8}$$

where c_j is the damping coefficient and k is the stiffness of the air mass-spring system. The equivalent damping ratio (ζ_{eq}) can then be defined by comparing Equations 5 and 8, giving

$$\zeta_{eq}=\frac{c_j}{k}\frac{\omega_{HH}}{2}=\frac{1}{2}\sqrt{\frac{\gamma c A_W P_a}{\rho_a l_e V_e}}\left[\begin{array}{l} C_L\dfrac{\rho_a q V_e^2}{2(\gamma A_W P_a)^2}\left|\dot{C}_{pi}+\dfrac{A_L\gamma P_a\overline{U}_h}{qV_e}\sqrt{\dfrac{C_{pi}-\overline{C}_{peL}}{\overline{K}_L}}\right|\left\{1+\dfrac{A_L\gamma P_a\overline{U}_h}{qV_e\dot{C}_{pi}}\sqrt{\dfrac{C_{pi}-\overline{C}_{peL}}{\overline{K}_L}}\right\} \\ +\dfrac{\rho_a\overline{U}_h l_e}{2qc\sqrt{\overline{K}_L(C_{pi}-\overline{C}_{peL})}}\left(\dfrac{A_L}{A_W}\right)\end{array}\right] \tag{9}$$

For non-leaky envelopes (A_L=0), the equivalent damping ratio (ζ_{eq}) simplifies to

$$\zeta_{eq}=\frac{c_j}{k}\frac{\omega_{HH}}{2}=C_L\frac{\rho_a q V_e^2}{2(\gamma A_W P_a)^2}\frac{1}{2}\sqrt{\frac{\gamma c A_W P_a}{\rho_a l_e V_e}}\left|\dot{C}_{pi}\right| \tag{10}$$

The damping effects of envelope flexibility and background leakage can then be quantified individually or in combination using ζ_{eq} by a spectral match of the solutions of Equation 5 and 8 by switching on and off the effect of the relevant dampers (i.e. flexibility and leakage). Such damping ratios (ζ_{eq}) with intrinsically loaded effects of flexibility and/or leakage provide for a better parameter than loss coefficient (C_L) to quantify the effect of the different dampers.

4 ANALYTICAL EXAMPLE USING THE TTU TEST BUILDING

An analytical example for the effect of envelope flexibility and background leakage on the fluctuating internal pressure response is provided for a building similar in dimensions to the TTU test building with a windward dominant opening (area ratio of 5%) under the following basic conditions:

V_o = 497m^3; A_W = 1.94m^2; $l_e=\sqrt{\pi A_W/4}$; c = 0.6; C_L= 1.2; $\overline{K}_L$ = 2.78; $\overline{U}_h$ = 30m/s;
$\overline{C}_{peW}=\overline{C}_{pi}$ = 0.7; $\overline{C}_{peL}$ = -0.3; I_u= 0.20; ρ_a = 1.185kg/m^3; γ = 1.4; P_a = 101.3KPa

Numerical simulations of Equations 5 and 8 using a fourth-order Runge-Kutta method with adaptive time-stepping capability were used for quantitative analysis and comparison. The external pressure coefficient time history used to force the internal pressure response was obtained by applying an aerodynamic admittance and random phase to the Fourier coefficients derived from the Kaimal spectrum using an Inverse Fast Fourier Transform (IFFT) technique.

4.1 *Effect of envelope flexibility*

The effect of flexibility on internal pressure for the non-porous TTU test building with a windward dominant opening is studied by varying the parameter b from 0 to 2 in steps of 0.5, i.e. from a rigid to a relatively flexible envelope system. Figure 2a presents the simulated internal pressure coefficient spectra for b = 0, 1 and 2.

Table 1. Effect of flexibility on damping w.r.t. spectral response at resonance

b	0	0.5	1.0	1.5	2.0
c_j/k	0.005	0.008	0.013	0.018	0.022
ζ_{eq}	0.038	0.049	0.069	0.086	0.096

The overall damping of the system at resonance is found to increase with flexibility in the building envelope. The associated reduction in the Helmholtz frequency from 2.4Hz down to 1.3Hz is also evident in the figure for an increase in b from 0 to 2. The increased damping effect of envelope flexibility is further confirmed in Table 1 which shows an increase in the quantities c_j/k (damping term in Equation 8) and ζ_{eq} with b. A spectral match between the solutions of Equations 5 and 8 was used to estimate these quantities.

An increase in the equivalent damping ratio (ζ_{eq}) by a factor of 2.5 is observed for an increase in b from 0 to 2. The decrease in the Helmholtz frequency with flexibility is however neglected in this analysis in order to study the effect of flexibility induced damping in isolation.

The effect of the decrease in the Helmholtz frequency with flexibility and its effect on the internal pressure resonant response in terms of the overall damping using the concept of equivalent damping ratio is shown in Table 2. In this case, an iterative process was used to estimate the quantities c_j/k and ζ_{eq} until a match between the RMS internal pressures and gain of internal to external pressure at resonance as predicted by Equations 5 and 8 were obtained.

The increased damping effect of envelope flexibility notwithstanding the shift (decrease) in the Helmholtz frequency towards the more energy containing region of the external pressure forcing spectrum is evident from the values of c_j/k and ζ_{eq} in Table 2. The reduction in Helmholtz frequency with envelope flexibility is found to partially compensate for the increased internal pressure damping in a flexible envelope, e.g. 6% when reduction the in Helmholtz frequency due to flexibility is accounted for in Table 2 against 9.6% when not considered in Table 1 for b=2.

Table 2. Effect of flexibility on damping w.r.t. equivalence of the RMS internal pressure

b	0	0.5	1.0	1.5	2.0
c_j/k	0.005	0.006	0.007	0.008	0.008
ζ_{eq}	0.038	0.047	0.051	0.057	0.060

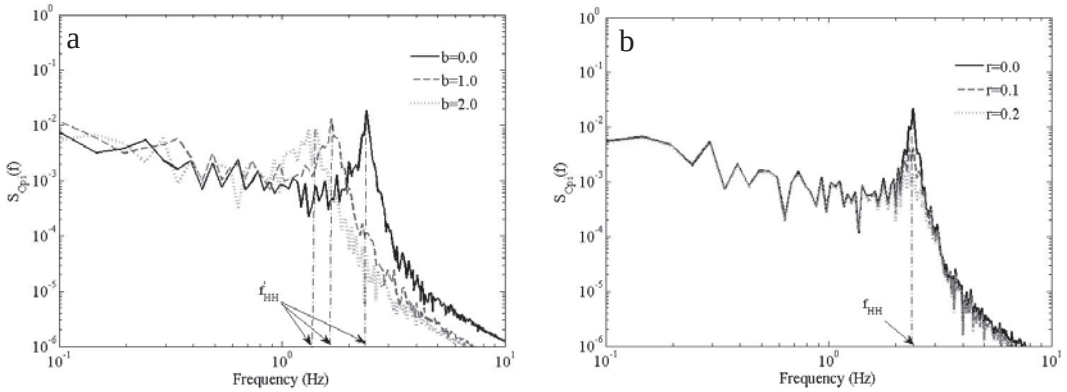

Figure 2. Simulated internal pressure coefficient spectra for the TTU building with (a) varying envelope flexibility and (b) varying envelope porosity

4.2 *Effect of background porosity*

The effect of background porosity on the internal pressure response for the rigid TTU test building with a windward dominant opening is studied by varying the porosity ratio r ($=A_L/A_W$) from 0 to 0.2 in steps of 0.05, i.e. from a non-porous to a relatively porous envelope system. Figure 2b presents the simulated internal pressure coefficient spectra for r = 0, 0.1 and 0.2.

Increase in envelope porosity is expectedly found to further limit the amplitude of internal pressure fluctuations at resonance. Thus the peak spectral response is found to have decreased by a factor of 15 with increase in porosity from 0 to 20%. The corresponding equivalent damping ratio is found to increase from around 3.8% for a non-porous building to around 11% for a porosity ratio of 20%. This will decrease the RMS and peak internal pressures to a great extent compared to the non-porous model predictions.

4.3 *Combined effect of envelope flexibility and background porosity*

The combined influence of envelope flexibility and background porosity, as occurs in most real building envelopes, is further investigated for the TTU setup using the same range of flexibility parameter b and porosity ratio r as discussed in the preceding sections. Figures 3a, b and c presents a measure of the quantities c_j/k, ζ_{eq} and RMS internal pressure coefficient ($\widetilde{C}_{pi}$) respectively as a function of the parameters b and r, visualized as 3-D surface plots.

The extent of the damping imparted by the two factors is evident in the plots. Particularly, the equivalent damping ratio for the TTU building with damping parameters b=2 and r=20% is found to be around 4 times higher compared to a rigid non-porous TTU building envelope. The corresponding RMS internal pressure coefficient (≈0.19) is found to decrease by around 27% for the flexible (b=2) and porous (r=20%) envelope compared to the rigid non-porous case (≈0.26).

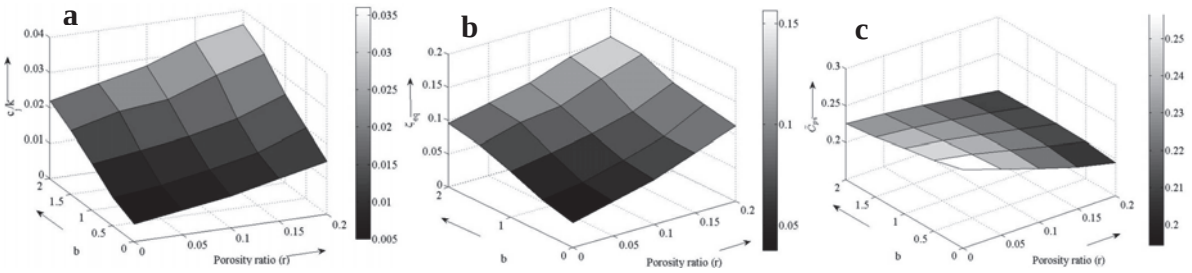

Figure 3. Simulated (a) c_j/k (b) Equivalent damping ratio (ζ_{eq}) and (c) RMS internal pressure coefficient for the TTU building as a function of envelope flexibility parameter, b, and background porosity ratio, r.

5 DESIGN APPROACH FOR INTERNAL PRESSURES IN REAL BUILDINGS

Recent internal pressure research [9,10] has been directed towards putting the dominant opening case in a non-dimensional format for useful design solutions. These studies have however looked into rigid non-porous envelope systems. This paper attempts to extend the work by incorporating the effects of envelope flexibility and background porosity into the ambit of the internal pressure design process. This is accomplished by numerically simulating the non-dimensional design Equation 7 for a range of realistic design parameters S^*, Φ_5 and r. Results are presented in the form

of non-dimensional design charts. It is worth noting that an experimental validation of the predictions of Equation 7 have been provided in Guha et al. [2] for selected cases of S^*, Φ_5 and r.

Typical values of the parameters S^* and Φ_5 for usual buildings encountered during normal design practices under wind speed conditions of 30-50m/s range from 0.1 to 15 and 10 to 100 respectively [11]. While values of S^* for small rigid structures of the size of garden-sheds at design wind speeds are usually around 10-15, a value of b (= $\gamma P_a/K_B$) around 2-5 for statically flexible large-span low-rise structures such as portal framed industrial buildings would render values of S^* to be less than 5. Hence S^* values of up to 5 are used in the current analysis. Values of Φ_5 are based on typical longitudinal integral length scales of 25-100m at the building ridge height of 5-7m in open and suburban terrains [11]. Porosities of buildings in the temperate climates of Australia/New Zealand are usually less than a conservative estimate of r=20% used in the current analysis. Figures 4a-d present the ratio of the simulated RMS internal pressure coefficients of leaky and flexible building to rigid non-porous envelopes as a function of the porosity ratio (r) for Φ_5 values 10, 20, 50 and 100 respectively.

The moderating effect of the background porosity on the internal pressure response is evident in all cases. The effect is more pronounced for higher porosity ratios (r) and larger Φ_5 (corresponding to smaller opening sizes). This is due to the reduced resonant response of internal pressure in smaller opening area-internal volume systems in which further damping effect of background porosity becomes significant. Reduction in the RMS internal pressure response for such cavity-opening systems with large S^* (i.e. small effective volume) is found to occur by as much as 50-70% compared to the non-porous building envelope at porosities beyond 10%.

For a given dominant opening size i.e. Φ_5 and porosity ratio (r), the RMS internal pressure ratios are found to decrease with decrease in effective building volume (i.e. large S^*). This is due to the moderating effect of background porosity and the associated reduction in the fluctuating internal pressure response becoming more pronounced for smaller building volumes.

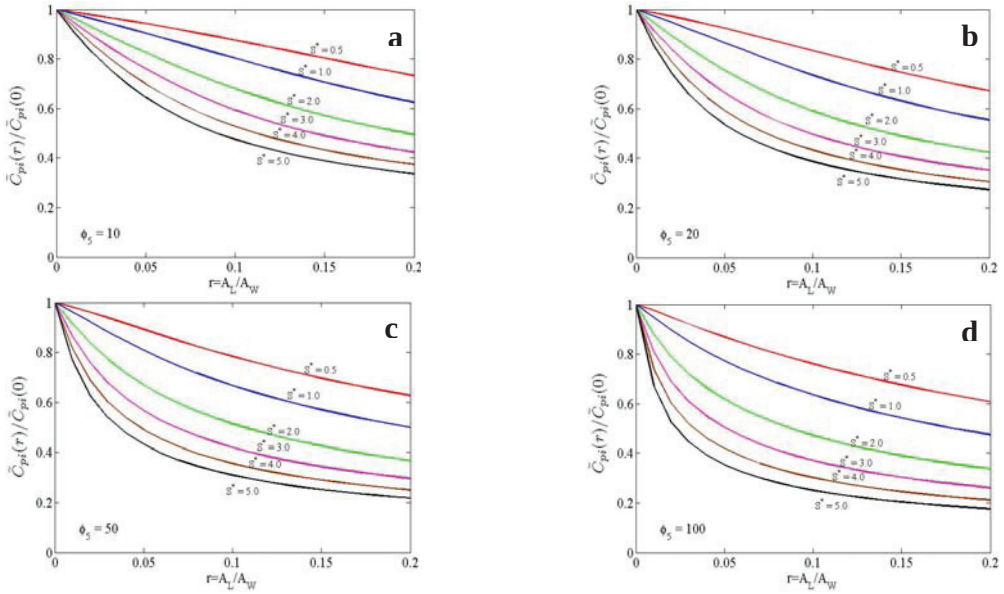

Figure 4. Simulated RMS internal pressure ratios for flexible and leaky envelopes to that for rigid non-porous buildings as a function of the porosity ratio for Φ_5= (a) 10 (b) 20 (c) 50 (d) 100

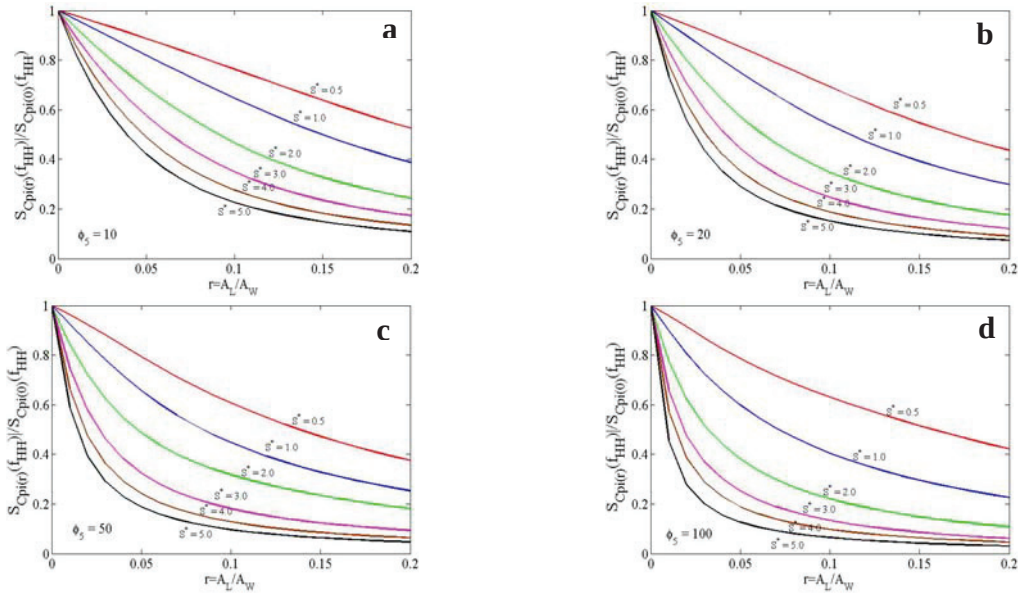

Figure 5. Simulated spectral ratios of internal pressure for flexible and leaky envelopes to that for rigid non-porous buildings for different building porosity ratios for Φ_5= (a) 10 (b) 20 (c) 50 (d) 100

Figure 5a-d reinforces the fore-going discussion by showing the ratio of the peak spectral response (at resonance) of the fluctuating internal pressure for different S^* and r for Φ_5 values of 10, 20, 50 and 100 respectively. Similar observations as in Figure 4 can be made.

Efforts into developing a suitable design solution of internal pressure by incorporating the damping effects of envelope flexibility and background leakage are made in Figure 6a-d by presenting the RMS internal to external pressure coefficient ratios as a function of S^* and r for Φ_5 values of 10, 20, 50 and 100 respectively.

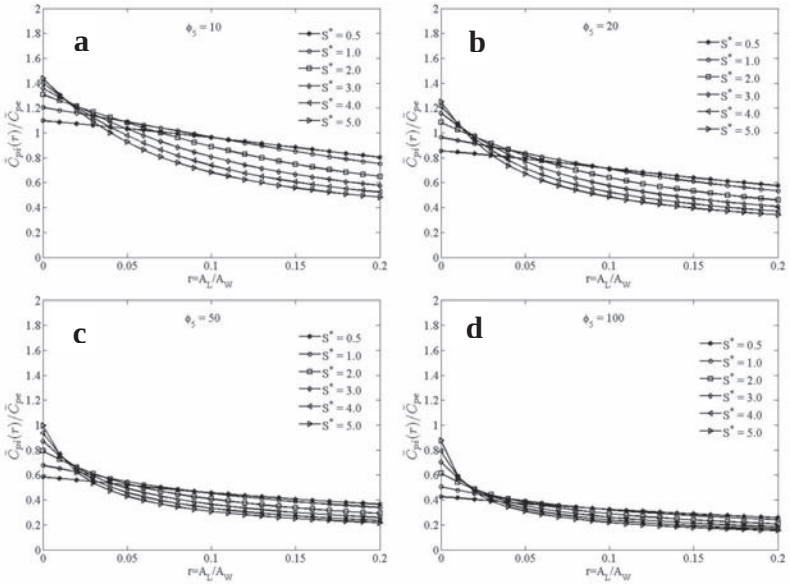

Figure 6. Simulated RMS internal to external pressure coefficient ratios for a range of building volumes and opening areas for different building porosity ratios for Φ_5= (a) 10 (b) 20 (c) 50 (d) 100

The moderating effects of envelope flexibility (small S^*) and background porosity (larger r) is clearly evident in all the plots. For a given opening size (Φ_5), the RMS internal to external pressure coefficient ratio is found to be higher for smaller volumes (larger S^*) up to a porosity ratio of around 5%, beyond which the RMS ratios are higher for larger volumes. This, as explained before, is due to the damping effect of background porosity gaining more prominence than the resonant response of internal pressure in smaller building volumes compared to the larger ones.

6 CONCLUSIONS

An analytical and numerical study of the fluctuating internal pressures induced through a dominant opening in real buildings with leaky and flexible envelopes is carried out. The increase in magnitude of the equivalent damping ratio with increase in envelope flexibility and background leakage is exhibited for the case of TTU test building using different values of flexibility and leakage parameter. In particular, the equivalent damping ratio for the TTU building with a flexibility parameter of 2 and porosity ratio of 20% is found to be around 4 times higher than for a rigid non-porous TTU building. The corresponding RMS internal pressure coefficient for such a building configuration is found to be about 27% less than the rigid non-porous building case.

Simulated ratios of the Root Mean Square (RMS) internal pressures and the peak spectral response of internal pressure for leaky and flexible buildings to that of rigid, nonporous envelopes presented in non-dimensional format also exhibit the damping influence of envelope flexibility and leakage. Non-dimensional charts of the RMS internal to external pressure ratios are presented for a realistic range of building volumes, opening areas and background porosities by incorporating the damping effect of flexibility and leakage in a form suitable for design purposes.

Coupled vibration between wind-induced internal pressures and large span roof for a two-compartment building with openings

Yu Xianfeng, Quan Yong, Gu Ming

State Key Laboratory of Disaster Reduction in Civil Engineering, Tongji University, Shanghai, China

ABSTRACT: The equations governing wind-induced internal pressure responses for a two-compartment building are derived based on some reasonable assumptions when the roof responds in dynamic and quasi-static manners, respectively. The gain functions, power spectra, and RMS values of internal pressure coefficients in both compartments are numerically analyzed. The results show that the dynamic model must be used to calculate the responses of internal pressure when the roof is flexible, while the simplified quasi-static model can be used for rigid roof. With increased roof natural frequency, all the three resonance frequencies of the "internal pressures - roof" coupled system increase; the peak internal pressure response also increases at the first two frequencies, but decreases at the third resonance frequency; the RMS internal pressure coefficients also increase, but their difference decreases.

1 INTRODUCTION

The dominant openings might be created due to either impact of flying debris or failure of windows and doors in severe wind storms. In the laminar uniform wind, an initial internal pressure overshoot which is higher than the mean external pressure at the opening will be produced when a sudden opening is created, then the response of internal pressure will exhibit damped oscillation, and it finally will keep constant with the external pressure. However, the overshoot phenomenon existed in smooth flow is lost amidst fluctuating turbulent wind in real life [1]. The steady-state internal pressure response for a building with a dominant opening can also be described with the Helmholtz acoustic resonator model. The resonance phenomenon will be occurred if there is sufficient energy at the Helmholtz frequency for the external pressure at the opening. So it will have a profound effect on building safety.

The effect of structure flexibility on internal pressure has been studied a lot for the single-cell building with a dominant opening. Vickery [2] treated the building deflections as quasi-static and suggested an effective volume method to consider the effect of building flexibility. Sharma and Richards [3] derived an equation governing the internal pressure for a building with a dominant opening and flexible roof, but the effect of external pressure on the roof movement failed to be considered. Yu et al [4] further considered the joint action of external and internal pressures on roof, and presented a linear internal pressure model. Sharma [5] derived an equation governing the response of internal pressure in any flexible building. Furthermore, a non-linear internal pressure governing equation was presented when the roof structure responds in a quasi-static manner, and the roof is under the joint action of external and internal pressures. Guha [6] derived an equation governing the internal pressure for a building with a dominant opening and flexible roof, however only considered the effect of internal pressure on roof. The studies of wind-induced internal pressures for a two-compartment building are much less compared with the single-cell building. Sharma [7] presented linearized equations governing the internal pressures for

a rigid and non-leaky two-compartment building. Yu et al [8] developed non-linear governing equations by considering the effect of background leakage. However, there are no theoretical and experimental studies on the effect of roof flexibility.

In this paper, the equations governing wind-induced internal pressure responses for a two-compartment building when the roof responds in dynamic and quasi-static manners is derived. Then, the gain functions, roof displacement, power spectra and RMS values of internal pressures are numerically analyzed.

2 GOVERNING EQUATIONS FOR A FLEXIBLE BUILDING

2.1 *Basic assumptions*

The object is a two-compartment building with flexible roof. There is an opening in the windward wall and an opening in the partition wall, and there are no background leakages. Besides, some reasonable assumptions are made as follows:

(i) The wall is rigid, while the roof is flexible.
(ii) The partition wall only plays a role of wind shield, but it doesn't provide support to the roof.
(iii) The roof behaves linearly.
(iv) The roof will produce a tiny rotation angle in theory for the fluctuating internal pressure in the compartment without an external opening is a little higher than that in the other one. However, it can be ignored for the roof is large and the wall is rigid.
(v) Internal pressures are completely relevant in their own compartments. This is the precondition for the theory of the internal pressure response and has already been validated by experiments [9].
(vi) The adiabatic law is applied for air in both compartments. It means the state equation gov erning the variation of the internal air pressure and density becomes:

$$P_i / \rho_i^{\gamma} = \mathrm{C} \tag{1}$$

where γ is the specific heat ratio for adiabatic air and is generally equal to 1.4, C is a constant, and P_i , ρ_i are the internal air pressure and density, respectively. After differentiating both sides of equation (1) and simplifying it, then:

$$dP_i = \frac{\gamma P_a}{\rho_i} d\rho_i \tag{2}$$

where P_a is the atmospheric pressure, which is the steady-state internal pressure.

2.2 *Governing equations*

The simplified model of internal pressures for a two-compartment building with flexible roof and openings is shown in Fig. 1. P_W , P_{i1} and P_{i2} are the transient wind pressures of windward wall, compartment 1 and compartment 2, respectively. L_{e1} and L_{e2} are the effective lengths of "air slugs" in the opening 1 and 2. A_{o1} and A_{o2} are the areas of the opening 1 and 2. $\forall_{01}$ and $\forall_{02}$ are the internal volumes of compartment 1 and 2, $\forall_0 = \forall_{01} + \forall_{02}$. c_1 and c_2 are the flow coefficients at the opening 1 and 2. C_{L1} and C_{L2} are the loss coefficients at the opening 1 and 2. m_r , k_r and ς_r are the mass, stiffness and damping ratio of the roof, respectively. A_{r1} and A_{r2}

are the roof areas of compartment 1 and 2, $A_r = A_{r1} + A_{r2}$. x_1 and x_2 are the displacements of "air slugs" in the opening 1 and 2, x_r is the displacement of flexible roof.

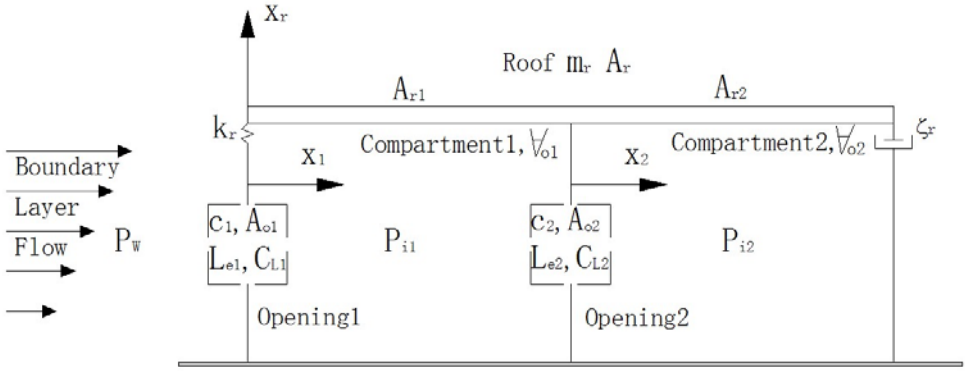

Figure 1. Model of a two-compartment building with linearly flexible roof structure

According to the unsteady form of the Bernoulli equation [2], the relationship between the airflow rate and the transient pressure drop for opening 1 is given by:

$$\rho_a L_{e1} c_1 A_{o1} \ddot{x}_1 + \frac{1}{2}\rho_a c_1 A_{o1} C_{L1} |\dot{x}_1| \dot{x}_1 = c_1 A_{o1} q_0 \left(C_{PW} - C_{Pi1}\right) \tag{3}$$

Similarly, the relationship between the airflow rate and the transient pressure drop for opening 2 is given by:

$$\rho_a L_{e2} c_2 A_{o2} \ddot{x}_2 + \frac{1}{2}\rho_a c_2 A_{o2} C_{L2} |\dot{x}_2| \dot{x}_2 = c_2 A_{o2} q_0 \left(C_{Pi1} - C_{Pi2}\right) \tag{4}$$

where $C_{Pi1} = P_{i1} / q_0$ and $C_{Pi2} = P_{i2} / q_0$ are the transient internal pressure coefficients of compartment 1 and compartment 2, $C_{PW} = P_W / q_0$ is the transient external pressure coefficient on the windward wall. ρ_a is the air density, $q_0 = \frac{1}{2}\rho_a U_0^2$ is the reference dynamic pressure of the approaching flow.

The changes in volumes of both compartments are:

$$\Delta\forall_1 = \forall_1 - \forall_{01} = A_{r1} x_r - c_1 A_{o1} x_1 + c_2 A_{o2} x_2 \tag{5}$$

$$\Delta\forall_2 = \forall_2 - \forall_{02} = A_{r2} x_r - c_2 A_{o2} x_2 \tag{6}$$

Then, according to the assumption (vi):

$$-q_0 \frac{\Delta C_{pi}}{\Delta\forall} \approx -q_0 \frac{dC_{pi}}{d\forall} = \frac{\gamma P_a}{\forall_0} \tag{7}$$

Substation of equations (5) and (6) into equation (7), and let $\upsilon = \frac{\forall}{\forall_0} = 1 + \frac{x_r}{H}$, $\dot{\upsilon} = \frac{\dot{x}_r}{H}$, $\ddot{\upsilon} = \frac{\ddot{x}_r}{H}$, there are:

$$C_{Pi1}=\frac{\gamma P_a}{q_0 \forall_{01}}\left[c_1 A_{o1} x_1 - c_2 A_{o2} x_2 - A_{r1} H(\upsilon - 1)\right] \tag{8}$$

$$C_{Pi2}=\frac{\gamma P_a}{q_0 \forall_{02}}\left[c_2 A_{o2} x_2 - A_{r2} H(\upsilon - 1)\right] \tag{9}$$

where H is the ridge height of the building.

Simultaneously solving equations (8) and (9) results in:

$$x_1=\frac{q_0 C_{Pi1}\forall_{01}+q_0 C_{Pi2}\forall_{02}}{\gamma P_a c_1 A_{o1}}+\frac{A_r H(\upsilon-1)}{c_1 A_{o1}} \tag{10}$$

$$x_2=\frac{q_0 C_{Pi2}\forall_{02}}{\gamma P_a c_2 A_{o2}}+\frac{A_{r2} H(\upsilon-1)}{c_2 A_{o2}} \tag{11}$$

Derivation of both sides of equations (10) and (11) leads to:

$$\dot{x}_1=\frac{q_0 \dot{C}_{Pi1}\forall_{01}+q_0 \dot{C}_{Pi2}\forall_{02}}{\gamma P_a c_1 A_{o1}}+\frac{A_r H\dot{\upsilon}}{c_1 A_{o1}} \tag{12}$$

$$\dot{x}_2=\frac{q_0 \dot{C}_{Pi2}\forall_{02}}{\gamma P_a c_2 A_{o2}}+\frac{A_{r2} H\dot{\upsilon}}{c_2 A_{o2}} \tag{13}$$

$$\ddot{x}_1=\frac{q_0 \ddot{C}_{Pi1}\forall_{01}+q_0 \ddot{C}_{Pi2}\forall_{02}}{\gamma P_a c_1 A_{o1}}+\frac{A_r H\ddot{\upsilon}}{c_1 A_{o1}} \tag{14}$$

$$\ddot{x}_2=\frac{q_0 \ddot{C}_{Pi2}\forall_{02}}{\gamma P_a c_2 A_{o2}}+\frac{A_{r2} H\ddot{\upsilon}}{c_2 A_{o2}} \tag{15}$$

Substation of equations (12~15) into equations (3~4) yields:

$$\begin{aligned}&\frac{\rho_a L_{e1}\forall_{01}}{\gamma P_a c_1 A_{o1}}\ddot{C}_{Pi1}+\frac{\rho_a L_{e1}\forall_{02}}{\gamma P_a c_1 A_{o1}}\ddot{C}_{Pi2}+\frac{\rho_a L_{e1}\forall_0}{c_1 A_{o1} q_0}\ddot{\upsilon}+\\&\frac{\rho_a C_{L1}\forall_0{}^2}{2(c_1 A_{o1})^2 q_0}\left|\frac{q_0\forall_{01}\dot{C}_{Pi1}+q_0\forall_{02}\dot{C}_{Pi2}}{\gamma P_a \forall_0}+\dot{\upsilon}\right|\left(\frac{q_0\forall_{01}\dot{C}_{Pi1}+q_0\forall_{02}\dot{C}_{Pi2}}{\gamma P_a\forall_0}+\dot{\upsilon}\right)+C_{Pi1}=C_{PW}\end{aligned} \tag{16}$$

$$\begin{aligned}&\frac{\rho_a L_{e2}\forall_{02}}{\gamma P_a c_2 A_{o2}}\ddot{C}_{Pi2}+\frac{\rho_a L_{e2}\forall_{02}}{c_2 A_{o2} q_0}\ddot{\upsilon}+\\&\frac{\rho_a C_{L2}\forall_{02}{}^2}{2(c_2 A_{o2})^2 q_0}\left|\frac{q_0\dot{C}_{Pi2}}{\gamma P_a}+\dot{\upsilon}\right|\left(\frac{q_0\dot{C}_{Pi2}}{\gamma P_a}+\dot{\upsilon}\right)+C_{Pi2}-C_{Pi1}=0\end{aligned} \tag{17}$$

Equations (16~17) are the general equations governing the internal pressure responses for a two-compartment building with flexible roof.

When the roof of the building is rigid, i.e. $\upsilon = 1$, $\dot{\upsilon} = 0$ and $\ddot{\upsilon} = 0$, the equations (16~17) can be simplified as follows:

$$\frac{\rho_a L_{e1} \forall_{01}}{\gamma P_a c_1 A_{o1}} \ddot{C}_{Pi1} + \frac{\rho_a L_{e1} \forall_{02}}{\gamma P_a c_1 A_{o1}} \ddot{C}_{Pi2} + \frac{\rho_a C_{L1} q_0 \forall_{01}^{\ 2}}{2(\gamma P_a c_1 A_{o1})^2} \left| \dot{C}_{Pi1} + \frac{\forall_{02}}{\forall_{01}} \dot{C}_{Pi2} \right| \left(\dot{C}_{Pi1} + \frac{\forall_{02}}{\forall_{01}} \dot{C}_{Pi2} \right) + C_{Pi1} = C_{PW} \tag{18}$$

$$\frac{\rho_a L_{e2} \forall_{02}}{\gamma P_a c_2 A_{o2}} \ddot{C}_{Pi2} + \frac{\rho_a C_{L2} q_0 \forall_{02}^{\ 2}}{2(\gamma P_a c_2 A_{o2})^2} \left| \dot{C}_{Pi2} \right| (\dot{C}_{Pi2}) + C_{Pi2} - C_{Pi1} = 0 \tag{19}$$

If the damping coefficients in equations (18) and (19) are linearized, they will become the internal pressure governing equations presented by Sharma [7]. Thus, the Sharma's governing equations [7] are a special case of the equations (16) and (17) derived in this paper.

2.2.1 *Responses of internal pressure when the roof responds in a dynamic manner*

In reality, many large span industrial building, their component structures, in particular the roof, exhibit greater flexibility than the wall. So they will behave in a dynamics manner in strong wind. As for a two-compartment building shown in Fig. 1, the response of the roof to the internal pressures will be governed by:

$$m_r \ddot{x}_r + 2m_r \zeta_r \omega_r \dot{x}_r + m_r \omega_r^2 x_r = A_{r1} q_0 C_{Pi1} + A_{r2} q_0 C_{Pi2} \tag{20}$$

The non-dimensional form of the equation (20) is:

$$\ddot{\upsilon} = \frac{q_0 \left(A_{r1} C_{Pi1} + A_{r2} C_{Pi2} \right)}{m_r H} - 2\zeta_r \omega_r \dot{\upsilon} - \omega_r^2 \left(\upsilon - 1 \right) \tag{21}$$

Equations (21) and (16~17) are the dynamic model of internal pressures for a two-compartment building with flexible roof. The equation (21) can be solved simultaneously with equations (16~17) to obtain the coupling responses of internal pressures and roof for specified parameter conditions.

2.2.2 *Responses of internal pressure when the roof responds in a quasi-static manner*

The dynamics model (Equations (21) and (16~17)) is a second-order differential equations, and it is hard to be solved for its complexity.

When the natural frequency of the roof is larger than the first expected Helmholtz frequency, the internal pressure responses are dominated by average and background components, while the resonance component can be ignored for its little contribution. Thus, the roof deflection is proportional to the applied load at all times [2], i.e. a quasi-static manner [3].

$$\upsilon = 1 + \frac{q_0 (C_{pi1} + C_{pi2})}{k_b} \tag{22}$$

where $k_b = (2\pi f_r)^2 \forall_0 m_r / A_r^2$ is the building bulk modulus defined as the ratio of increase in pressure to volumetric strain.

Substitution of the time derivation of υ into equations (16~17), and let $b = \gamma P_a / k_b$, yields:

$$\frac{\rho_a L_{e1}\left(\forall_{01}+b\forall_0\right)}{\gamma P_a c_1 A_{o1}}\ddot{C}_{Pi1}+\frac{\rho_a L_{e1}\left(\forall_{02}+b\forall_0\right)}{\gamma P_a c_1 A_{o1}}\ddot{C}_{Pi2}+\frac{\rho_a C_{L1} q_0}{2(\gamma P_a c_1 A_{o1})^2}\cdot$$
$$\left|\left(\forall_{01}+b\forall_0\right)\dot{C}_{Pi1}+\left(\forall_{02}+b\forall_0\right)\dot{C}_{Pi2}\right|\left[\left(\forall_{01}+b\forall_0\right)\dot{C}_{Pi1}+\left(\forall_{02}+b\forall_0\right)\dot{C}_{Pi2}\right]+C_{Pi1}=C_{PW} \tag{23}$$

$$\frac{\rho_a L_{e2}\forall_{02}(1+b)}{\gamma P_a c_2 A_{o2}}\left(\ddot{C}_{Pi2}+\frac{b}{1+b}\ddot{C}_{pi1}\right)+$$
$$\frac{\rho_a C_{L2} q_0 \forall_{02}{}^2(1+b)^2}{2(\gamma P_a c_2 A_{o2})^2}\left|\dot{C}_{pi2}+\frac{b}{1+b}\dot{C}_{pi1}\right|\left(\dot{C}_{pi2}+\frac{b}{1+b}\dot{C}_{pi1}\right)-C_{Pi1}+C_{Pi2}=0 \tag{24}$$

Equations (23~24) are the quasi-static model of internal pressures for a two-compartment building with flexible roof. It is actually an approximate model of the dynamic model when the natural frequency of roof is considerably larger than the lower Helmholtz frequency.

3 NUMERICAL EXAMPLE

Take a two-compartment building as an example to analyze the dynamic and quasi-static responses of internal pressure. The two-compartment building is similar as the TTU test building, whose basic parameter values are as follows:

$\forall_{01}=200m^3$, $\forall_{02}=300m^3$, $A_{o1}=2m^2$, $A_{o2}=2m^2$, $L_{e1}=\sqrt{\pi A_{o1}/4}$, $L_{e2}=\sqrt{\pi A_{o2}/4}$, $c_1=0.6$, $c_2=0.6$, $C_{L1}=1.2$, $C_{L2}=1.2$, $\bar{U}_0=30m/s$, $\gamma=1.4$, $P_a=101300Pa$, $\rho_a=1.22kg/m^3$, $A_{r1}=50m^2$, $A_{r2}=75m^2$, $H=4m$, $m_r=3500kg$, $\varsigma_r=0.1$, $\omega_r=2\pi f_r$, $f_r=$3Hz, 5Hz, 7Hz, 10Hz.

The time history of wind speed can be simulated by the superposition of the harmonic [10] based on Davenport spectrum, and then the time history of external pressure coefficient at the windward opening can be further obtained according to the quasi-steady theory. The responses of internal pressure can be calculated by inputting the external pressure coefficient obtained in last step into the governing equations derived in the present paper. The simulated wind speed and its verification are shown in Fig. 2.

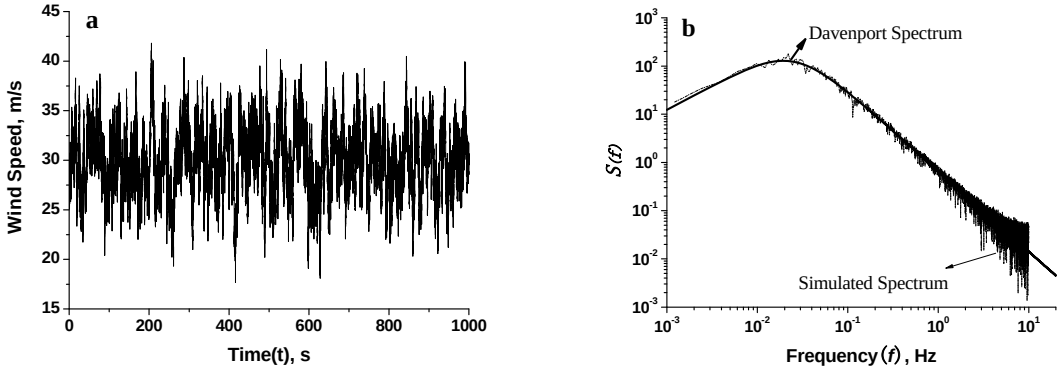

Figure 2. (a) Simulated time-history wind speed and (b) its verification

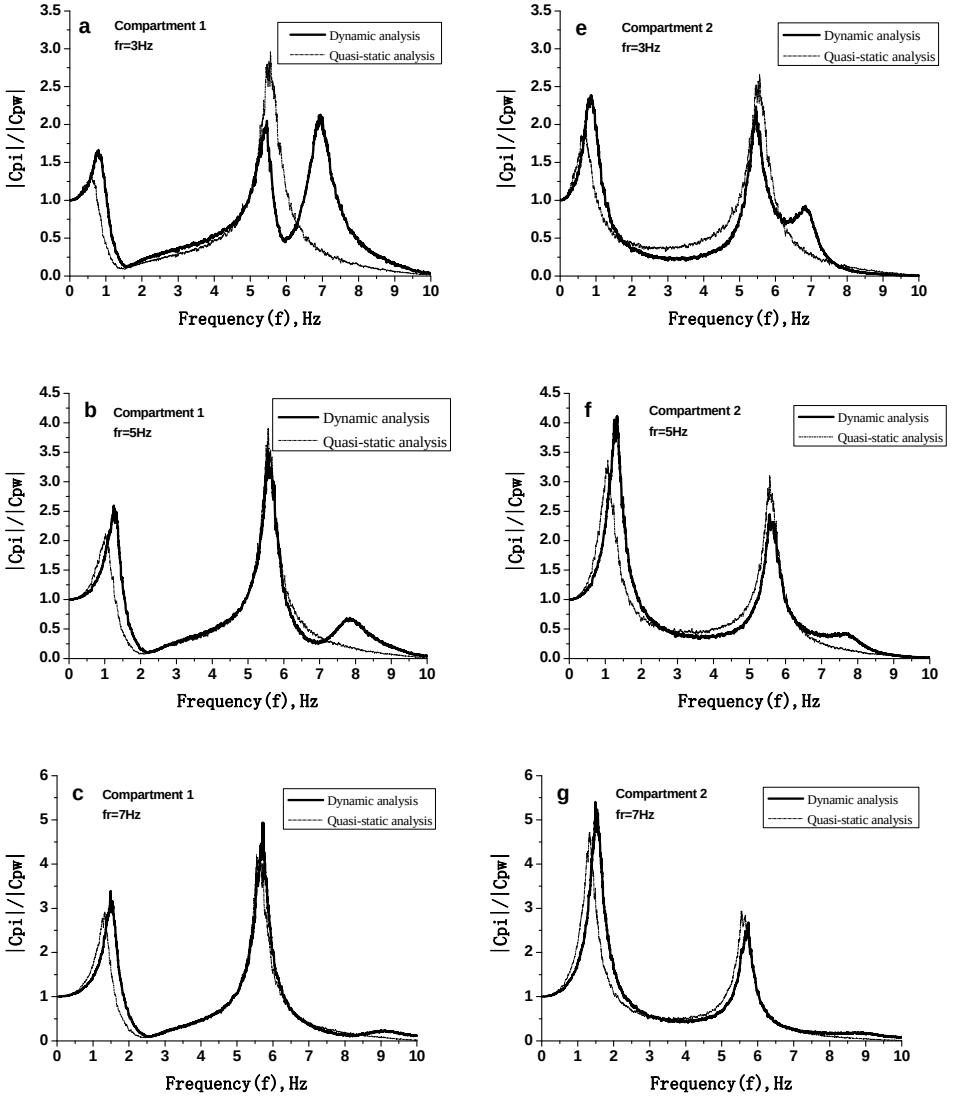
The gain functions of internal pressures calculated from the dynamic and quasi-static models for different roof flexibilities are shown in Fig. 3, in which Figs 3a,b,c,d are the results of compartment 1 and Figs 3e,f,g,h are the results of compartment 2. The two-compartment building

with flexible roof and openings is similar to a coupled dynamic system which contains three "mass-spring-damping" subsystems. It can be seen from Fig.3 that three resonance peaks are evident from dynamic analysis while only two resonance peaks are obtained from quasi-static analysis. Furthermore, the first two resonance frequencies obtained from dynamic analysis is the same as that obtained from quasi-static analysis. Besides, the internal pressure response in compartment 2 is higher than that in compartment 1 calculated from both models. However, the third resonance peak gradually disappears when the roof natural frequency gradually becomes larger, and the gain function obtained from the dynamic model is gradually consistent with that from quasi-static model.



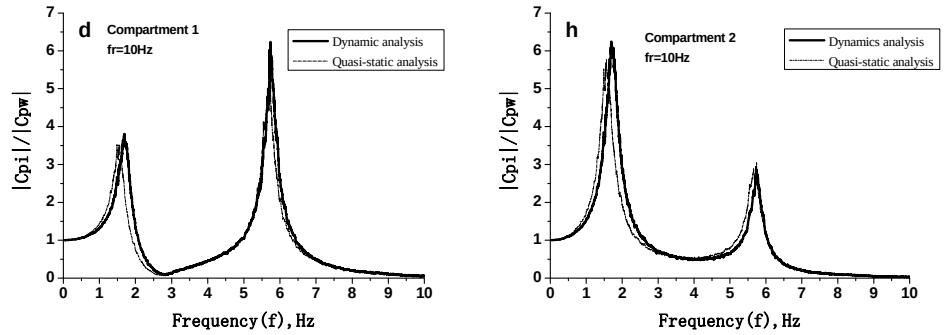


Fig 3. Gain function of internal pressure for dynamic and quasi-static analysis

The gain functions of internal pressures in both compartments, the roof displacement over external pressure at the windward opening calculated from dynamic model for different roof natural frequencies are shown in Fig.4. It is shown from Figs 4a,b that three resonance frequencies of the "internal pressure - roof" coupled system increase with increased roof natural frequency. The first two resonance peaks of internal pressure are also increase with increased roof natural frequency, while the third resonance peak decreases and finally disappears. It is shown from Fig 4c that the restoring force of the roof increases with increased roof natural frequency at the first two resonance frequencies, and the restoring forces at the first resonance frequency are much larger than these at the last two resonance frequencies.

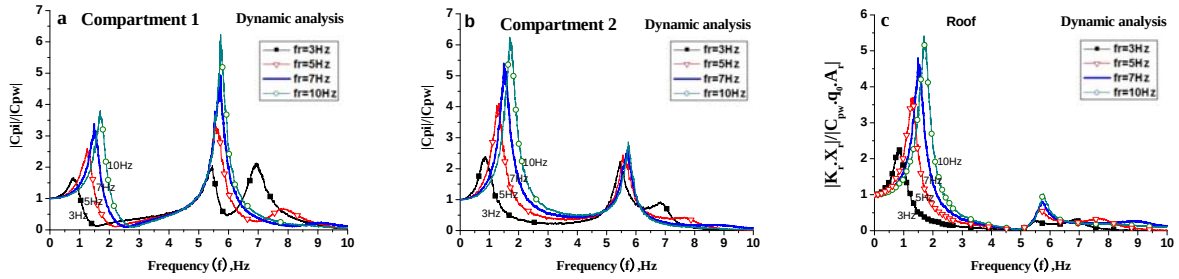

Figure 4. Gain function of (a) internal pressure for compartment 1 (b) internal pressure for compartment 2 and (c) roof displacement over external pressure for different roof flexibilities

The power spectra of internal pressure coefficients in both compartments obtained from the dynamic model for different roof flexibilities are shown in Fig.5. It is shown that the resonance energy of internal pressure in compartment 2 at the first resonance frequency is higher than that in compartment 1 for all kinds of roof flexibilities. The resonance energies of internal pressure in both compartments at the third resonance frequency decrease with increased roof natural frequency. This is in agreement with the analytical results of Fig.3.

The RMS internal pressure coefficients in both compartments and RMS roof displacement for different roof flexibilities are list in Table 1. It is shown that the RMS internal pressure coefficient in compartment 2 is large than that in compartment 1. The RMS internal pressure coefficients obtained from both models increase with increased roof natural frequency, but their difference decreases. It is because with increased roof natural frequency, i.e. the roof flexibility gradually decreases, the additional damping also decreases. Moreover, the RMS value of the roof displacement decreases with increased roof natural frequency.

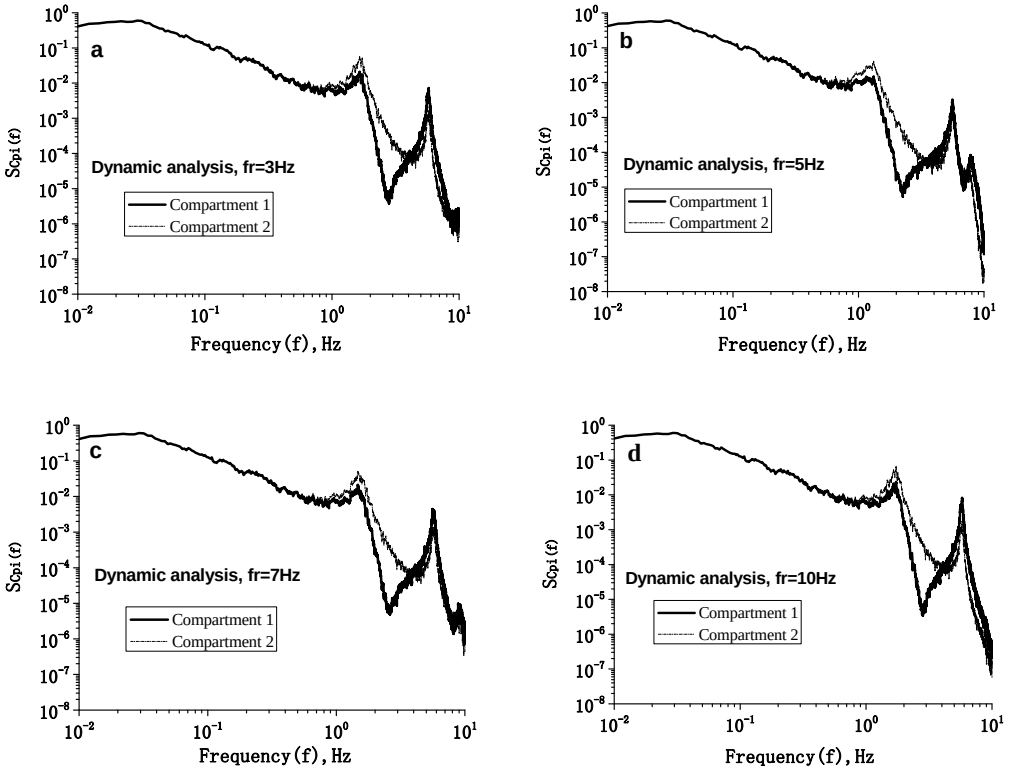

Figure 5. Power spectra of internal pressure coefficients in both compartments

Table 1. RMS internal pressure coefficients in bot compartments and RMS roof displacement for different roof flexibilities

Roof frequency	$\tilde{C}_{pi}$ (Dynamic analysis)		$\tilde{C}_{pi}$ (Quasi-static analysis)		$\tilde{x}_r$ (Dynamic analysis)
	Compartment 1	Compartment 2	Compartment 1	Compartment 2	
3 Hz	0.236	0.250	0.233	0.248	0.0136
5 Hz	0.243	0.262	0.242	0.261	0.0051
7 Hz	0.247	0.269	0.246	0.269	0.0026
10 Hz	0.251	0.274	0.249	0.273	0.0013

4 CONCLUSIONS

As for a two-compartment building with flexible roof and openings, the equations governing wind-induced internal pressure responses are derived based on some reasonable assumptions when the roof responds in dynamic and quasi-static manners. The unsteady form of the Bernoulli equation, the law of mass conservation, and adiabatic equation are used for the derivation. A two-compartment building similar to the TTU test building is taken as an example to analyze the characteristics of gain functions, power spectra and RMS values of the internal pressure coefficients and roof displacement. Some main conclusions are drawn:

(1) The governing equations derived in the present paper can be used to analyze the internal pressure responses for a two-compartment building with flexible roof and openings. The dynamic model must be used to calculate the responses of internal pressure when the roof is flexible, otherwise, the simplified quasi-static model can be instead.

(2) The first two resonance frequencies of the “internal pressure - roof” coupled system obtained from the dynamic model is consistent with that obtained from the quasi-static model. The internal pressure response in compartment 2 is larger than that in compartment 1. When the roof natural frequency gradually becomes larger, the gain functions obtained from the dynamic model are gradually in accord with these from the quasi-static model.

(3) With increased roof natural frequency, the three resonance frequencies increase, and the first two resonance peaks of internal pressure are also increase, while the third resonance peak decreases and finally disappears. Besides, the restoring forces of the roof at the first two resonance frequencies also increase with increased roof natural frequency.

(4) The RMS internal pressure coefficient in compartment 2 is large than that in compartment 1. The RMS internal pressure coefficients obtained from both the dynamic and quasi-static models increase with increased roof natural frequency, but their difference decreases. Moreover, the RMS value of the roof displacement also decreases with increased roof natural frequency.

ABSTRACT: Tornadoes pose serious threat to buildings and structures. Reducing the risk to building structures requires the understanding of tornado-structure interaction, the surface and internal pressures developed and the net wind loads acting on the building. In the present investigation an attempt is made to investigate the effect of ground roughness on the internal pressure developed inside a building model exposed to a stationary vortex generated by a tornado-like flow simulator at Tokyo Polytechnic University. Results show that the internal pressures decrease in magnitude with introduction of roughness, whereas the resulting local roof forces increase in magnitude with introduction of roughness.

KEYWORDS: Tornado, Ground Roughness, Swirl Ratio, Building Structures, Internal Pressure

1 INTRODUCTION

The real time investigations on the nature of tornadoes are impractical because of unpredictability, short life span and danger. Many strategically important buildings such as Nuclear power plants and hospitals should be designed against tornado wind. Every year Japan experiences around 17~20 tornadoes, distributed over the mainland, though some recent studies by Tamura et al. predicts as high as 35-40. Though the human fatalities associated with tornado-occurrence in Japan are very less, the damage to building roofs and walls and the building as a whole is extensive. On an average 385 residential structures are partly or completely damaged due to tornadoes in Japan every year, Niino et al (1997). Recently several strong tornadoes attacked Japan at Nobeoka and Hokkaido in 2006.

Wind pressure studies estimated from boundary layer wind tunnels along with full-scale studies are used in building codes. But in local disturbances like a tornado, where there is a rotational wind component together with a significant vertical component of velocity, the nature and distribution of pressures and resulting wind loads will be quite different from a straight line wind. This demands the analysis of tornado-structure interaction different from a boundary layer phenomenon.

A comprehensive investigation will be possible only through a thorough understanding of the damage characteristics, the failure modes of structures in a tornado wind, the commonly occurring structural damages, the relation between the tornado parameters and type of structures that failed etc. Based on this knowledge based information, identical conditions need to be simulated in situ for careful and systematic velocity and pressure measurements and estimate the tornado wind loads varying the geometrical and dynamic parameters influencing tornado-building

interaction to gain a clear insight into the underlying mechanism that inflict damage. This in turn could help the broader aim of tornado wind resistant building design.

During the past few decades, there have been attempts to simulate tornado-like flow situations in laboratory and expose scaled building models to the vortex-type flow [Chang (1971), Jischke & Light (1983), Mishra et al (2008), Haan et al (2010), Yang et al (2011)]. Many of these studies were limited to the surface pressures on buildings under these extreme flow-regimes. But recently, attempts are done to understand the internal pressures developed under such flow situations [(Kikitsu et al (2011), Sabareesh et al (2011)].

Internal pressure studies become significant in the view of openings created on the building walls under such local disturbances like a tornado. The internal pressures will respond to the changes in external pressures, if the opening porosity is higher.

2 EXPERIMENTAL SETUP

In the present work an attempt is made to determine the internal pressures and resulting local roof wind force for a building under tornado-like flow and exposed to two different terrain conditions.

The tornado-like flow simulator at Tokyo Polytechnic University that could generate a stationary tornado-like flow was used. The tornado-like flow generator is essentially the same as used in Sabareesh et al. (2012) with the confluence height being reduced to 200mm for the present case. The parameters governing tornado-like flow has been found to be in close agreement with those that are attainable in other laboratory simulator flows as explained in Sabareesh et al. (2012).

The building model was of size 30mm x 30mm x 15 mm, and was located at the centre of the simulator floor. A square central hole constituting an opening porosity of 3.9% was kept open in the building wall. The definition of opening porosity in the present case is the ratio of opening area to single wall area. A volume chamber was placed beneath the simulator floor as per the requirements to scale the internal volume to maintain similarity in dynamic response of volume between full scale and model scale, see Figure 1.

Two different terrain conditions were used for this study. The first was a plain floor without any roughness, which can be categorized as a near smooth terrain, the second used a 5mm artificial grass carpet on the simulator floor, see Figure 2. The roughness in the second case can be estimated as typically about $1/30^{th}$ of the height of roughness element (Leslie, 1977), or using a procedure described in Counihan (1971) which results in an effective roughness in the range of Z_0 =0.17~0.28mm. The effects under two different swirl ratio cases are discussed.

Figure 1. Scaled volume chamber

Figure 2. Building model exposed to artificial roughness

2.1 *Velocity Measurements*

The variation of velocity field to the rotating flow determines the type of flow field in the simulator. The scalar component of velocity was measured at definite radial locations from the simulator centre to the periphery and simultaneously at different heights above the floor in these radial locations. A multi-channel thermistor type anemometer probe which can measure simultaneously the mean component of velocity at different locations was used for this purpose.

With increase in roughness the outer boundary of core thickens, and the higher velocity region shifts up to greater heights above the floor of simulator. A lower mean velocity region can

be observed close to the ground with increase in surface roughness. Away from the core regions, the effect of surface roughness on mean velocity was negligible.

Also it is observed that the core updraft velocity increases with increase in roughness as shown in Figure 3 for different swirl ratios.

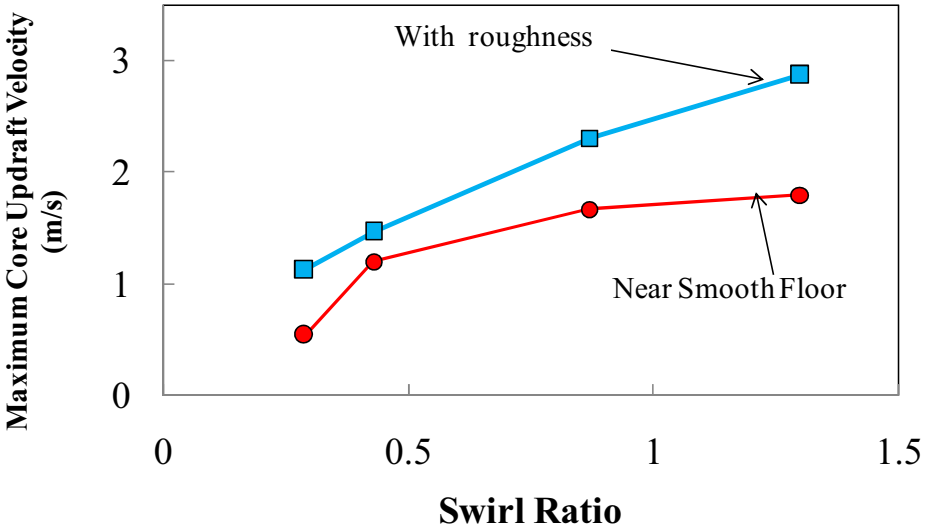

Figure 3Variation of core updraft velocity with roughness at different swirl ratio

2.2 *Pressure Measurements*

Simulator floor was fitted with pressure taps on its surface. The building model was also fitted with pressure taps in the inside apart from the outer pressure taps. Synthetic resin tubes 1m long connected each pressure tap with the pressure measurement scan valve, which is capable of simultaneously measuring the pressures at these taps.

Pressure sensors were employed, which could simultaneously measure pressures at multiple points. Sampling frequency of data points was 700 Hz. Measured voltage signals were transformed to time series of wind pressures. Effects of tube system were removed by analyzing the transfer function of tube system and eliminating it from the raw wind pressures.

Internal pressures were simultaneously measured at 10 pressure taps distributed evenly inside the building model and the volume chamber and numerically averaged. There were a total of 25 pressure taps distributed on the roof external face. The pressure coefficient (Cp_j) at any point' $_j$' is defined by equation (1).

$$Cp_j = \frac{P_j - P_\infty}{q_r} \tag{1}$$

Where, 'q_r' is the reference dynamic pressure obtained from velocity at roof height. 'P_∞' is the reference static pressure measured far from simulator centre.

Minimum values (*Cpi (minimum*) of the internal pressure coefficients were obtained. The time scale was obtained employing the ratio between the core radius of the tornado vortex and maximum wind speed in the flow region (approx. 2.4m/s). Using this time scale, the full scale equivalent of model scale time was estimated for the entire length of pressure data assuming a F3 tornado having a core size of 30m and maximum wind speed of 92m/s. The time histories corresponding to 1minute in full scale from a conservative view point were measured for 21

samples. The minimum values in the time history were obtained independently for each of these 21 segments. The average of the minimum values of the 21 segments defines the minimum peak pressure coefficient presented in the results.
The net local roof force coefficients per unit area around a point '*j*' $C_{F(t)}$ was derived as the difference between external, $Cpe_{j(t)}$ and internal, $Cpi_{(t)}$ pressure coefficients,

$$C_{F_{(t)}} = Cpe_{j(t)} - Cpi_{(t)}$$

3 RESULTS AND DISCUSSIONS

The roughness heights are normalized with respect to building height.

Analysing the effect of roughness, it was found that for both the swirl ratio examined with increase in roughness, the minimum value of peak internal pressure coefficients showed a decrease in magnitude, see Figure 4. This may be because the flow gets retarded near the surface layers as observed from the velocity distribution near the surface in presence of roughness, see Sabareesh et al(2012). This inturn reduces the pressure coefficients across the building surface and interiors. Roughness on the ground reduces the near ground velocities, which tends to decrease in magnitude the external pressures on building walls outside the opening. This in turn reduces the internal pressure coefficients inside the building, as the internal pressures respond to the changes in external pressure when the opening porosity is higher.

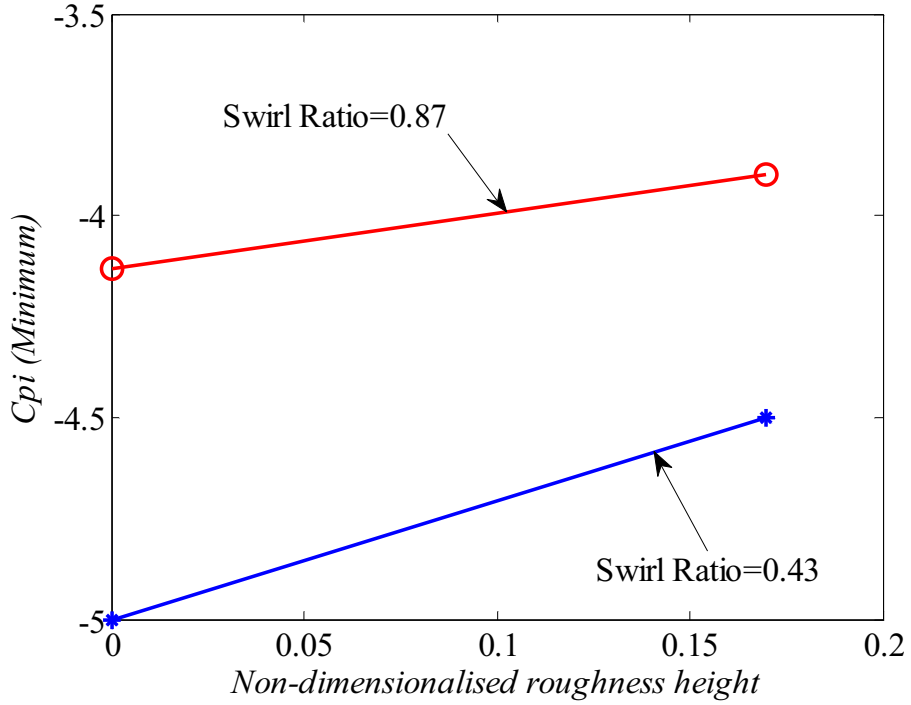

Figure 4. Variation of minimum internal pressure coefficient with terrain condition

Comparing the variation of external pressure coefficients with the internal pressure coefficients, see Figure 5, it is found that with introduction of roughness the external pressure coeffi-

cients show a steeper descent in magnitude compared to the internal pressure coefficients showing that the decrease in internal pressure within the building model is rather gradual.

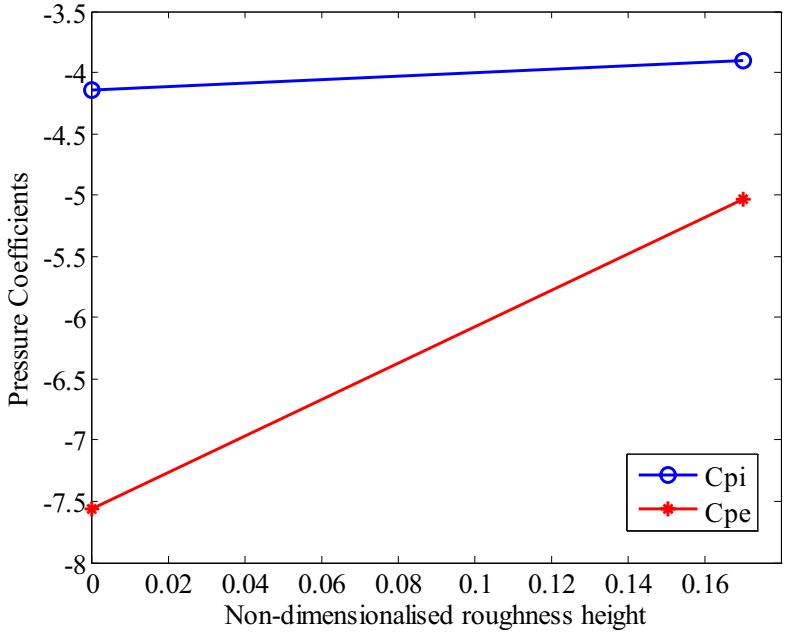

Figure 5. Variation of minimum pressure coefficients with terrain condition

Analyzing the Helmholtz frequency for the flow through the openings, see Figure 6, it is found that with increase in roughness the peak of Helmholtz resonance slightly shifts to the higher frequency side.

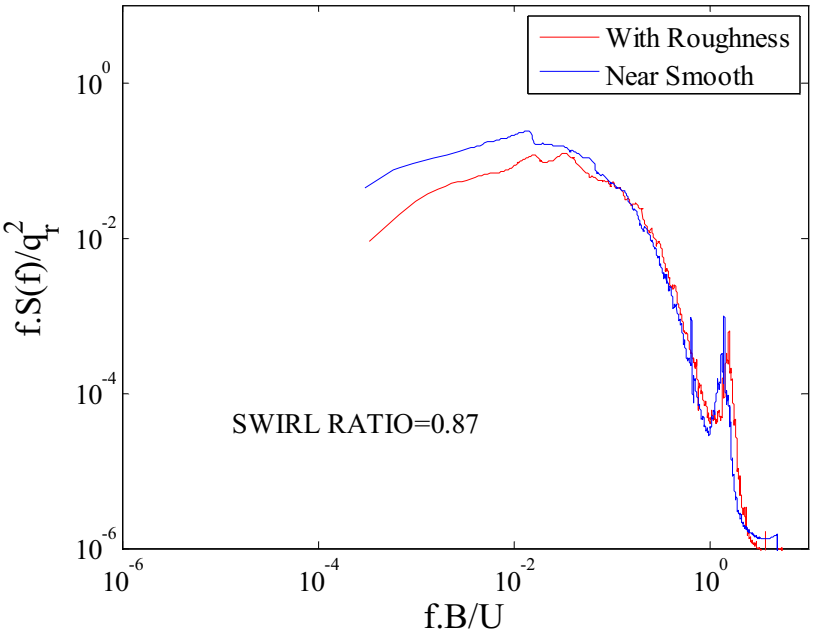

Figure 6. Variation of Helmholtz resonance with introduction of roughness

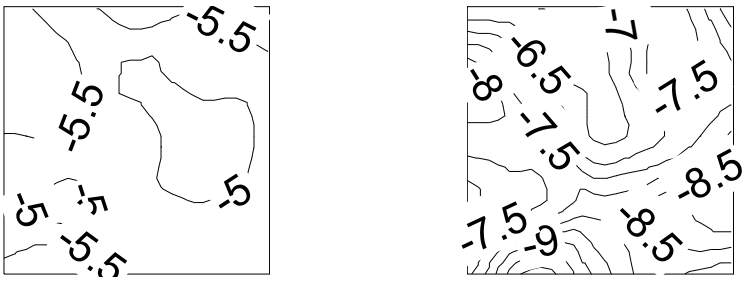

(a) (b)

Figure 7 Local roof wind force coefficient (a) Smooth Terrain (b) With roughness

Figure 7 shows the local wind force coefficient contours on the building roof for the two roughness cases at Swirl ratio S=0.87. The effects on the local roof wind force were the opposite of that experienced for the internal pressures. The smoother terrain case experienced lower magnitude local roof wind force compared to the rougher terrain. This may be attributed to the increase in core updraft velocity associated with increase in terrain roughness which increases the magnitude of suction forces on roof surfaces. These effects repeated for the two swirl ratios examined.

3.1 *Conclusions*

1. With the introduction of roughness the internal pressures decrease in magnitude irrespective of swirl ratio.
2. External pressures shows higher decrease compared to internal pressures with the introduction of roughness.
3. Helmholtz resonance shows a shift in peak to the higher frequency side with introduction of roughness.
4. The net roof force increase in magnitude with introduction of roughness.

ABSTRACT: The pressure and flow field around a target low-rise model immersed in a large group simulating various area densities were investigated using three-dimensional numerical RANS turbulence models. Wind pressure coefficients obtained from the numerical results were compared with those of wind pressure measurements, and the flow fields around the model were compared with those obtained from flow visualization. The results show that for the wind pressure coefficients for the isolated model, more reasonable results were obtained when the rng k-ε model was used, but there was little difference between turbulence models for the target model in a large group. For the flow field around the model, the RANS turbulence models were able to reproduce the overall flow pattern generally, even though some differences were found.

KEYWORDS: Group of low-rise buildings; Computational fluid dynamics; Wind pressure measurement; Flow visualization

1 INTRODUCTION

As low-rise buildings are normally built in large groups, the flow field around a low-rise building of interest is totally different from that around an isolated building. The significance of this different flow field should be focused on not only from structural but also from environmental viewpoints because the flow field determines wind pressure distributions and the degree of scalar dispersion. Flow field conditions are strongly dependent on building geometry and arrangement characteristics, more or less incident flow conditions, by interacting and overlapping, which governs the wind force/pressure characteristics as well as the nature of ventilation and dispersion of pollutants in urban street canyons.

Wind pressure measurements for a low-rise building in a large group have been performed by many researchers (Sun et al., 2008; Kim et al., 2011, 2012). Sun et al. (2008) investigated peak pressure coefficients through a number of wind tunnel tests, and reported that shielding effects generally depend on area density and relative height ratio between the target building and surrounding buildings, and although the shielding effects were significant in most cases, the positive peak wind pressure coefficients were increased by 100% in some cases. Most recently, Kim et al. (2011, 2012) measured fluctuating wind pressures applied to a cubical low-rise building immersed in various area densities and long upstream distances under suburban flow conditions. After a detailed examination of wind pressures and forces characteristics, methodologies of wind load estimation were suggested based on the interference factor for the structural frame and zoning interference factor for components and cladding.

The remarkable growth in computer technology has enabled increasing application of numerical simulations to a large group of low-rise buildings to the problems including wind loads,

flow conditions and pollutant dispersion. Much of the works have focused on investigating the flow and pollutant dispersion problems within urban street canyons using the RANS turbulence model. Chang and Meroney (2003) investigated the effect of surrounding buildings with different separation distances on flow distributions and transport from steady point sources of pollutants, or chemical and biological agents, in an idealized urban environment. Lien and Yee (2004) studied the neutrally-stratified flow within and over a large group of 3-dimensional cubical buildings using two turbulence models: the standard k-ε model and the Kato-Launder k-ε model. Santiago et al. (2007) examined the wind flow and pollutant dispersion inside and above a three-dimensional cubic array to describe and explain the flow structure and tracer dispersion using the standard k-ε turbulence model.

Most recent numerical studies have discussed flow and pollutant dispersion, and although some previous studies have discussed the pressure and flow field for a target low-rise building in large group, the simulated area density was very limited, mostly an area density of 25%. The purpose of the present study was to investigate the pressure and flow field for a target low-rise building immersed in various area densities ranging from 6% to 44% by comparing numerical results with wind pressure measurements and flow visualizations using a DPIV system. For the numerical simulation, three-dimensional RANS turbulence models were implemented.

2 WIND TUNNEL TEST AND COMPUTATIONAL FLUID DYNAMICS

Wind tunnel tests were conducted at the Tokyo Polytechnic University in Japan. A 0.1m cubical building model was used for the target low-rise building, and the same sized cubes made of wood were used as dummy models. Area density, C_A, was defined as the ratio of the area covered by the building to the building lot area, and varied as 6%, 11%, 16%, 25%, and 44%. A schematic of the wind tunnel test is shown in Figure 1, and the experimental procedures were as follows.

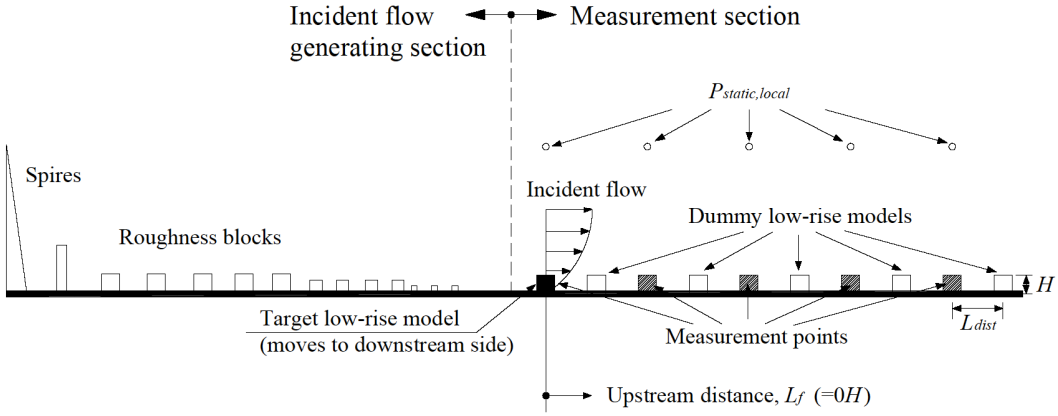

Figure 1. Schematic of wind tunnel test

As shown in Figure 1, half the wind tunnel was used as an incident flow generating section using spires, barriers, and three different-sized blocks. The incident flow was measured at L_f=0H. To clarify the effect of surrounding buildings, the wind pressure measurement of the isolated model was conducted at L_f=0H. After arranging the dummy low-rise models, the wind pressure measurements for the target model were conducted by moving it downstream at specified intervals determined by area density. Here, the term “target model” is used to indicate the model surrounded by dummy low-rise models in order to differentiate it from “isolated model”. In previous studies,

the dummy models were arranged on the upstream side while the target model was fixed at a position. But in the present study, the target model was moved to the downstream side, which makes the changes of wind pressures and flow conditions more understandable depending on various area densities and upstream distances. The number of measurement points was dependent on area density, and there were 9 measurement points for area densities of 11%, 16%, and 44%, and 6 measurement points for area densities of 6% and 25%. 125 pressure taps were installed, and all pressures were measured simultaneously using a multi-channel pressure measurement system, and the tubing effects were numerically compensated using the gain and phase shift characteristics of the pressure measurement system. As an incident flow, a turbulent boundary layer representing a suburban area with a power-law exponent of 0.2 (U_H≈7.2m/s, $I_{u,H}$≈23%) was simulated as shown in Figure 2 (thick solid line). The Reynolds number based on U_{ref} and B was about 5×10^4, and the wind direction was fixed at 0˚, with the incident wind normal to the model surface.

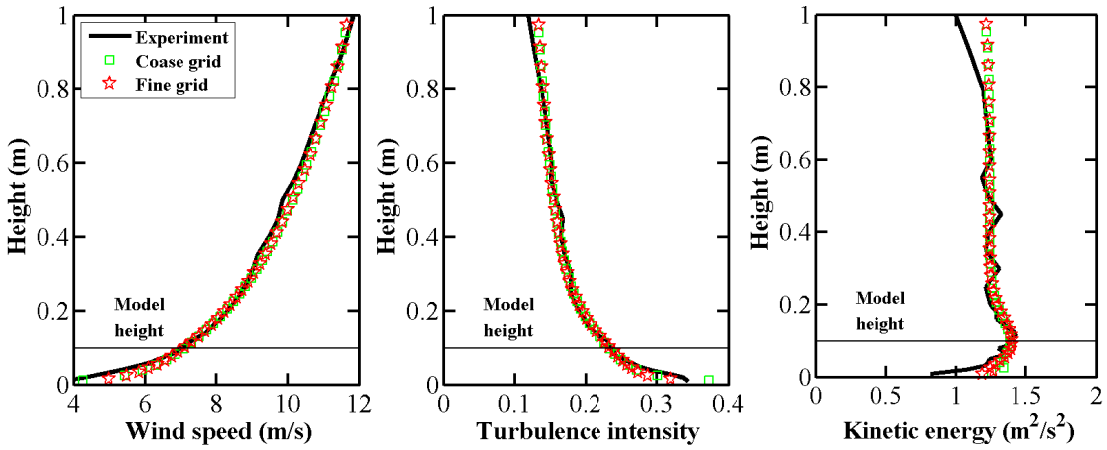

Figure 2. Comparison between incident flow conditions from wind tunnel test and simulation

Flow visualization using a Dynamic Particle Image Velocimetry (DPIV) system was carried out in a Boundary Layer Wind Tunnel at Shimizu Institute of Technology, Japan. The system consisted of a high-speed digital video camera, a double pulse ND: YAG laser, and a particle generator. Tracer particles were discharged from the particle generator, which was located at the end of the group of low-rise buildings, and then circulated in the wind tunnel. The particles were illuminated by a pulsed laser light sheet. The image size was adjusted to be large enough to adequately capture the flow field. A pixel resolution of 800×600 was used, and 2000 pictures were taken, resulting in sampling frequencies of 1000 frames per second. The measuring time was set to 2.95 seconds (5900 pictures).

Fluent, included in the package of ANSYS 13.0, was used to carry out all numerical simulations based on the finite volume method. In the present study, well-known turbulent Reynolds Averaged Navier-Stokes (RANS) models, the standard k-ε model and the rng k-ε model, were used for the turbulent flow of an incompressible viscous fluid. The modified law-of-the-wall function was used in combination with RANS turbulence models. As input parameters for the modified law-of-the-wall function, K_S and C_S needed to be input to the solver, and K_S and C_S were determined using the incident flow from the wind tunnel test considering the relationship between K_S and z_0 for the fully rough regime (Blocken et al., 2007). The obtained z_0 for the incident flow was 4.76×10^{-4}, and using C_S =1, K_S was set to 0.001 for the wind tunnel's floor roughness condition. Note that this K_S was smaller than y_P, which is the distance from the floor to the center point P of the wall adjacent to the cell. The boundary conditions of the two sides and the

top were modeled as slip walls, and the free outlet boundary condition was used. Inlet profiles for streamwise mean wind speed, turbulent kinetic energy, and turbulent dissipation rate were simulated using a user-defined function. Turbulent kinetic energy was obtained considering only the streamwise fluctuating component, and turbulent dissipation rate was obtained assuming local equilibrium of $G_k=\varepsilon$ (Tominaga et al., 2008). Lateral and vertical wind speeds were assumed to be zero. For the isolated model, two grid systems were employed: a coarse grid with y^+ larger than 61 and a fine grid with y^+ larger than 30. The simulated profiles at the model position in the empty three-dimensional computational domain are shown in Figure 2 for the fine and coarse grids, and show good agreement with incident flow from the wind tunnel test regardless of the y^+ values. Here, the reference wind speed U_{ref} means the mean wind speed at the model position. Other important computational conditions and the position of the target model are summarized in Table 1. For the isolated model, two grids were employed to examine the grid dependence of the results, and for the target model, the computational domain was reduced considering the symmetry condition. One example of a grid for the target model when C_A=25% is shown in Figure 3.

Table 1 Computational conditions

		C_A=0%	C_A=6%	C_A=11%	C_A=16%	C_A=25%	C_A=44%

3 RESULTS AND DISCUSSION

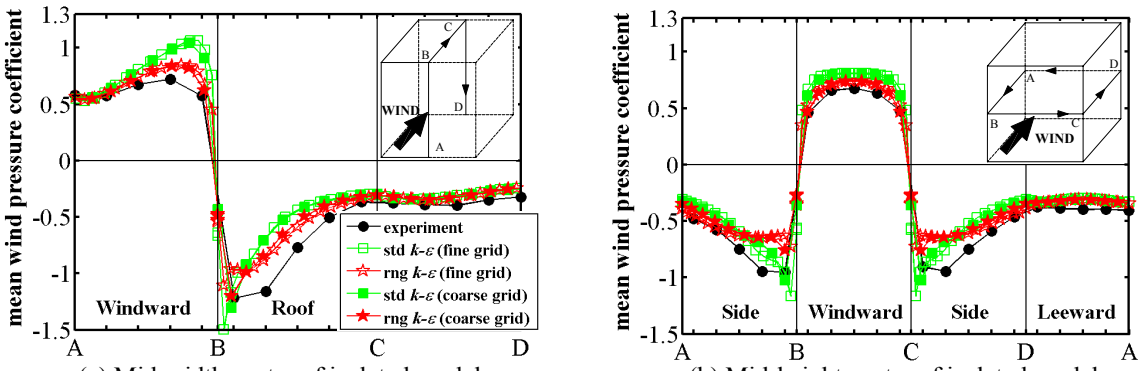
3.1 *Results for isolated model*

Mean wind pressure coefficients are defined as:

$$\overline{C}_p = \frac{\overline{P} - \overline{P}_{ref}}{0.5\rho U_{ref}^2} \tag{1}$$

where, $\overline{P}$ is the time-averaged surface pressure and $\overline{P}_{ref}$ is the time-averaged reference static pressure in the computational domain, which is at exactly the same position as the pitot tube in the wind tunnel test.

Figure 4 compares the mean wind pressure coefficients from the wind tunnel test with the simulation results from the coarse and fine grids. Differences are observed near the stagnation point on the windward surface and on the leading edges of the roof and side surfaces where large suctions occur due to the separated shear layer. On the leeward surface, the simulation results show slightly larger values than the experimental values (smaller absolute value). From the different turbulence models, clear differences are also observed near the stagnation point and leading edges. For the standard k-ε model, the mean wind pressure coefficient near the stagnation point is larger than unity, which is theoretically impossible and which is also much larger than the experimental values. Contrary to the results of the standard k-ε model, those of the rng k-ε model show relatively good agreement with the experimental results on the windward surface. On the side surfaces, the variation trend of the rng k-ε model is similar to that of the experimental value, but the values are much larger than the experimental results and the standard k-ε model results. Focusing on the smallest mean wind pressure coefficient (larger absolute value), it seems that the standard k-ε model results in more reasonable but slightly conservative values. There is little difference between the pressure coefficients on the leeward surface given by the two turbulence models, and it is interesting to note that almost the same results were obtained for the two different grids, although the fine grid gives slightly larger absolute values.



(a) Mid-width center of isolated model (b) Mid-height center of isolated model

Figure 4. Comparison of mean C_p for isolated model

Wind pressure coefficients at mid-width center were compared quantitatively using three statistical parameters, normalized mean square error (NMSE, Eq. (2)), fractional bias (FB, Eq. (3)), and correlation coefficients (R), and the results are summarized in Table 2. For comparison, the numerical results corresponding to pressure tap positions were selected. NMSE indicates a value of normalized discrepancies between the computed and experimental values, and FB gives

information about overestimation (negative value of FB) or underestimation (positive value of FB).

$$NMSE = \frac{1/n\sum_{i=1}^{n}(E_i - C_i)^2}{1/n\sum_{i=1}^{n}(E_i C_i)} \quad (2); \qquad FB = \frac{(E_i - C_i)}{0.5(E_i + C_i)} \quad (3)$$

As shown in Table 2, the NMSE of the rng k-ε model is very small compared to those of the standard k-ε model on the windward and roof surfaces, while that on the leeward surface is almost the same. As expected, the FB of the windward surface is negative, while those of the roof and leeward surfaces are positive, meaning that the numerical results are overestimated for the windward surface and underestimated for the roof and leeward surfaces. The FB of the rng k-ε model is smaller than that of the standard k-ε model, showing especially large differences on the windward surface. Like NMSE, FB shows little difference on the leeward surface. Similar observations can be made for correlation coefficient R. Considering the different grids, NMSE and FB obtained from the coarse grid are smaller than those obtained from the fine grid, implying that the numerical results from the coarse grid better correspond to the experimental results, but the differences between them are not significant. The statistical parameters at mid-height center show a similar trend to the mid-width center, generally showing numerical results from the coarse grid using the rng k-ε model in better correspondence with the experimental values.

Table 2 Comparison of normalized mean square error (NMSE), fractional bias (FB) and correlation coefficient (R)

		NMSE		FB		R for all points	
		std k-ε	rng k-ε	std k-ε	rng k-ε	std k-ε	rng k-ε
Fine Grid	Windward Surface	0.1	0.01	-0.23	-0.09	0.90	0.97
	Roof Surface	0.15	0.06	0.36	0.23		
	Leeward Surface	0.04	0.04	0.21	0.19		
Coarse Grid	Windward Surface	0.08	0.01	-0.21	-0.06	0.91	0.97
	Roof Surface	0.12	0.06	0.26	0.2		
	Leeward Surface	0.03	0.04	0.18	0.18		

Using the numerical results obtained from the rng k-ε model with the coarse grid, prediction of peak pressure coefficients on the windward and roof surfaces were attempted, considering that the largest maxC_p occurred on the windward surface (maxC_p≈2.95) and the smallest minC_p occurred on the roof surface (minC_p≈-4.75). The largest maxC_p was obtained near the stagnation point, and the smallest minC_p was obtained at pressure tap near the edges. For the pressure taps shown as solid thick lines in Figure 5, the relationship between normalized turbulent kinetic energy (k/U_{ref}^2) and fluctuating wind pressure coefficients (rmsC_p) were examined, and the results are shown in Figure 5. There is a clear linear relationship between them, implying that rmsC_p can be estimated by k/U_{ref}^2. From these relationships, peakC_p values were obtained from various peak factors (g). The comparisons are shown in Figure 6, showing good agreement with the experimental data when $g_{\max}$=5 for windward and $g_{\min}$=-6 for roof surface.

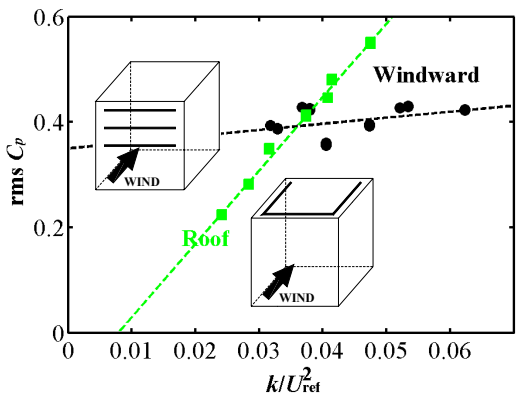


Figure 5. Relationship between k/U_{ref}^2 and rmsC_p

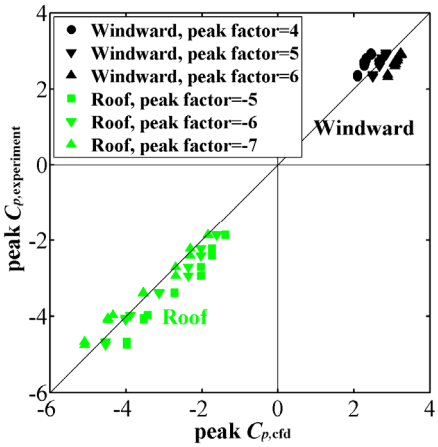

Figure 6. Comparison of peakC_p from numerical and experimental results

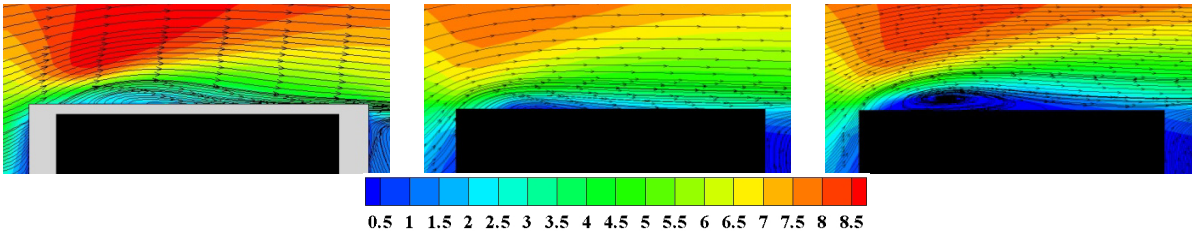
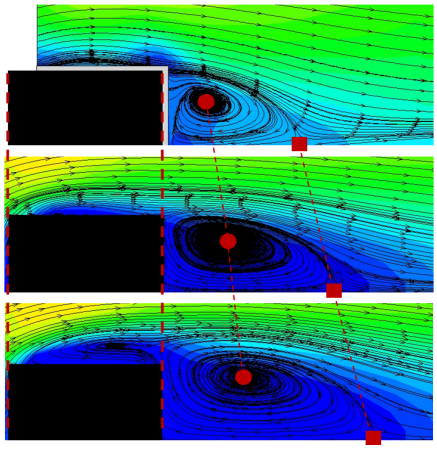
The flow conditions on the roof are shown in Figure 7 using contours of mean wind speed and streamlines for the coarse grid. The black rectangle indicates the isolated model, and the gray region in Figure 7(a) indicates a mask region where the particles cannot be captured by the high-speed digital video camera. From the DPIV result in Figure 7(a), it is not clearly ascertained but there is a reverse flow region on the roof. This region is well reproduced by the rng k-ε model (Fig. 7(c)), but not by the standard k-ε model (Fig. 7(b)).



(a) DPIV (b) Standard k-ε (c) Rng k-ε

Figure 7. Contours of wind speed and streamlines on roof of isolated model

The flow fields measured and simulated at mid-height center are shown in Figure 8 for the coarse grid. The three black rectangles indicate half the isolated model adjusted to the same scale, making direct comparison possible. The flow field including the circulation in the wake seems to be simulated appropriately, but some differences were found. The circulation center (red solid circle) and wake center (red solid square) move to the downstream side for the simulation results, and the deviation is more for the rng k-ε model. There is reversed flow on the side surface for the rng k-ε model as on the roof, and these reverse flows are responsible for the larger mean wind pressure coefficient



(a) DPIV

(b) Standard k-ε

(c) Rng k-ε

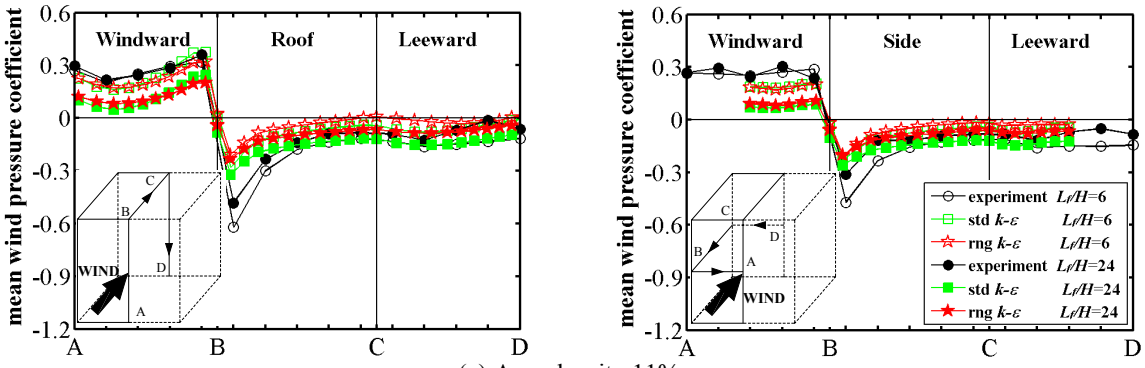
Figure 8. Comparison of flow field of isolated building for mid-height center

(smaller absolute value) on the leading edge on the roof and side surfaces, as shown in Figure 4. The results for the flow fields of the fine grid show a similar trend.

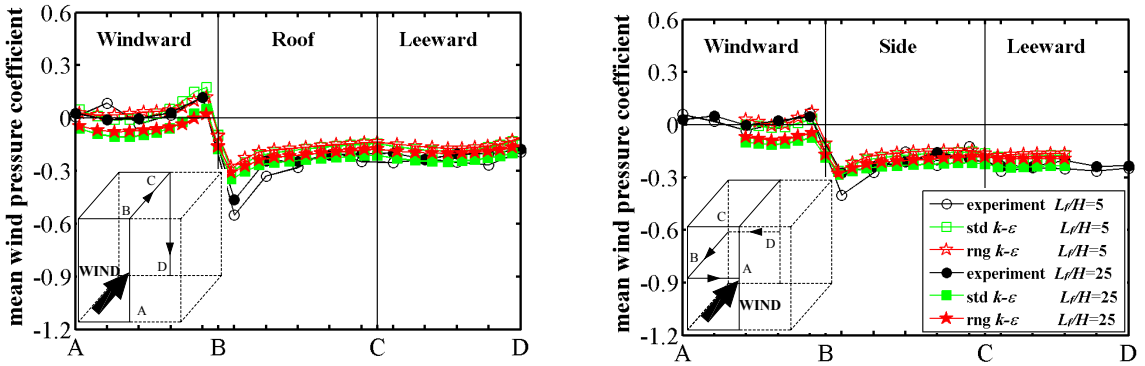
Summarizing the above results, it was found that there is clear dependence of wind pressure on the turbulence models, but little dependence on grid, meaning that the numerical simulations for the grids with (30~61)<y^+ result in almost identical results. Thus, the simulation of the target model surrounded by a large group of dummy models was conducted for the grid with (30~62)<y^+<(roughly 400).

3.2 *Results for target model*

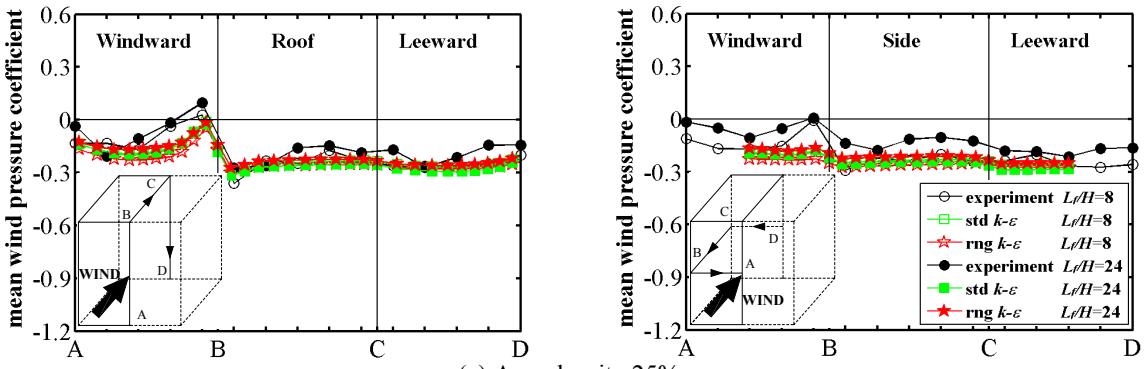
Figure 9 shows the variation of mean wind pressure coefficients derived from wind tunnel tests (solid and open circles), the standard k-ε model (solid and open squares), and the rng k-ε model (solid and open stars) at mid-width and mid-height center at L_f/H=8 and 24 for various area densities. Note that as only half of the target model was used in the simulation, the results from half the windward and leeward surfaces were used for the mid-height center. For all area densities, the variation trends of the numerical results along the two centers are similar to the experimental results, and correspondence becomes better at higher area density. For example, the mean wind pressure coefficients on the windward surface decrease with area density, and at higher area density the coefficients at all surfaces become similar. However, large differences were found near the separation region on the roof and side surfaces as for the isolated model, showing larger values than the experimental results (smaller absolute value). But the differences in the turbulence models are generally small for all surfaces at different upstream distances, showing similar degrees of correspondence to the experimental results.



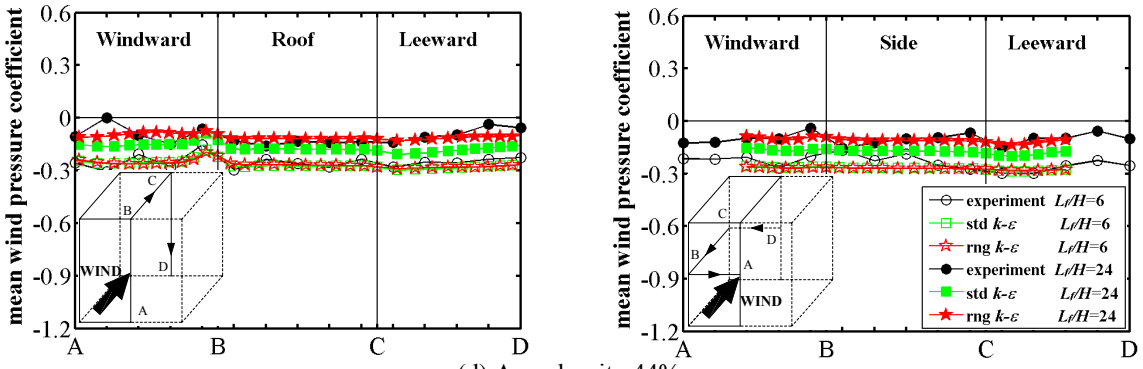
(a) Area density 11%



(b) Area density 16%



(c) Area density 25%



(d) Area density 44%

Figure 9. Comparison of meanC_p for various area densities (Mid-width center (left) and mid-height center (right))

3.3 Flow over large group of low-rise buildings

The variations of mean wind speed and turbulence intensity are shown in Figure 10. In simulation and experiment, the profiles were measured without the target model, and in the wind tunnel tests the profiles were measured from 0.1m (model height) to 0.4m using hot wire. The mean wind speed profiles from the wind tunnel tests and simulations agree well with each other, showing little differences depending on the turbulence models. But in the turbulence intensity profiles, the turbulence intensity for the standard k-ε model is slightly higher than that for the rng k-ε model when the height is less than 0.4, and is more consistent with the wind tunnel test results. The profiles from the standard k-ε model seem to be more similar to the wind tunnel test results. For other area densities, similar results with a similar degree of correspondence to the experimental results were obtained.

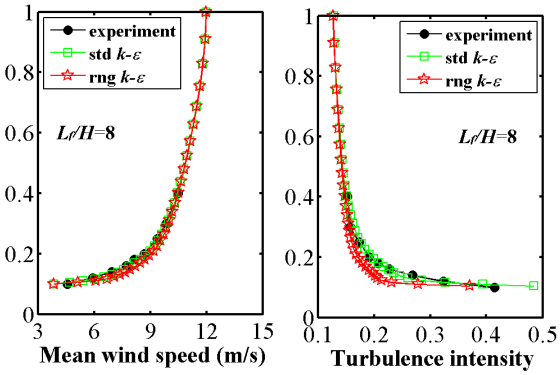


Figure 10. Comparisons of mean wind speed and turbulence intensity profiles at C_A=25%

4 CONCLUSIONS

Mean wind pressure coefficients of the isolated model obtained from the rng k-ε turbulence model match well with those from the pressure measurement. However, the differences in turbulence models were small for the target model in a large group, and the correspondence to experimental data was generally good, still showing some discrepancy near a large suction area. Using a limited number of pressure taps on the windward and roof surfaces, the prediction of peakC_p was attempted, and the results agreed with the experimental results, once the peak factors were given appropriately. For the flow field, the RANS turbulence models were able to reproduce the overall flow pattern around the model generally, but some differences were found i.e., the rng k-ε model provided reasonable simulation near the regions where large suctions occur, and in other many regions the standard k-ε model gave more similar results to experiment.

ABSTRACT: This paper figures the resulting wind loading on a building structure, as observed in the wind tunnel. In the laboratory, the natural downburst downdraft phenomenon and spreading out is replicated using a round jet impinging onto a flat plate. An extensive experimental simulation was conducted to study the effects of the static downburst at various distances from the prismatic building structure to the jet. The outcome is better understanding of wind loading on buildings produced by downburst generated outflows and this paper evaluates the reliability of experimental simulation to simulate downburst type wind loads on buildings.

KEYWORDS: wind loading; downburst; building aerodynamics; impinging wall jet model

1 INTRUDUCTION

Downburst is a weathering phenomenon occurred within a thunderstorm. When the severe convection of atmosphere developed into the vigorous stage, the weight of the precipitation acts to accelerate the air downwards. In the regions where the thunderstorm happens frequently, the strong downward air current could get together in a very short time and suddenly hit the ground surface, the diffusion of the reflected air is expanding in all directions with high wind velocity. So, the downburst is characterized by an intense localized downwards and an outburst of strong winds near the ground.

Fujita described downburst as a small downdraft having an outburst of damaging winds with the horizontal extent of the damaging winds being less than 4 km [1]. A strong downburst can result in damaging winds near 75 m/s. Vickery & Twisdale found that up to 75% of the peak gust wind speeds occurred during thunderstorms [2]. This kind of disaster can destroy the main body of the structures and their exterior-protected construction both. The annual insured property loss from thunderstorm winds in the U.S.A. is $1.4 billion on an average. Almost all of the damages due to thunderstorms can be assumed to be caused by intense downdraft winds, downbursts.

2 DOWNBURST MODEL

Two methods have been used in general to simulate and study downburst outflow characteristics. These are the impinging wall jet model and the “ring vortex” model (Fig. 1).

There is a steady flow against a flat plate in the impinging wall jet model. This impingement gives rise to a wall jet. As air touches the ground, the vertical component of the wind decelerates downwards and the horizontal component of the wind accelerates outward from the impact center. So, the impact pressure field is generated. However, there are no hydrostatic pressure changes in this model.

In the second type of model, the downwards flow shapes into a vortex ring before approaching the ground. After touchdown, it is the radial outflow, which influences the surface structures. In conclusion the first model seems to replicate the effects of downburst better. The schematic of a wall jet for JAWS is shown in Figure 2 [3].

3 EXPERIMENTAL SIMULATION

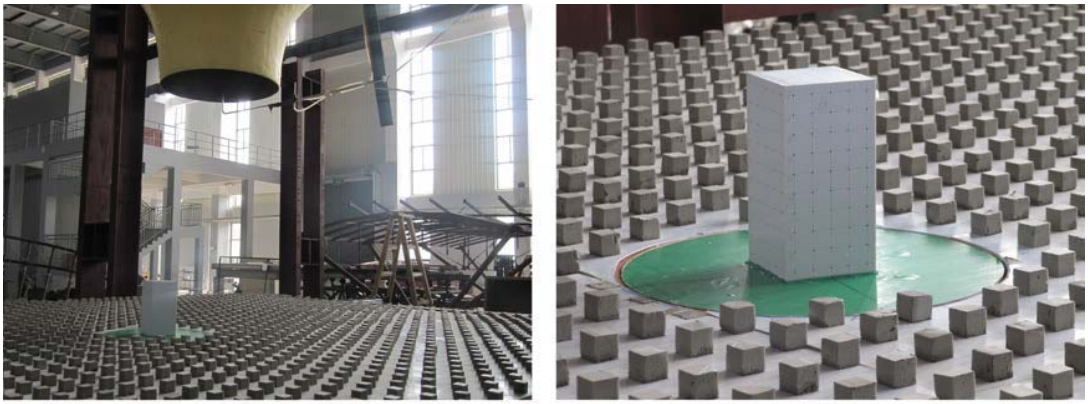
The current research focuses on the simulation of a stationary downburst using experimental methods.

Compared with the natural boundary layer type wind flow, the extent of work done to study the effects of downburst wind on civil engineering structures is very limited. Only a few case studies on downburst-generated wind loading on building structures have been found in the literature.

The first to use an impinging jet model to simulate downburst were Selvam and Holmes [4]. And then, Holmes [5] and Letchford and Illidge [6] undertook physical model studies of a jet impinging on a wall to study topography effects in downburst. Savory et al. [7] also studied the effects of failure of lattice transmission towers due to tornado and downburst induced wind loading. Sengupta et al. [8] studied the pressure distribution on a cubic building. Chay and Letchford

[9] also studied the effects of stationary jet on cubic building models and used a translating jet (which was moved manually) to see the effects to jet translation speeds [10]. Sengupta and Sarkar [11-13] have reported their findings on laboratory and numerical simulation of both static and translating downbursts and compared them to wind loads on cubic as well as tall buildings due to a translating tornado using the Tornado/Downburst Simulator in the WiST laboratory at Iowa State University. Lin and Savory [14], Kim and Hangan [15] have studied the outflow velocity characteristics and the effects of these wind fields over buildings.

Because the downburst is sudden and random occurrence in nature, there is currently no field data available for study. So, the only possible mechanism to study the effects of downburst type of wind loads on buildings is through laboratory simulation. The primary objective of the present work was to perform a systematic parametric study of laboratory simulation of stationary downburst using an impinging jet to determine the pressure distribution on cube-shaped buildings. The effects of the building's location with respect to the center of the downburst were the main focus of the parametric study.



(a) (b)

Figure 3 (a) the equipment of the experimental simulation (b) model building dimensions and pressure tap locations

The experimental setup is shown in Figure 3(a). Here the downburst is modeled as an impinging jet coming out of a pipe and hitting against on a flat wooden board placed below. Roughness elements situated on the plate uniformly could establish the essential coincidence between the experimental simulation and the downburst wind practical condition. The diameter (D) of injection nozzle used to generate the impinging jet was 500 mm. The height (H) of the injection nozzle from the ground board was 1000 mm. So, H/D = 2 was resulted. And the impinging jet velocity was used, V = 10 m/s. This resulted in a Reynolds number of 3.45×10^5 based on the diameter of injection nozzle (D). The building model was made of rigid plastics. The structure is designed as a high-rise building and the size is set as 100 mm (W, 0.1D) × 100 mm (L, 0.1D) × 200 mm (H, 0.2D). The main focus of the parametric study was the location with respect to the center of the downburst of the building model. For the current work, L1 = 0 mm (0D), L2 = 250 mm (0.5D), L3 = 300 mm (0.6D), L4 = 400 mm (0.8D), L5 = 450 mm (0.9D), L6 = 500 mm (1.0D), L7 = 550 mm (1.1D), L8 = 600 mm (1.2D), L9 = 750 mm (1.5D) were used as a series of the various distances from the model to the injection nozzle.

Digital pressure transducers were used to measure the pressures on the surface of the building model. Pressure taps were uniform distributed on the building model that were tested on the front, back, left, right and top surfaces. A total of 225 pressure taps were used with 25 taps on the top surface and 50 taps on the each surface of the others. The arrangement of pressure taps for the building model is shown in Figure 3(b). Four 64-channels scanning valve pressure trans-

ducers were used to measure both the static and fluctuating pressures on the building model. And the sampling rate to acquire the data was 312.5Hz.

4 RESULTS AND DISCUSSION

The pressure coefficient Cp was normalized with the impinging jet velocity V, where Cp is defined as:

$$C_P = \frac{P - P_s}{0.5\rho V^2} \tag{1}$$

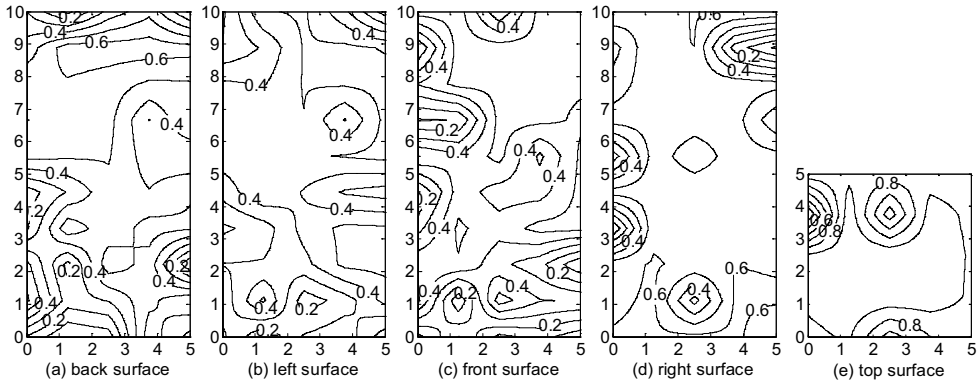


Figure 4 pressure coefficient for building model at 0D

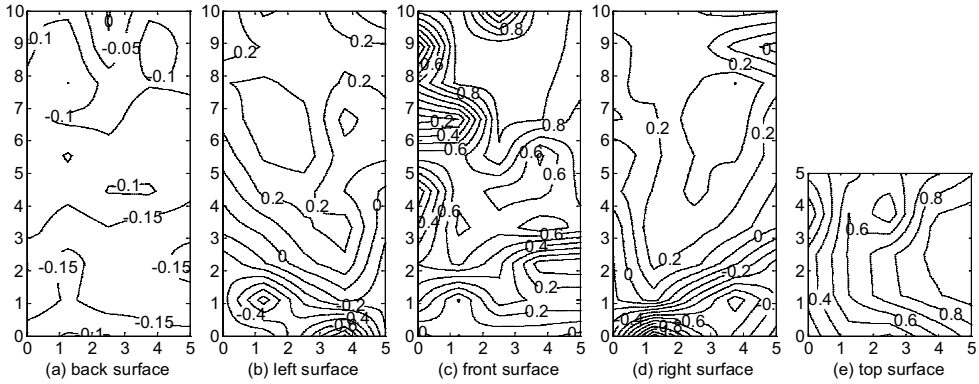

Figure 5 pressure coefficient for building model at 0.5D

The building model is placed directly under the direct impact of the jet downdraft in Figure 4. The impinging jet downwards reaches the top of the building model before attacking on the plate. Not only is the top surface subjected to a significant amount of negative lift, but also the other surfaces are suffering the pressure of the downburst wind.

At location 0.5D (Fig. 5), same as the building location 0D, there is no flow separation on the top of the building model. The top surface is still partly under the injection nozzle and the pressure distribution is still positive. But the pressure on the back surface is reduced obviously and the wind loadings on the left and right surfaces are decreased slightly. Meanwhile, the front surface is endured stronger wind and the pressure is raised perpendicularly.

As mentioned above, the building model is subjected to a downward force on the top surface and a positive pressure on the front surface. This wind loading generated by downburst is different from those produced by natural wind with a regular straight line type flow, and is not considered in the current design practice.

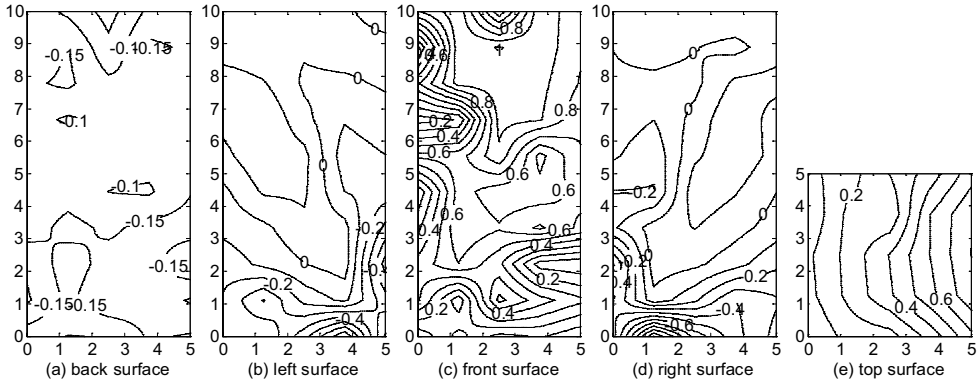

Figure 6 pressure coefficient for building model at 0.6D

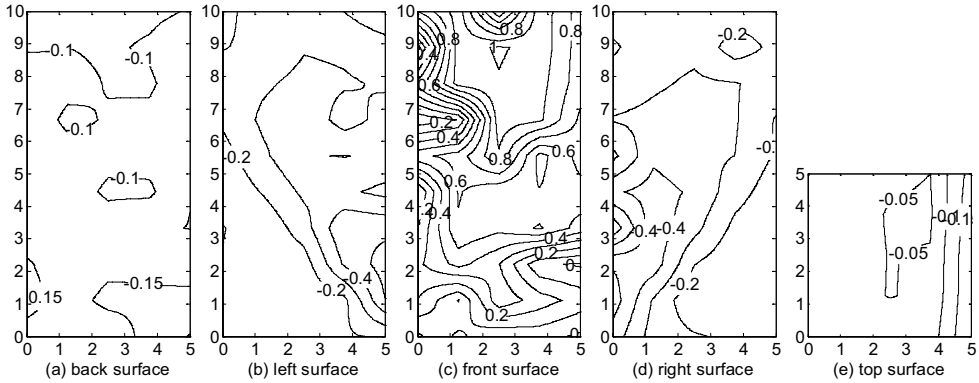

Figure 7 pressure coefficient for building model at 0.8D

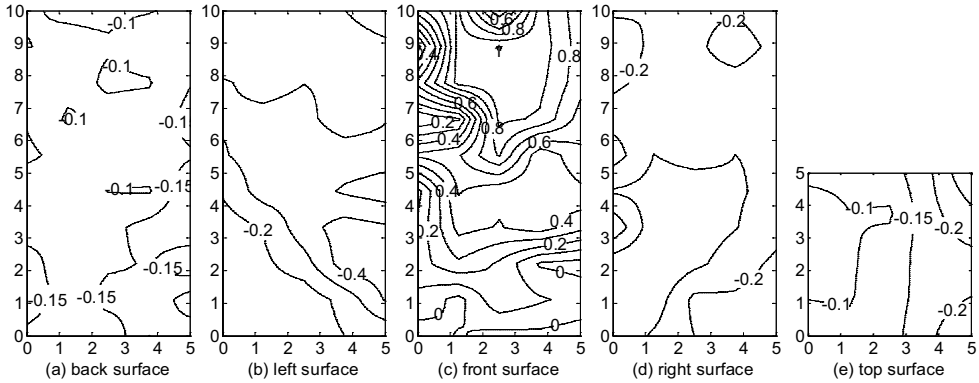

Figure 8 pressure coefficient for building model at 0.9D

When the building model is at a distance of 1.0D from the center location of the injection nozzle, the front surface is subjected to higher positive pressures. Though the pressure distribution on the back surface of the building model is identical almost, there is some difference on the

top surface and the left and right side faces. It can be seen that the pressure distributions are observed to change: the suction or negative pressure is generated (Figs 6-11).

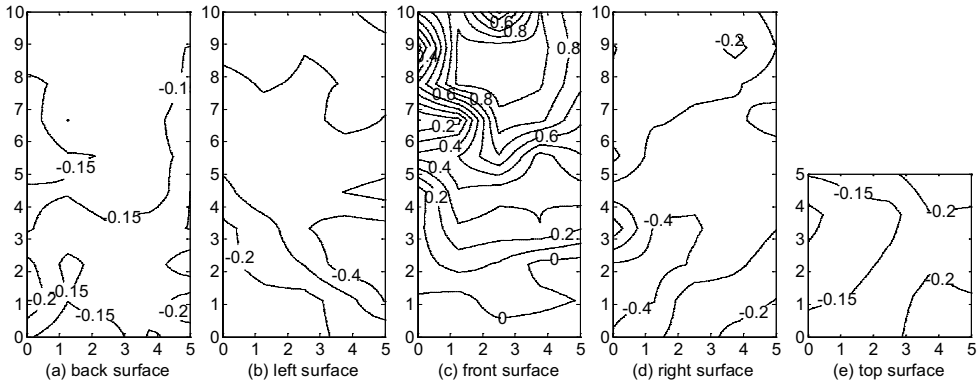

Figure 9 pressure coefficient for building model at 1.0D

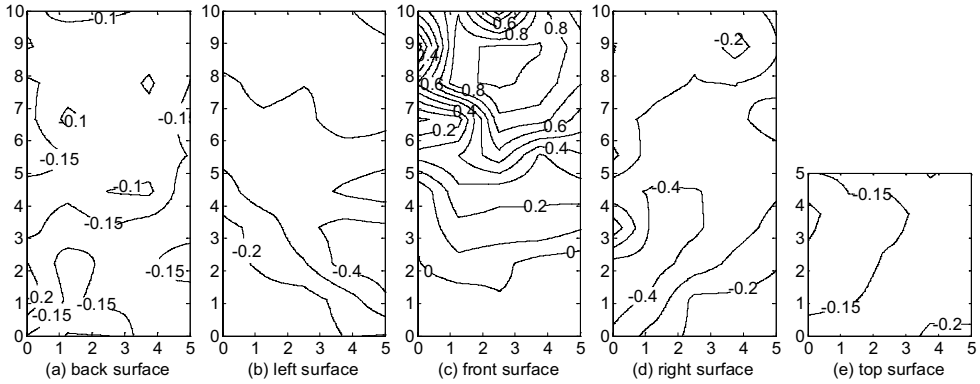

Figure 10 pressure coefficient for building model at 1.1D

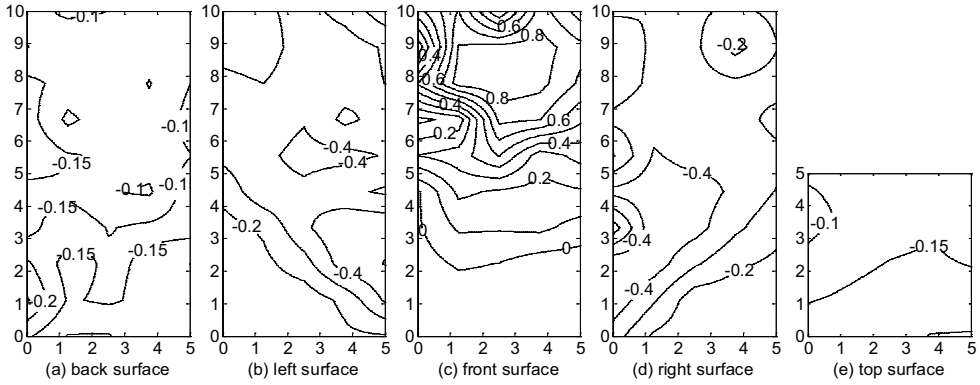

Figure 11 pressure coefficient for building model at 1.2D

When the building is placed at 1.5D (Fig. 12), the positive pressure on the front surface is reduced clearly and the negative pressure on the left and right side face and the top surface is decrease appreciably. So the effect of downburst on the building model is turn to be weakened.

Based on the experimental simulation results, four conclusions can be made with respect to the wind loading generated by downburst on the surface of the prismatic building structure.

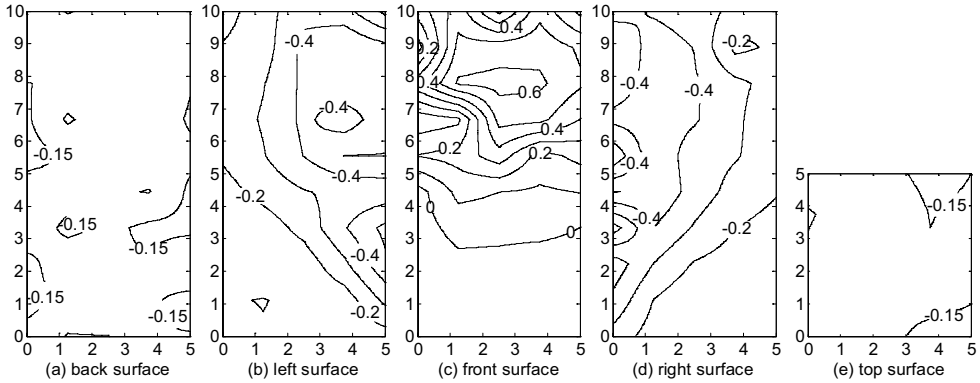

Figure 12 pressure coefficient for building model at 1.5D

The first is that the building is subjected to the maximum wind pressure when it is exactly under the injection nozzle (0D). (Fig. 13)

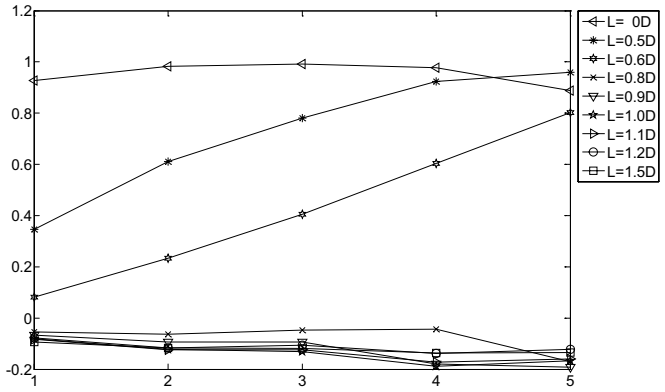

Figure 13 pressure coefficient on top surface

Secondly, the maximum positive pressure on the building is generated when the building is located at 1D from the center of the impinging jet. (Fig. 14)

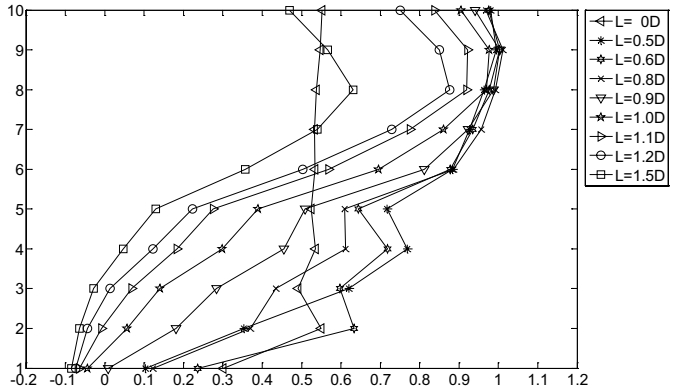

Figure 14 pressure coefficient on the front surface

Thirdly, the pressure distributions on the left and right surfaces are converted form positive pressure to negative pressure for building location 0.8 D and beyond from the center of the injection nozzle. (Fig. 15-16)

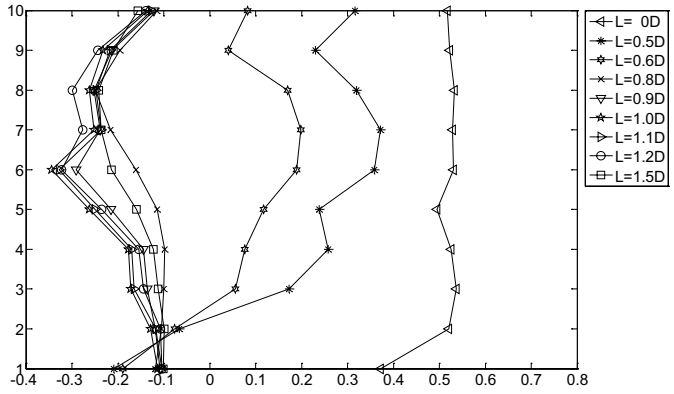

Figure 15 pressure coefficient on the left surface

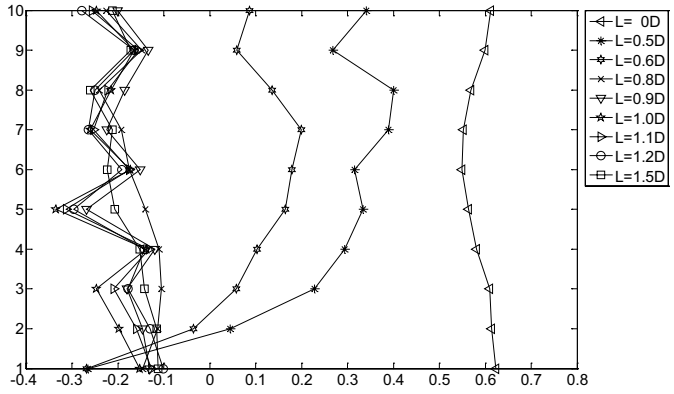

Figure 16 pressure coefficient on the right surface

Fourthly, the wind loading on the back surface is smaller than the other surfaces all but the placed 0D. (Fig. 17)

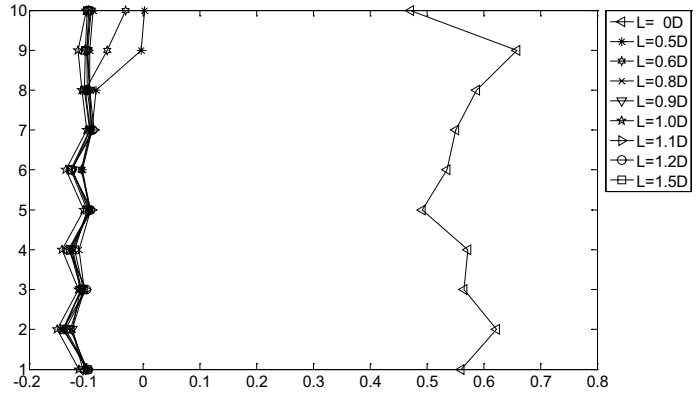

Figure 17 pressure coefficient on the back surface

The maximum and the mean values of pressure coefficients on the surfaces of the building model are given in table 1.

5 SUMMARY AND CONCLUSIONS

The primary mission of this work presented here was to subject an impinging jet to simulated downburst winds and to test a prismatic building model to study the aerodynamic loading.

Wind loadings on the building model at various distances from the center of the injection nozzle were studied. It was found that the top surface experienced a significant amount of pressure when it is straight under the center of the impinging jet. A symbol change in the loads on the building was generated by varying the distance. When the model placed at 1.0D, the wind loadings are somewhat greater than the other locations. This should be paid more attention in the practical engineering of the downburst-prone areas.

6 ACKNOWLEDGEMENTS

This research has been made possible through funding from the National Key Technology R&D Program (No. 2006BAJ03B04) for the 11th five-year plan. The information of the downburst was generously provided by Chao Li and Yang Zhao. Fei Wu's help are also acknowledged.

The simulation of non-synoptic effects for wind damage studies

Matthew Haines [a], Mark Sterling [a], Andrew Quinn [a]

[a] *School of Civil Engineering, The University of Birmingham, UK*

ABSTRACT: This paper presents a brief analysis of the pressure distribution on a physical model building (scale 1:1000) arising as a result of the passing of a non stationary gust front. The gust front is generated using the University of Birmingham's "downburst" simulator. Issues and challenges relating to the simulation of such pressures in a flow field akin to a moving downburst are briefly discussed. There is tentative evidence to suggest that there are differences in the pressure distribution arising as a result from a non stationary gust front compared to boundary layer flow. However, these differences are far from conclusive.

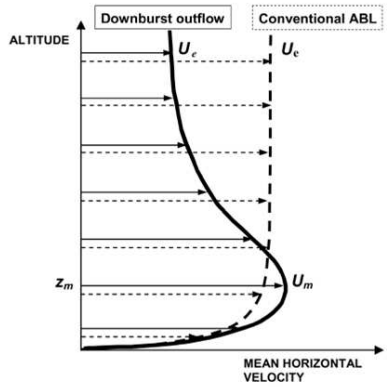
KEYWORDS:thunderstorm, downburst

1 INTRODUCTION

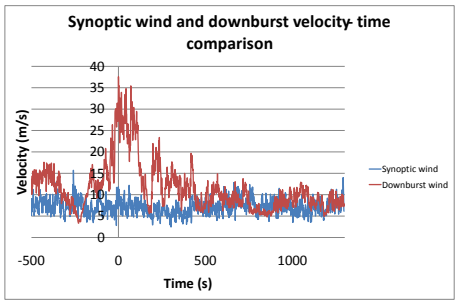
It is now an accepted fact that the disruption and economic losses arising as a result of extreme storms are increasing at a significant rate ABI (2005). There is also tentative evidence to suggest that these storms are increasing in frequency and magnitude due primarily to climate change effects, although it is acknowledged that such evidence is far from conclusive (Kasperki, 1998). Any increases in magnitude and frequency of extreme storms are likely to result in serious damage to the urban infrastructure, the world economy and society as a whole. In European terms, it is predicted that by 2080, there will be an increase in "wind-related insured losses from extreme European storms by at least....€25-30bn" (ABI, 2005) . However, it is perhaps worth noting that these estimates do not take into account society's increasing exposure to extreme storms, due to growing populations, wealthier populations and increasing assets at risk, e.g., ".. if Hurricane Andrew had hit Florida in 2002 rather than 1992, the losses would have been doubled, due to increase coastal development and rising asset values." (ABI, 2005).

Within the last few years, thunderstorm downburst type events have received considerable interest (Chay and Letchford (2002a), Lin and Savory (2006), McConville et al. (2009)). Figure 1a illustrates that severe thunderstorms can produce a streamwise velocity distribution which differs from the typical boundary layer flow.

In order to assess the potential damage that could be caused by these extreme wind events a number of studies have examined the wind loading present during an extreme event, for example Chay and Letchford (2002a) studied the flow around a simple cube. Mason (2009) examined the effect of surface roughness on the flow characteristics and noted the importance of possible Reynolds number effects. Sterling et al. (2011) discussed the multiple scales that could be used when interpreting physical simulations and as a resulted noted that it can be difficult to ensure that the scaling requirements of ISO2009, i.e., "for thunderstorms...wind methods should be used that adequately generate the spatial and temporal variation of wind speeds and turbulence characteristics within such systems" occur in simulations. Work by Sterling and co-workers (McConville et al. (2009); Sterling et al. (2011)) has sought to examine such events using physical experiments at relatively large scale in order to try and minimise the problems associated with scaling and it is with such experiments that the current work is concerned.



(a) Streamwise vertical profile



(b) Synoptic and downburst velocity time history

Figure 1: (a) A schematic illustration of the mean streamwise velocity profile corresponding to a 'typical' downburst and a typical boundary layer wind. (Lin and Savory, 2006). (b) A comparison of a synoptic and downburst wind velocity time history.

1.1 *Flow around simple structures*

Figure 2 illustrates the distribution of pressure coefficient (C_p) over the central portion of a cubic structure arising as a result of a typical boundary layer flow normal to a cube. The pressure coefficient is defined as:

$$C_p = \frac{p - p_{ref}}{\frac{1}{2}\rho_{ref} {V_{ref}}^2} \tag{1}$$

where p is the pressure in the location being measured, p_{ref} is a reference pressure taken outside of the flow, ρ_{ref} is the density of the air and V_{ref} is typically taken to be the mean velocity at an equivalent height of $10m$ above the ground.

The flow around a simple cube in a boundary layer flow has been studied in a number of wind tunnel and full scale experiments including but not limited to Baines (1963), Castro and Robins (1977), Hunt (1982) and Hölscher and Niemann (1998). As illustrated in figure 2 the (mean) pressure distribution on the windward wall of a cube in boundary layer flow has a positive mean C_p value, with a slight increase as the leading edge of the cube is approached. There is then a sharp reduction in C_p associated with flow separation on the leading edge of the cube, resulting in a region of high negative pressure which gradually reduces as the windward edge is approached. Flow reattachment then occurs and towards the leeward edge of the roof and on the leeward wall there is a slight negative mean C_p value.

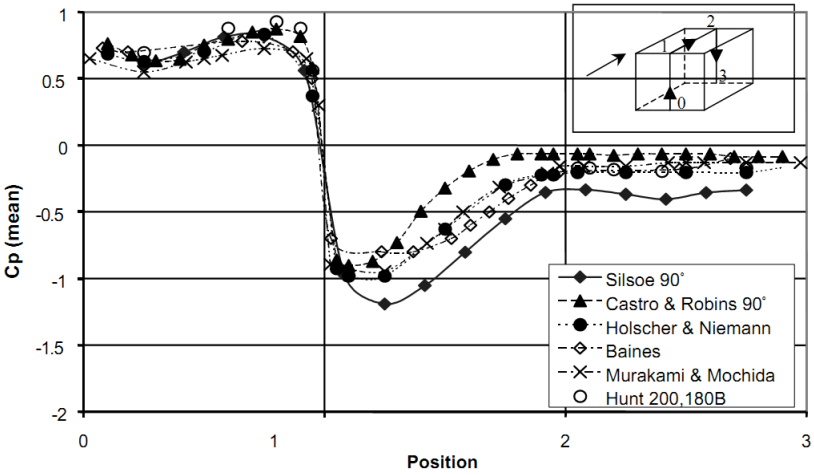


Figure 2: Vertical central section mean pressure coefficients with the wind normal to one face (0^o). From Richards et al. (2001)

There have also been a number of full scale tests on cubic structures. Richards et al. (2001) and Hoxey and Richards (2002) examined the flow structure around a full scale simple cube in synoptic wind flow conditions in a wind tunnel and a full-scale in a rural sight located in Bedfordshire, England.

Chay and Letchford (2002a), Chay and Letchford (2002b) and Mason et al. (2009) have previously looked at the flow around a simple cube in a simulated downburst outflow. Chay and Letchford (2002a) used a stationary wall jet in order to simulate the impinging nature of the flow but did not create the ring vortex structure observed by Fujita (1985) in a full scale downburst. At a distance of $\frac{X}{D} = 1$ (where X is the distance from the centre of the impingement and D is the diameter of the nozzle), the general trend of the pressure coefficients over the windward wall and leeward wall of the building were found to resemble cubes placed in boundary layer flow (albeit with differences in magnitude). Noticeable differences over the roof were found. However, it should be stressed that the results varied with respect to different X/D values.

Chay and Letchford (2002b) used a translating jet and more successfully produced the pressure field seen in a downburst. However because of the non-stationarity of the data a direct comparison to previous boundary layer flow tests could not be made. For low translating speeds no downburst gust front was formed and the profile of the event closely matched the stationary jet case. However when translating speeds were increased a gust front was formed and previous assumptions regarding the quasi-steady nature of the jet broke down. As a result using the standard pressure coefficient definition seen in equation (1) was not appropriate.

Instead the following definition of pressure coefficients was used which took into account the translating velocity component of the flow:

$$C_{PE}(t) = \frac{P(t) - P_{ATMOS}}{\frac{1}{2}\rho V^2_{EAVES,\frac{X}{D}}} \tag{2}$$

$V^2_{EAVES,\frac{X}{D}}$ is the smoothed eaves height velocity and it was calculated from V_{ref} by fitting a polynomial to the time history.

Chay and Letchford (2002b) also looked at taking into account the static pressure variation caused by the passage of the translating jet. This gave the only the wind induced forces on the structure, internal pressures were assumed to reach equilibrium with their surroundings. The

following equation was used:

$$C_{PE}(t) = \frac{P(t) - \overline{P_{STATIC,\frac{x}{D}}}}{\frac{1}{2}\rho V^2_{EAVES,\frac{x}{D}}} \tag{3}$$

Where $P_{STATIC,\frac{x}{D}}$ was modelled using a study of P_{STATIC} in the translating jet. However this had little effect on the values of the pressure coefficients for the largest magnitude pressues and suctions compared with equation (2).

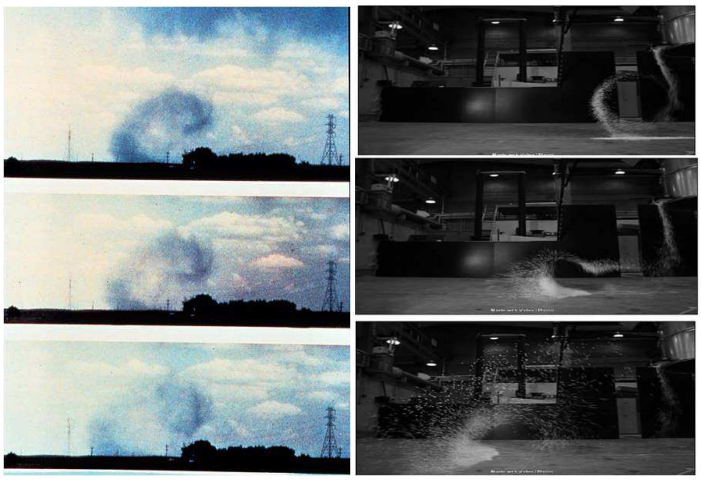
The above treatment resulted in the transient wall jet event closely matching the pattern of pressure coefficients found in boundary layer flow for the windward and near the leading edge of the roof. However the magnitude of the pressure and suction coefficients were found to be far greater in the translating flow than the stationary wall jet case. It was also found that the surface pressures on the cube were well correlated for the translating wall jet flow.

Since these experiments there has been little in the way of examination of downburst flow around simple or complex structures in a physical simulation. There has however been more recent interest in using numerical modelling to look at wind loading on more complex structures. Chen and Letchford (2004) used a numerical model based upon empirical models of downbursts and then examined the impact on models of a cantilevered tower. The examination of downburst loading on transmission lines has also attracted interest within the numerical modelling community because of the destructive impact downburst events have on such structures. Shehata et al. (2005), Shehata and Damatty (2007), Shehata and Damatty (2008) and Fu et al. (2010) looked at transmission line failure with reasonable success at simulating the failure of a section of transmission line which had already failed.

There have also been a limited number of full scale measurements. Lombardo (2009) examined the response of the Texas Tech. Wind Engineering Research Field Laboratory (WERFL) in downburst winds.

2 THE BIRMINGHAM SIMULATOR

The Birmingham downburst simulator consists of nine axial flow fans each with a cross sectional area of $0.85m^2$ used to direct air downwards into a transition section which narrows to a circular cross section of diameter 1m. The latter is suspended $2m$ above the floor. This opening can be closed with the use of a series of flaps and opened suddenly to create a pulse of air which then travels to the ground and spreads out horizontally as a vortex, in a similar manner to downburst outflow (illustrated in figure 3). Further information can be found in McConville et al. (2007) and McConville et al. (2009). In order to simulate the translating aspect of a downburst two tracks were positioned on the ground and a translating rig built which passed under the simulator, the opening mechanism was automated to release when the rig was at a specific distance from the centre of impingement.



(a) NOAA photo library Image ID: nssl0106

(b) The Birmingham downburst simulator

Figure 3: A visual comparison between an actual downburst event and a physical simulation.

Since the experiments undertaken by McConville et al. (2007; 2009) a number of modifications have been made. These include the addition of a translating platform with false floor to enable different surface roughness effects to be studied as well as making it far simpler to examine the velocity flow field of the simulator.

3 DATA COLLECTION METHODS

A $244 \times 98 \times 104mm$ model was pressure tapped down the centreline so that the pressure field around the centre of the simulated downburst could be studied. The arrangement of the pressure taps can be seen in figure 4.

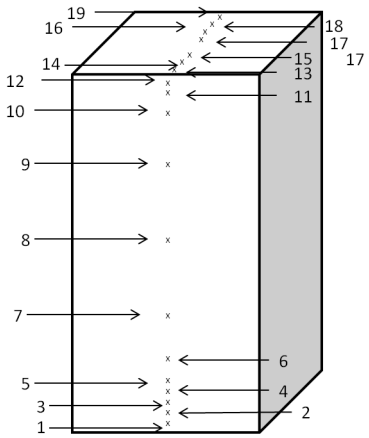


Figure 4: The arrangement of pressure taps on the model building

The location of the pressure taps is defined in terms of distance from the ground on the windward face measured around a line extending over the central portion of the building. For example, a tap on the windward face at the base would have a position of $0mm$ while a tap on the base of the leeward face would have a position of $592mm$. In what follows the location of the taps have been expressed in terms of a normalised distance, i.e., the distance from the base of the building at the leading edge divided by $592mm$. Hence, the location of the taps shown in figure 4 are: tapping 2 (0.0338), 4 (0.0676), 8 (0.2061), 10 (0.3784), 12 (0.4037), 13 (0.4206), 15 (0.4747), 16 (0.5000), 17 (0.5253), 19 (0.5794), 22 (0.6149) and 24 (0.7872).

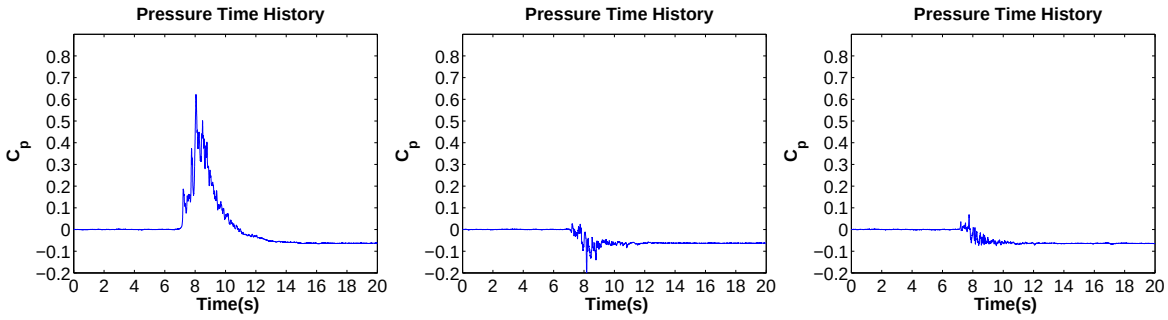
Hjemfelt (1988) found that for the JAWS project data that the maximum wind speed occurred at a height of $80m$ and a distance of $1.5km$ from the centre of impingement. Using these values a very rough scaling parameter for height can be found. In the simulator peak wind speed occurred at a height of $20mm$, which gives a (vertical) length scaling of $1 : 4000$. However there is an inconsistency in length scaling if the downburst diameter is examined. The

average downburst diameter found by Hjemfelt (1988) was 1.8km, the diameter of the downburst simulator was $1m$, giving a length scaling of $1:1800$. This inconsistency highlights one of the difficulties in simulating downburst winds, it is exceedingly difficult to produce a flow field which matches a real world situation. Therefore the results below should be treated with caution, they may not be entirely representative of a full scale downburst wind striking a cube at full scale.

4 RESULTS

Preliminary investigations of the wind induced pressure field on a simple structure indicated that the use of a translating platform raised an important issue in terms of the wind loading experienced by the building, i.e., once the release mechanism had been fired the fans continued to rotate (due to the inertial of the fans it was not possible to stop rotation instantly). Hence, as the building moved through the jet a positive pressure field around the entire building was created and as such the flow field was considered not to be representative of a 'typical' downburst. Hence, in order to general a more appropriate simulation it was decided the building would remain stationary.

Figure 5 illustrates the pressure coefficient time series for three pressure taps located around the building arising as a result of a passing gust front associated with the ring vortex. The mechanism for generating the gust front is outlined in McConville et al. (2009). The building is located at a normalised distance of $\frac{X}{D} = 1.4$ from the centre of the impingement. The pressure coefficient is calculated using equation (1) but with V_{ref} taken as the peak velocity associated with the gust front at an equivalent height of $10m$ above the ground. In order to smooth the data an ensemble average of 5 velocity times series were used and a 50 point moving average time wind implemented (in keeping with McConville (2008)). This yielded a value of V_{ref} equal to $15ms^{-1}$.

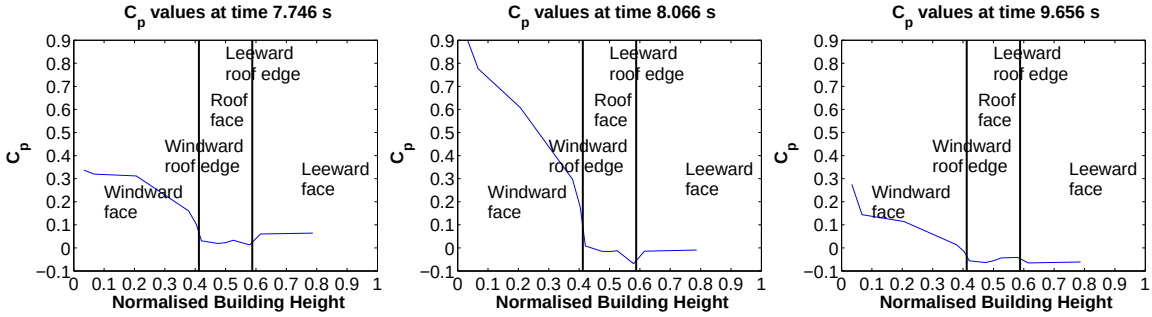


(a) C_p time history at tapping 8 (b) C_p time history at tapping 16 (c) C_p time history at tapping 24

Figure 5: Pressure time histories at the centres of the windward,roof and leeward faces

Figure 5a is illustrative of the general trend in pressure with respect to time for all of the taps on the windward face. The only difference between the windward face pressure taps is the magnitude of the pressure coefficients, which is greater at the lowest height of $20mm$ and reduces with height.

At the centre of the roof (figure 5b) there is a slight reduction in C_p values, possibly indicative of flow separation occurring on the edge between the windward face and the roof. A comparison between figures 5 and 2 illustrates the differences between the C_p values of boundary layer and downburst flow. It would appear that flow separation is far less obvious in the downburst case than for boundary layer flow. As a result of this the recovery on the leeward side of the building back to atmospheric pressure is not as noticeable as the boundary layer case. However, it needs to be appreciated that the pressure coefficients in figures 2 and 5 are not directly comparable but the comparison is somewhat instructive.



(a) C_p variation at different heights time 7.746*s* (b) C_p variation at different heights time 8.066*s* (c) C_p variation at different heights time 9.656*s*

Figure 6: Variation of C_p at different vortex locations (times)

Figure 6 illustrates the values of C_p across the various faces of the model at different phases of the vortex interaction with the building. In order to estimate the location of the vortex with respect to time, a crude form of PIV was used (see figure 3b).

A general trend across all phases of the interaction is the reduction with height of C_p coefficients on the windward face of the building. The exact trend varies depending on the degree of interaction of the building with the vortex: figure 6a illustrates the time at which the vortex is just impacting on the front face of the building. The vortex at this stage has fully developed but has yet to interact wholly with the building, hence relatively constant values of C_p over a proportion of the windward face can be observed. In figure 6b the vortex is fully interacting with the building and it is hypothesised that the vertical velocity profile seen in figure 1a will have developed against the windward face. Compared to figure 6a there is a slight decrease in the value of pressure coefficients on the roof of the building. In both their is a reduction on the roof-leeward edge of the building before rising again on the leeward face of the building and staying roughly on the leeward face. After the vortex has passed the values of the pressure coefficients on the windward face reduce to around the values seen as the vortex began to interact, only with a trend more similar to that seen when the vortex was interacting. The pressure coefficients on the roof and leeward face are roughly constant with a slight drop on the windward-roof edge and a slight raise on the roof-leeward edge, which is in contrast to the reduction seen at other points of the vortex interaction.

5 CONCLUSION

From a relatively low resolution study of the pressure field around a modelled high rise structure in a downburst flow it would appear that there are some differences between the established C_p loadings seen in a boundary layer flow and the simulated downburst used in this study. One of the most notable differences is the effect of the large (non-stationary) gust front. The pressure time histories on the model building showed a general trend of having a large positive C_p value on the windward face of the building with a slight negative C_p value on the roof and leeward faces. The largest C_p values were seen when the vortex was interacting most strongly with the building with the weakest seen after the vortex had passed over the building.

An initial study of the aerodynamics of photovoltaic panel arrays mounted on large flat-roofs

R. Nicolas Pratt [a] & Gregory A. Kopp [a]
[a]*Boundary Layer Wind Tunnel Laboratory, Faculty of Engineering, University of Western Ontario, London, ON, Canada*

ABSTRACT: Pressure and velocity measurements, acquired during wind tunnel testing, associated with a PV array mounted on a low-rise building during a southern wind have been presented. The mean flow field outside the separation bubble was found to be similar to a bare roof. Peak uplifts were characterized by large suctions over the top to centre of the upper side of the panel. Positive vertical velocity fluctuations and streamwise gusts were also found to be correlated with peak events

KEYWORDS: Wind loads; solar arrays; low-rise buildings; aerodynamics; turbulent flow

1 INTRODUCTION

An initial study of the aerodynamics of roof-mounted photovoltaic (PV) arrays has been undertaken, with the goal of understanding and mitigating the aerodynamic loads, most importantly uplift, which act on such arrays. Existing published work on the subject is mainly limited to investigations of the aerodynamic loads, without extensive discussion on the aerodynamic mechanisms. This work builds on pressure experiments previously conducted at the Boundary Layer Wind Tunnel Laboratory (BLWTL) at the University of Western Ontario (UWO) [1]. This previous work involved extensive pressure measurements acquired during wind-tunnel testing and provided significant insight into the flow field which develops over a roof-mounted PV array. To further elucidate the aerodynamic mechanisms associated with wind loading on PV arrays we conducted experiments using synchronized time-resolved particle image velocimetry (TR-PIV) and pressure measurements. The use of PIV allows the spatial development of the flow field to be examined in greater detail than is possible with pressure measurements alone.

Several studies [2,3,4,5] report the effect of shielding by leading rows of panels on trailing rows whereby loads were reduced on the trailing rows of panels. The use of the term shielding should be used with some caution as, shown by Kopp *et. al.*,[1] shielding (implying a reduction in uplift for panels downstream of one another) is highly dependent on not only the wind direction but also the area of the roof under consideration. A north wind, for example, led to positive mean loads on the first few leading edge panels which are in the separation bubble; downstream of the bubble net uplifts were observed to increase as the as the wind moves over the array. Hence, although panels are in the wake of leading panels, no shielding effect was observed for this flow direction.

The primary basis for our study is the work of Kopp *et al.*,[1] which indicated that two critical wind directions (those resulting in the highest uplift) exist for roof mounted PV arrays: Southern winds (170°-180°) and northern cornering winds (30°-60°). These two wind directions were observed to be critical for area-averaged pressure coefficients over various panel areas. For northern cornering winds, the peak loads arose from the interaction of the corner vortex (i.e., the so-

called “delta-wing” vortex formed at the corner of the building) with the array. The peak uplifts for southern winds most often occurred in the first two southern rows. These rows were located within the separation bubble that forms when the flow separates from the southern edge of the roof. Hence the flow in the separation bubble at the height of the array was travelling upstream relative to the freestream velocity, resulting in uplift on the panels. Peak events were characterized by peak factors approaching 10, indicating the rarity of these events. In the reattached region, for southern winds, the panels experienced a net down-force. For a north wind (0°) essentially the opposite effect occurred; panels within the separated region experienced a net down-force, while panels downstream of reattachment experienced a net uplift. The mechanisms that resulted in the peak loads on solar panels are still unclear, although it was suggested [1] that higher turbulence levels being convected above the roof on rare occasions could be related to the peak loads.

Our study will focus on the flow-field that develops during southern winds. South winds are of interest as this represents one of the critical wind directions for panel uplift identified in Kopp *et al* [1]. In particular, they observed that peak uplifts occur within the separation bubble (approximately located in the first 3 rows of panels). By focusing initially on the southern winds it is possible to avoid the complications that would be associated with performing PIV during the cornering wind events, which would likely necessitate the use of either stereoscopic or dual-plane PIV to resolve the three dimensionality of the flow. Similarly, this experiment will focus of on the model north-south centerline to minimize any error associated with out of plane velocity components; while the mean velocity in the cross-stream direction is zero due to symmetry, although turbulence is, of course, always three-dimensional.

2 EXPERIMENTAL SETUP

2.1 *Model details*

The model used in the present experiments is the same 20° tilt angle model used by Kopp *et al.* [1]. The model is a 1:30 scale low rise building to which an array consisting of 12 rows of 12 modules each of which was chord mounted on the roof (i.e., the width in the north south direction when mounted on the roof); noting that the modules normally tilt towards the south in the northern hemisphere. In the geometrical description of the building and PV array that follows all units are in full-scale. The roof height, H, of the building is 7.3 m. The chord of the modules is 1.00 m, and the length is 1.65 m. Rows were modeled without gaps hence each row was 20 m long. The ground clearance is 0.16 m and the distance between the rows is 1.68 m. The roof setback was 2.9 m. For full details of the model design refer to Kopp *et al* [1].

The blockage for the model was less than 3%, while the roof height based Reynolds number was 1.9×10^5. Full-scale Reynolds numbers would be larger by the length scale multiplied by the velocity scale, so the present experiments are about two orders of magnitude low (while still remaining about one order of magnitude higher than the minimum allowed in the ASCE # 67 [6]).

2.2 *Terrain simulation*

The experiments were conducted in a simulated open country terrain characterized by a roughness length, z_0, of 0.03 m. The terrain simulation was achieved by matching the wind tunnel profiles to the ESDU mean profiles, ESDU turbulence intensities and ESDU velocity spectra [7, 8,

9]. There was excellent agreement between experimental and target mean and intensity profiles. The agreement between the measured and target spectra were also reasonable given the large scale of the flow simulation. For a comparison of measured profiles and spectra with the ESDU profiles refer to Kopp *et al* [1]. Testing was conducted in the Boundary Layer Wind tunnel I at UWO which has a working cross section of 3.4 m wide and a variable height, nominally 2.4 m at the measurement location, with an upstream fetch of 39 m.

2.3 *Surface pressure measurements*

Pressure measurements were made along the top and bottom surface of the panels along the north-south centreline. For each panel 3 taps were located on the top surface while 1 tap was placed on the bottom surface. The location of the 12 pressure taps is shown in Figure 1. Pressure measurements were made at a sample rate of 500Hz and low-pass filtered at 200 Hz. Full details of the pressure measurement system and pressure tubing can be found in Ho *et al* [10].

The measured pressures were referenced to the dynamic pressures at the upper level of the wind tunnel where the flow is uniform with low turbulence levels. The pressure coefficients were then re-referenced to the dynamic pressure at roof height using mean velocity profiles which were established without the building in the tunnel.

2.4 *Particle Image Velocimetry measurements*

In order to investigate the flow field with both good spatial and temporal resolution the TR-PIV system developed at UWO's BLWTL was utilized to measure the flow field velocity. The system consists of a double-head diode-pumped Q-switched, Nd:YLF laser operating at 1000 Hz. The seeding particles used in this study were created by atomizing olive oil. Images were captured using two Photron FASTCAM-1024PCI CMOS cameras operating in tandem. The cameras have a spatial resolution of 1024x1024 pixels and are able to stream individual images to a PC at 1000 Hz, giving a sampling rate of 500 Hz for velocity data. Full details of the TR-PIV system can be found in Taylor *et al* [11]. The experimental setup, showing the position of the cameras and the laser sheet illuminating the field of view shown in Figure 2.

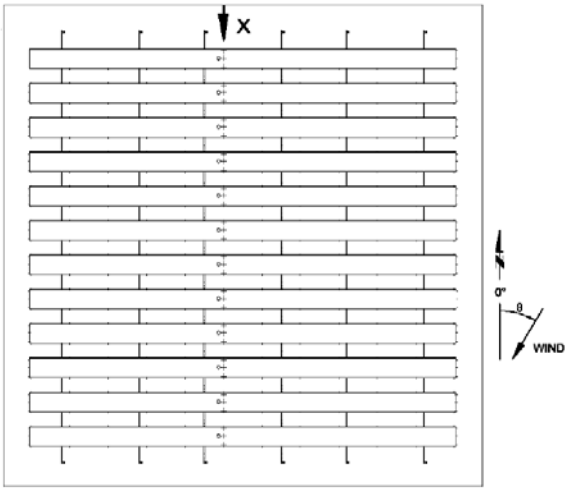

Figure 1. Sketch of the array layout with coordinate definition (x) and wind direction (θ). Taps on the uppers surface of the panels are marked with '+', while taps on the underside are marked with '○'.

Figure 2. Photograph of experimental setup showing positioning of cameras and laser sheet

2.5 *Synchronization of pressure and velocity data*

One of the difficulties in these experiments was the synchronization of the pressure and velocity data, given that both the pressure data acquisition system (DAQ) and the PIV system were both designed to operate independently of each other. Synchronization was achieved by connecting the PIV camera triggers to the pressure DAQ analog input. As both the pressure DAQ and camera triggers operate at 500 Hz, on separate clocks, some ambiguity was expected in the synchronization. Based on the first and last peaks of the camera trigger signal the start and finish of the PIV operation could be determined and then the pressure time history was trimmed to match the PIV data series. However, after this process the pressure time series contained 11 more data points than the PIV measurements; thus there is an uncertainty of 22 ms between the pressure and velocity data; this uncertainty is less than 0.015% of the entire sampling period. To overcome this uncertainty vector fields during peak events were compared to pressure distributions over the 11 data point uncertainty range to subjectively determine the correct synchronization. This issue will be corrected in future experiments.

After synchronization the pressure and velocity time series were approximately 160 s long. Assuming a full-scale gust speed of 45 m/s at 10 m (giving a velocity ratio of 1:2.6), the resultant full-scale sampling period is approximately ½ an hour.

3 STATISTICAL DESCRIPTION

3.1 *Flow field*

As discussed large peak uplifts have been observed within the separation bubble for a southern wind direction (180°). In this section we discuss the features of the leading edge flow field associated with a southern wind. The mean streamwise velocity profiles are plotted in Figure 3 while the vertical velocity profiles are shown in Figure 4. The velocities are normalized by the roof-height velocity (U_H) while the lengths are normalized by the roof height, H. While it has been shown that normalized pressure data for a separating-reattaching flow collapses if the streamwise distance is normalized by reattachment length [12], the presence of the panels perturbs the reattaching shear layer such that the reattachment location is ambiguous, and as such the roof height was seen as a more appropriate normalizing scale. As shown in Figures 5 and 6 the outer flow field at the leading edge is similar to that of a typical separating-reattaching flow, however, it is clear that within the separation bubble the flow is significantly altered. The separation bubble is essentially divided by the panels into three smaller recirculation zones, with the additional complication of flow separating from the trailing edge of each panel and entering into the subsequent recirculation region. From a visual inspection of the streamlines it appears that the large scale (that associated with building rather than the panels) separated shear layer has reattached by the 3rd to 4th downstream panel (~ 0.8-1.0 H). Both the reattachment length and height of the separation bubble are similar to what would be observed over a bare-roofed low-rise building (not shown here).

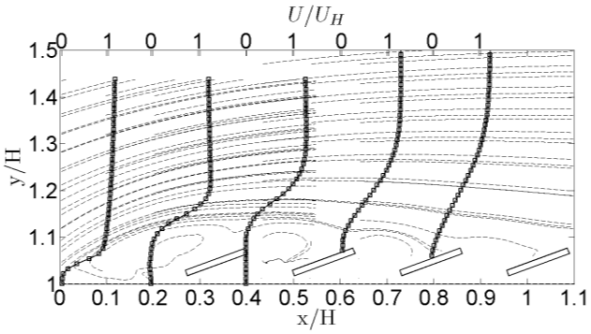

Figure 3. Mean streamwise velocity profiles for a wind direction of 180°. Streamlines are shown by the dashed lines for reference.

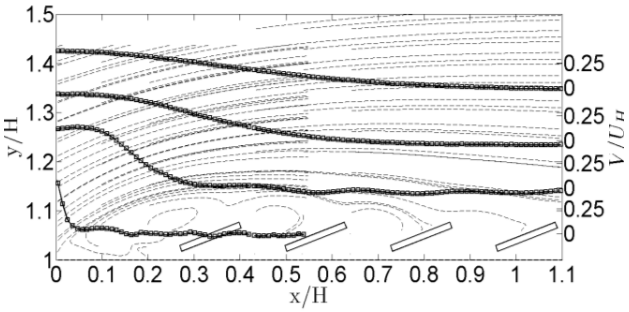

Figure 4. Mean vertical velocity profiles for a wind direction of 180°. Streamlines are shown by the dashed lines for reference.

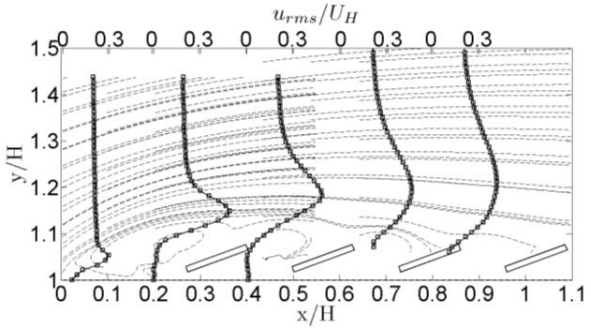

Figure 5. RMS streamwise velocity profiles for a wind direction of 180°. Streamlines are shown by the dashed lines for reference.

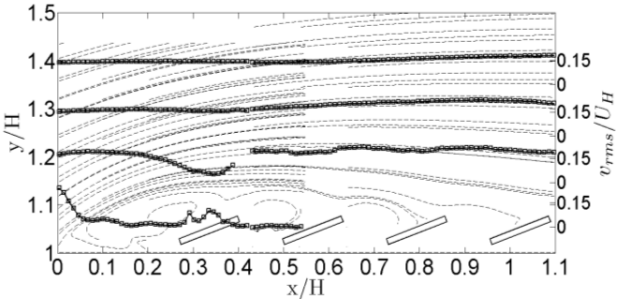

Figure 6. RMS vertical velocity profiles for a wind direction of 180°. Streamlines are shown by the dashed lines for reference.

Root mean square (rms) streamwise and vertical velocity profiles are shown in Figures 7 and 8 respectively. The maximum streamwise rms velocities are associated with the separating shear layer and are approximately twice the magnitude of the maximum vertical rms velocities. The vertical rms velocities are almost constant outside the separation bubble.

3.2 *Pressure field*

Figure 3.5 shows the mean pressure coefficients (Cp_{mean}) for the point pressures along the centerline and the net pressure coefficient for the ring of four taps around each panel's centerline. Figure 3.6 shows the corresponding RMS pressure coefficient (Cp_{rms}) for the centerline taps and centerline net pressures. Figure 3.7 shows the peak pressure coefficients (Cp_{min}) for the centerline net pressures. The mean, RMS, and peak pressure coefficients all appear to follow the same trend, the peaks all occur on the first southernmost panel followed by a monotonic reduction along the array (with the exception of the absolute peak at the 3rd southernmost panel). The distinction between the panels within the separation bubble and those in the reattached flow zone is clear from the stabilization of in mean, rms and peak pressure coefficients by the 3rd to 4th southernmost panels. Furthermore peak factors,

$$g = \frac{|Cp_{min} - Cp_{mean}|}{Cp_{rms}} \quad (1)$$

shown Figure 10 exhibit a peak around reattachment. Kopp *et al.* noted that towards the leeward side of the array for a southern wind the loads become similar to those observed or an equivalent ground-mounted system [1].

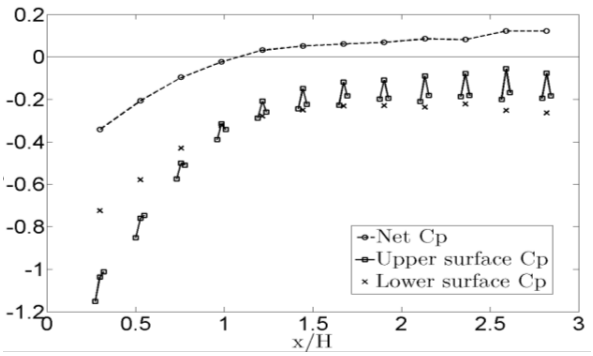

Figure 7. Mean pressure coefficients for a wind direction of 180°.

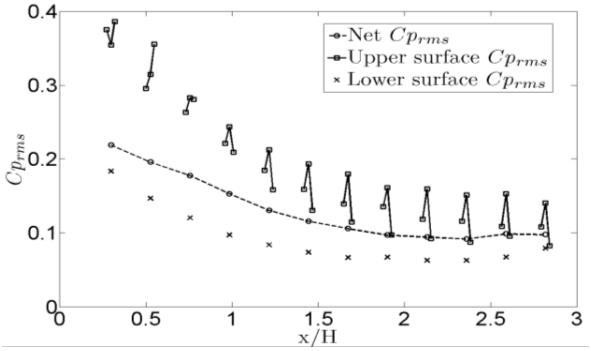

Figure 8. RMS pressure coefficients for a wind direction of 180°.

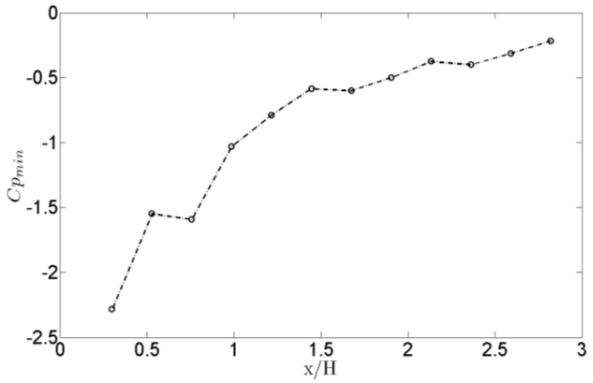

Figure 9. Peak pressure coefficients for a wind direction of 180°.

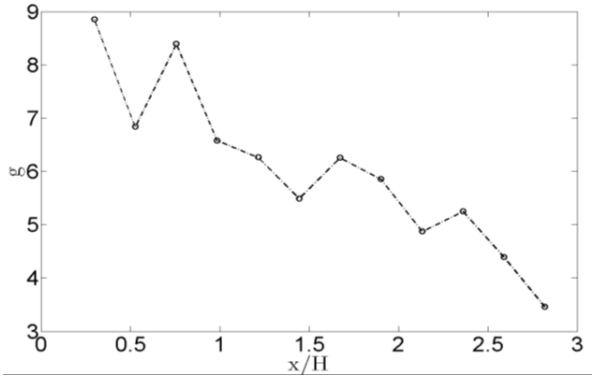

Figure 10. Peak factors for a wind direction of 180°.

4 PEAK UPLIFT EVENTS

A primary concern in our experiments was the determination of the aerodynamic mechanisms associated with the peak uplift events. As the highest uplift is experienced by panels within the separation bubble, caused by the flow separating from the leading edge of the building, the pressure and velocity fields associated with peak events was investigated for the 2nd southernmost panel, located at ~0.6 *H*. The pressure field for the 1st peak event is shown in Figure 11. The 1st peak uplift event is clearly dominated by the high suction at the upper side of the top of the panel. The suctions at the centre and bottom of the top of the panel are also almost double their mean values. In contrast the pressure on the lower surface of the panel exhibits only a minimal deviation from the mean. Streamwise and vertical velocity profiles for the 1st peak are shown in Figure 12; the associated vector field is also shown with the mean velocity subtracted to accentuate the velocity fluctuations. The flow field associated with the 1st peak shows large vertical fluctuations near the top of the panel which could explain the large suctions in this region. Near the lower edge of the panel large velocity fluctuations are not evident. The 1st peak also appears to be associated with only a mild streamwise gust.

The pressure field for the 2nd peak event is shown in Figure 13. As with the 1st peak, the 2nd peak is characterized by a strong suction on the upper side of the top panel. The lower portion of

the top of the panel also exhibits an increased suction, however, this is less pronounced than at the top of the panel. The suction on the underside of the panel is also moderately increased during the 2nd peak, relative to the mean. Examining the velocity profiles during the 2nd peak, shown in Figure 14, the extent of vertical fluctuations in the vicinity of the panel is less than during the 1st peak however large vertical fluctuations are observed ~0.1 *H* above the panel's lower edge. As with the 1st peak the 2nd peak appears to be correlated with a mild streamwise gust.

In contrast with the first two peaks the pressure field during the 3rd peak, shown in Figure 15, is characterized by strong suctions at not only the top of the upper surface, but also near the centre of the top surface of the panel. Suction at the bottom of the top surface and the underside of the panel are also moderately increased. Turning to the velocity profiles associated with the 3rd peak, shown in Figure 16, large vertical fluctuations are again evident with maximum vertical velocities approaching the reference speed above the top of the panel. There also appears to be a negative streamwise fluctuation above the panel associated with the 3rd peak in addition to a strong streamwise gust in the freestream further above the panel.

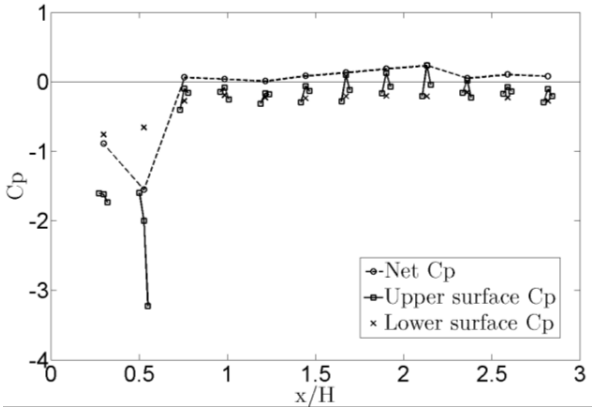

Figure 11. Instantaneous pressure coefficients during 1st peak uplift event on the 2nd southernmost panel for a wind direction of 180°.

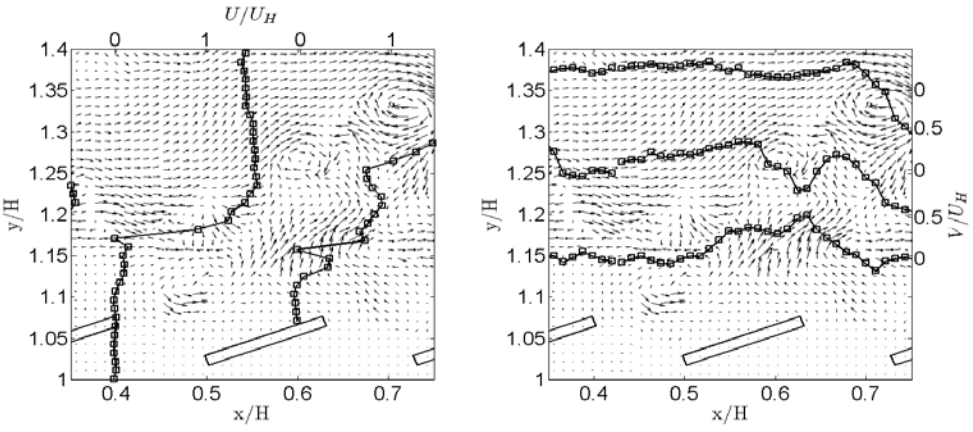

Figure 12. Instantaneous streamwise and vertical velocity profiles during 1st peak uplift event on the 2nd southernmost panel for wind direction of 180°. Vector field shows fluctuating component of velocity only.

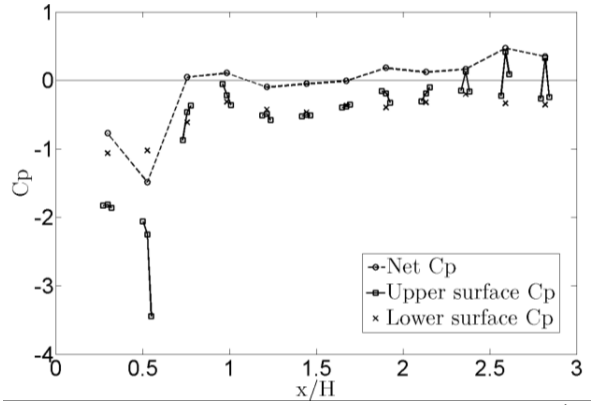

Figure 13. Instantaneous pressure coefficients during 2nd peak uplift event on the 2nd southernmost panel for a wind direction of 180°.

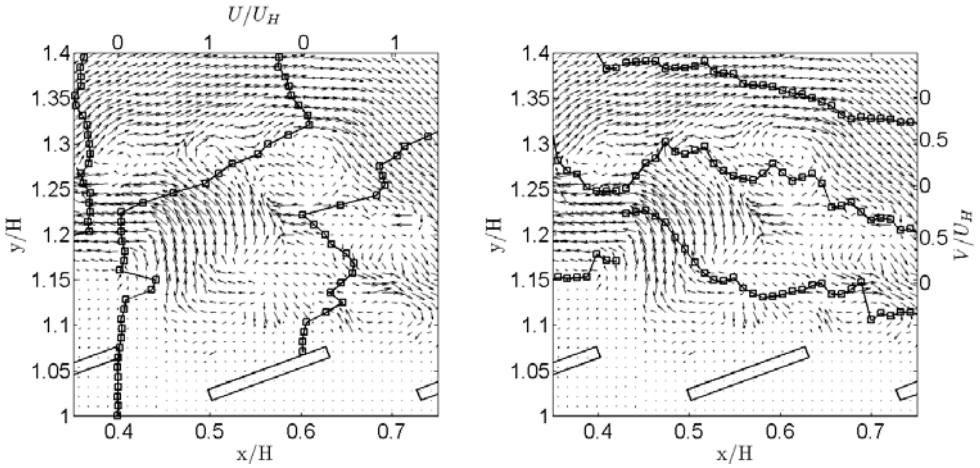

Figure 14. Instantaneous streamwise and vertical velocity profiles during 2nd peak uplift event on the 2nd southernmost panel for a wind direction of 180°. Vector field shows fluctuating component of velocity only.

The vector maps for the first 3 peaks on 2nd southernmost panel all show some level of vortex activity, to quantify these vortices instantaneous swirling strength maps were calculated, shown in Figure 17. While vorticity has traditionally been used to identify vortices, vorticity also identifies regions of shear. Thus, strong shear layers will often mask vortices in vorticity maps. Swirling strength on the other had isolates swirling motion associated with vortices from pure shear [13]. From Figure 4.8 it is clear that while vortices are certainly present during peak events they appear uncorrelated in strength, size, and location with peak uplift events.

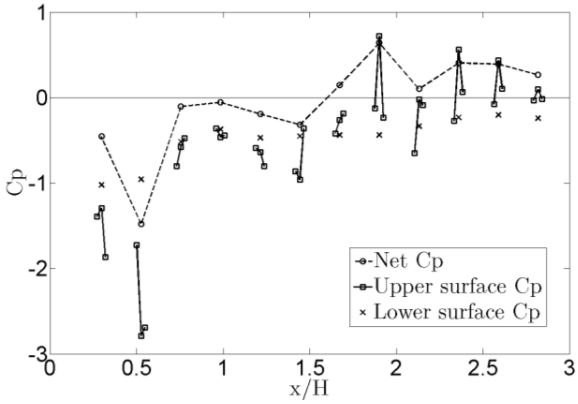

Figure 15.Instantaneous pressure coefficients during 3rd peak uplift event on the 2nd southernmost panel for a wind direction of 180°.

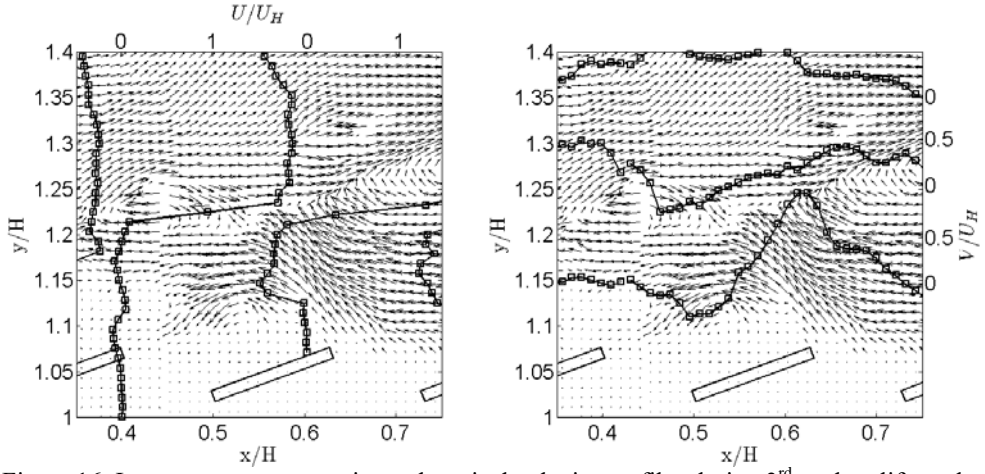

Figure 16. Instantaneous streamwise and vertical velocity profiles during 3rd peak uplift on the 2nd southernmost panel event for a wind direction of 180°. Vector field shows fluctuating component of velocity only.

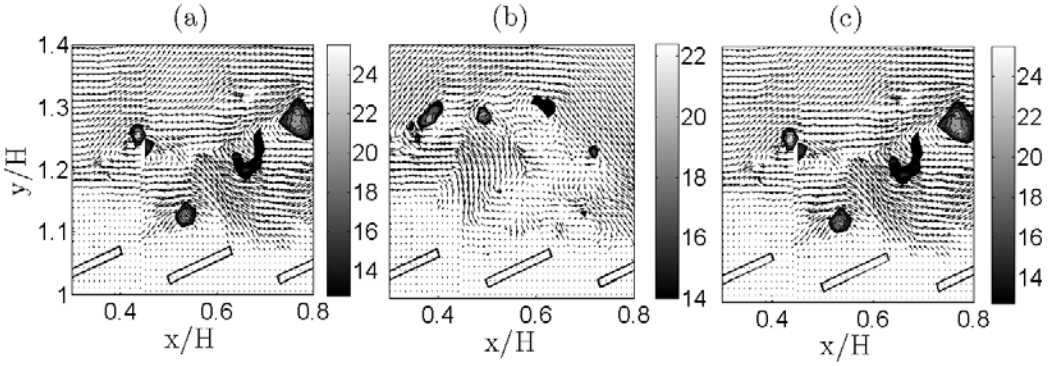

Figure 17. Instantaneous swirling strength maps for (a) 1st peak , (b) 2nd peak and (c) 3rd peak uplift on the 2nd southernmost panel for a wind direction of 180°. Vector field shows fluctuating component of velocity only.

5 CONCLUSIONS

We have presented both pressure and velocity measurements associated with a PV array mounted on a low-rise building during a southern wind. It was found that the separating-reattaching

flow caused by the flow separating at the leading edge of the building was similar to that observed for a bare-roof building in that the height and length of the separation bubble were close to what one would expect for a similar bare-roofed building. The details of the flow within the separation bubble were of course different from a bare-roof building due to the presence of the panels.

The pressure and flow fields associated with peak uplift events on panels within the separation bubble were also examined as these panels experience some of the largest loads seen by the entire array. It was found that the peak events were characterized by large suctions over the top to centre of the upper side of the panel. While suctions also increased towards the bottom of the panel topside as well as the panel underside these increases were much less pronounced. Large positive vertical velocity fluctuations were found to be well correlated with peak uplifts along with mild to strong streamwise gusts further above the panels. While vortices appear in the vicinity of panels experiencing peak uplifts, these vortices seem uncorrelated with the peaks as the size, strength and location of these vortices vary significantly from peak to peak.

6 ACKNOWLEDGEMENTS

This research was supported by NSERC, under the Discovery Grants program. The second author (GAK) gratefully acknowledges the many interesting discussions and enthusiastic support provided by Mr. Chris Tilley and Mr. Rob Ward of SunLink Corporation, and also for the use of the wind tunnel models, which were developed for testing of SunLink's system.

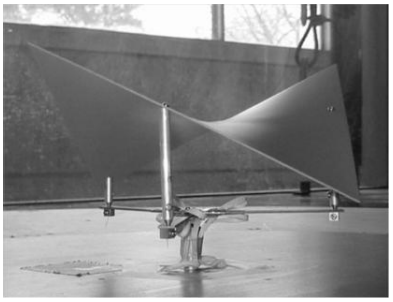
ABSTRACT: The present paper discusses the design wind force coefficients for hyperbolic paraboloid (hereafter "HP") free roofs constructed of membrane structures, based on a structural analysis for various conditions as well as on a CFD analysis. The application of the wind force coefficients obtained from wind tunnel experiments with rigid models is investigated. The influences of roof deformation on the wind forces and the resultant load effects are also investigated.

KEYWORDS: Wind force coefficient, Hyperbolic paraboloid roof, Membrane structure, Wind tunnel experiment, CFD (Computational Fluid Dynamics), Structural analysis.

1 INTRODUCTION

The purpose of the present study is to propose the design wind force coefficients providing the equivalent static wind loads on HP-shaped membrane structures, in which the dynamic load effect is considered appropriately. Pun and Letchford (1993) reported the analysis of an HP-shaped tension membrane roof subjected to fluctuating wind loads (Ref. 1). To the authors' best knowledge, few studies of wind loads on HP-shaped membrane free roofs have been done since. Even for free roofs of the other shapes, the number of studies on the wind loads is quite limited. Recently, Nagai et al. (2012) (Ref. 2) have investigated the wind loads on a horn-shaped membrane structure.

The authors have carried out a series of wind tunnel experiments and CFD analyses to investigate the wind forces on rigid free roofs with various configurations, i.e. gable, troughed, mono-sloped, and HP-shaped roofs (Ref. 3, 4). Figure 1(a) shows an HP-shaped rigid model used in the wind tunnel experiments. Based on the results, we have proposed the design wind force coefficients for HP free roofs (Ref. 5), assuming that the roof is supported by the four corner columns (see Fig. 1(b)), in which the axial forces involved in the columns are regarded as the



(a) Picture of an HP model

(b) Four corner columns

Figure 1. Experimental model and a supporting system

most important load effect for discussing the design wind force coefficients.

In practice, however, there are many other supporting systems, such as a 'post and guy cable system'. Moreover, the membrane roof is not rigid but rather flexible, the deformation of which is larger than that of conventional roofs such as metal roofs. Therefore, regarding the application of the proposed wind force coefficients, the following questions have arisen: (i) Can they be applied to membrane structures with the other supporting systems? The structural characteristics such as arrangement and stiffness of the members may affect the responses significantly (Ref. 6); (ii) Can they be applied to flexible roofs that deform under wind loading? The roof deformation may change the wind force significantly; (iii) Do they overestimate or underestimate the wind loads for suspension structures?

Therefore, the present paper investigates these subjects, based on structural analyses of the roofs with three types of structural systems and CFD analyses of the wind forces on the deformed roof. Finally, a discussion is made of the design wind force coefficients.

2 DEFINITION OF WIND FORCE AND MOMENT COEFFICIENTS

2.1 *Roof types*

Three models (Models A - C) with different rise/span (or sag/span) ratios have investigated in previous studies (Fig. 2). Focus is on the model A in the present study. The plan of the roof is a square of 15 m by 15 m, and the mean roof height H is 8 m in full scale.

2.2 *Definitions*

Figure 3 shows the definition of the aerodynamic forces and moments, where D and L represent the drag and lift, respectively; M_x and M_y are the moments about the x and y axes, respectively. These values are normalized as follows:

$$C_D = \frac{D}{q_H ha} \quad C_L = \frac{L}{q_H S} \quad C_{Mx} = \frac{M_x}{q_H Sa} \quad C_{My} = \frac{M_y}{q_H Sa} \qquad (1), (2), (3), (4)$$

where q_H = reference velocity pressure at the mean roof height; h = difference in height for the roof ; a = horizontal (projection) width of the roof; and S = projection area of the roof. For the purpose of simplicity, the design wind force coefficients on the roof are specified by two uniformly distributed values (C_{NW} and C_{NL}) over the windward and leeward halves (Fig. 4), which are defined by

$$C_{NW} = \frac{N_W}{q_H S/2} \quad C_{NL} = \frac{N_L}{q_H S/2} \qquad (5), (6)$$

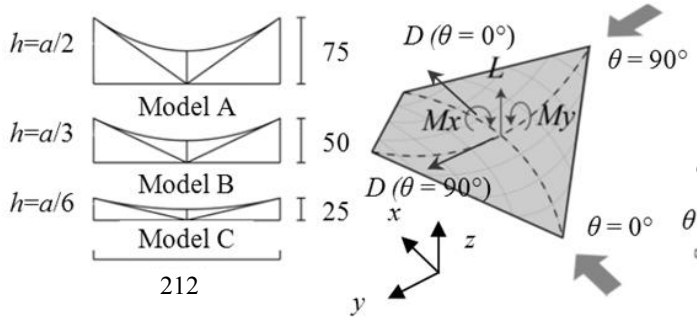


Figure 2. Roof shapes (mm)

Figure 3. Definition of D, L, M_x and M_y

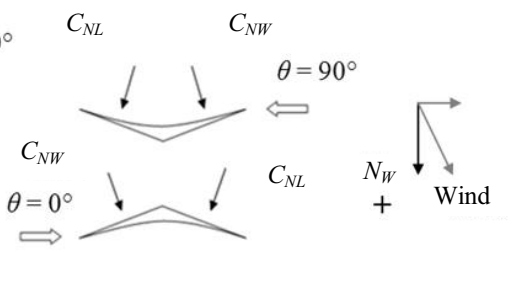

Figure 4. Dimensions of C_{NL} and C_{NW}

where N_W and N_L represent the normal wind forces, positive downward, on the windward and leeward halves, respectively. The coefficients C_{NW} and C_{NL} can be represented by C_L and C_{My} for the wind direction $\theta = 0°$ as follows:

$$C_{NW} = -C_L - 3\sqrt{2}C_{My} \quad C_{NL} = -C_L + 3\sqrt{2}C_{My} \qquad (7), (8)$$

3 WIND TUNNEL EXPERIMNET

3.1 *Arrangement and Procedure*

The wind tunnel model is made of 1 mm thick acrylic plate with a geometric scale of 1/100. Figure 1(a) shows a model mounted on the force balance that was designed, built and gauged for this experiment. The Y-shaped force balance is made of 1.2 mm thick phosphor bronze in order to measure the lift L and the aerodynamic moments M_x and M_y (Ref. 5). The experiments were carried out in a boundary layer wind tunnel with a working section 1.4 m wide, 1.0 m high and 6.5 m long at the Department of Architecture and Building Science, Tohoku University, Japan. A turbulent boundary layer with a power law exponent of α = 0.18 for the mean velocity profile was generated on the wind tunnel floor. The turbulence intensity I_u and longitudinal length scale L_x of the flow at a height of z = 100 mm are 0.17 and 0.16 m, respectively. The measurements were carried out at a wind speed of $U_H \approx 6$ m/s at the mean roof height H. The design wind speed is assumed 31.5 m/s, as a typical value of strong wind events; therefore, the velocity scale is approximately 1/5.25. The geometric scale of the model and the velocity scale yield a time scale of approximately 1/19. The wind direction θ is changed from 0° to 90° at a step of 15°. The outputs of the strain meters were sampled simultaneously at a rate of 200 Hz for a period of 32 sec, which approximately corresponds to 10 min in full scale. The measurements were repeated six times under the same condition. The statistics of the aerodynamic coefficients are evaluated by applying ensemble average to the results of the six consequence runs. Figure 5 shows a phase-plane representation of the C_L - C_{My} relation when θ = 0°. The circle in the figure represents a condition where the C_L value becomes an extreme (the maximum and minimum peak) in each run. It is seen that the peak values of C_L and C_{My} do not necessarily occur at the same time. The envelope of the trajectory is approximated by a hexagon as shown in Figure 6.

4 PROPOSED DESIGN WIND FORCE COEFFICIENTS

4.1 *Design wind force coefficients*

The authors have proposed a procedure to obtain the design wind force coefficients (Ref. 5),

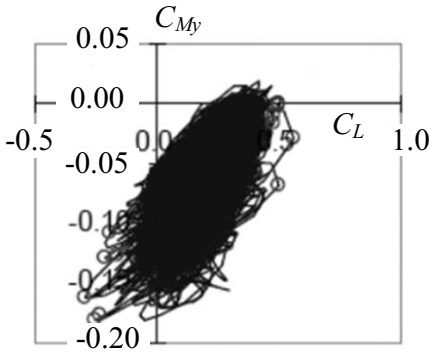

Figure 5. C_L- C_{My} trajectory for Model B (h/a = 1/3)

*1) Using C_{My} for $\theta = 0°$, C_{Mx} for $\theta = 90°$

assuming that the roof is rigid and simply supported by the four corner columns. The procedure is summarized as follows. Focus is on the incremental axial forces induced in the columns by the wind forces as one of the most important load effects for evaluating the wind force coefficients. The incremental axial forces are computed for the combination of C_L and C_{My} (for $\theta = 0°$) or C_{Mx} (for $\theta = 90°$) at each apex of the hexagon as shown in Figure 6. The roof is divided into two areas, i.e. the windward and leeward halves, and the design wind force coefficient is assumed constant in each area. The design wind force coefficients C^*_{NW} and C^*_{NL} for these halves are presented as follows:

$$C^*_{NW} = \frac{\gamma C_{NW0}}{G_f} \qquad C^*_{NL} = \frac{\gamma C_{NL0}}{G_f} \tag{9), (10}$$

where C_{NW0} and C_{NL0} are the basic values, computed from Equations (7) and (8), respectively, by using a combination of C_L and C_{My} (or C_{Mx}) at each apex of the hexagon. Table 1 summarizes the values of C_{NW0} and C_{NL0} at the six apexes for two wind directions, i.e. $\theta = 0°$ and $\theta = 90°$ (see Fig. 4). In the study, two sets of the C_{NW0} and C_{NL0} values are selected from the six sets at the apexes, which induce the maximum tension and compression in the columns.

The value of γ in Equations (9) and (10) is a correction factor for the influence of wind direction (Ref. 5). It is obtained by calculating the ratio of the actual maximum or minimum axial force in a wind direction range of 0° ± 45° (WD1) or 90° ± 45° (WD2) to the predicted value from C_{NW0} and C_{NL0}. In practice, the value of $\gamma = 1.0$ is used in the present study, because the maximum tension and compression are induced when $\theta = 0°$ for WD1 and $\theta = 90°$ for WD2. Note that this is not the case for gable and troughed roofs (Ref.3). G_f is the gust effect factor for considering the dynamic load effect. The value of $G_f = 2.0$ is used for evaluating the design wind force coefficients in this study.

5 EFFECT OF ROOF SUPPORTING SYSTEM

5.1 *Analytical models*

Three structural systems are often used for membrane structures, i.e. frame, suspension and air-supported types. Focus is on the frame and suspension types in the present analyses. Figure 7 shows the analytical models. In Frame-model 1 (F1 model), the roof structure is constructed of the perimeter girders and binding beams, which divide the roof area into twelve zones (Fig. 7(a)). The frame is covered with pre-stressed membrane. The pre-stress is 4 kN/m both in the warp and fill (weft) directions of membrane. The warp direction is shown in Figure 7(b). The fill direction is perpendicular to the warp direction. The self-weight of membrane is assumed 12 N/m^2. Frame-model 2 (F2 model) consists of the perimeter girders and pre-stressed membrane (Fig. 7(b)). In

	$E = 1.57 \times 10^8$ kN/m^2 (Spiral)

Table 2(c). Beam and Post

Elastic modulus:	$E = 2.05 \times 10^8$ kN/m^2
Poisson's ratio:	$\nu = 0.3$

these Frame-models, the roof girders are supported by the four corner columns. On the other hand, Suspension-model (S1 model) consists of the curved perimeter cables and pre-stressed membrane; the roof is supported by the posts and guy cables at the four corners, as shown in Figure 7(c). The column bases of the F1 and F2 models are fixed, while the posts of the S1 model are pin-supported. The connection of elements in the F1 and F2 models is rigid. The material of the columns, beams, posts and cables is steel; that of the membranes is PTFE-coated glass fiber plain-weave fabric. The projection area of the S1 model is approximately 82% of that of the Frame models because of the curved perimeters. The S1 model is the most flexible among these three models, which causes the largest deformation to the roof under wind loading. On the other hand, the F1 model is relatively rigid. Moreover, the roof membrane slightly deforms in the downward direction due to the self-weight. Therefore, the initial shapes of these three roofs are slightly different from each other due to the difference in the supporting system.

5.2 *Structural analyses*

The structural analyses are conducted by using a program named MAGESTIC, in-house software of Taiyo Kogyo Corp., based on a finite element method with the Newton-Raphson method, in which the geometrical nonlinearity is taken into account. The membrane material is assumed orthotropic and elastic. Furthermore, it is assumed that the membrane carry only tension; in other words, it does not resist compression and bending moment. The design wind speed is 31.5 m/s. The corresponding velocity pressure is 605 N/m^2. The six wind force coefficients calculated from the C_{NW0} and C_{NL0} values in Table 1 for each wind direction are used in order to find the critical condition that gives the maximum load effect; they are provided by the combination of C_L and C_{My} (or C_{Mx}) corresponding to the six apexes of the hexagon. In the analyses, the stresses

are calculated based on the Building Standard Law of Japan and Design Standard for Steel Structures published by the Architectural Institute of Japan. For the membranes and cables, tensile stresses are calculated from the tensile forces; for the beams and columns, the extreme fiber stresses are calculated by combining the axial forces and bending moments; for the posts of the S1 model, axial stresses are calculated from the axial forces. The allowable stresses and

		Ca1	6	4	1.01
		Ca2	6	3	1.06
		Ca4	6	3	1.07

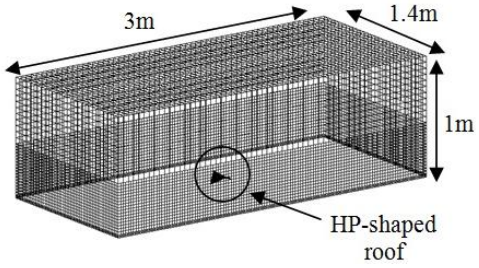

Figure 10. Numerical model

material constants (Table. 2) are also determined based on the Law and Standard. Moreover, the ratio of the computed stress to the allowable stress is calculated, which is called 'stress ratio' in the present paper. The each member size is determined so that the stress ratios are less than 1.0. Figure 8 and 9 shows the results of structural analyses for the F1 and S1 model, respectively. In the figures, the maximum stress ratios for the members, i.e. membrane (Mem), cable, column, beam and post, are shown for the six apexes of the hexagon in Figure 6.

5.3 *Load effects*

The design wind force coefficients are provided by the two combinations of C_L and C_{My} (or C_{Mx}) so that the incremental axial force induced in the columns becomes the maximum compression and tension. In this HP-shaped roof case, the two combinations are the ones corresponding to Apexes 3 and 4 for the wind direction $\theta = 0^o$ and Apexes 4 and 6 for the wind direction $\theta = 90^o$. The combination corresponding to one of the two Apexes (hereafter called "expected Apex") is expected to become the critical condition for the stress ratio of the members.

In Figures 8 and 9, the results for the wind direction $\theta = 90^o$ indicate that the stress ratio of them becomes the maximum for the combination of C_L and C_{Mx} corresponding to Apex 4 or 6 (hereafter called "maximum Apex"). On the other hand, for the wind direction $\theta = 0^o$, the stress ratio does not necessarily becomes the maximum for the combination of C_L and C_{My} corresponding to the Apex 3 or 4. Similar feature is also observed for F2 model. Such cases are summarized in Table 3. In the table, the load combination (i.e. the maximum Apex number) that provides the maximum stress in the member is shown, together with the ratio of the maximum stress to that corresponding to the expected Apex 3 or 4. The ratios for 'Mem' and B3 of F1 model are approximately 1.4, while the ratios range from 1.0 to 1.2 for the other members. The reason why the load combination other than the Apex 3 or 4 induces the maximum stress in the member is not clear at present. However, this may be due to the difference in stress distribution in the roof structure between rigid and flexible roofs. These results suggest that the design wind force coefficients proposed before will be improved so that they can be applied to flexible roofs.

6 EFFECT OF ROOF DEFORMATION

6.1 *CFD analyses of wind forces for the initial roof shapes*

First, CFD analysis is performed for the initial roof shapes of the F1, F2 and S1 models (hereafter "CFD1"). A three dimensional analysis with RANS (Reynolds Averaged Navier-Stokes) model is made by using an open source software named 'OpenFOAM version 1.5' in

order to calculate the mean C_D, C_L and C_{My} (or C_{Mx}) values. The computational domain is 1.0 × 1.4 × 3.0 m, in which an HP-shaped roof with the same configuration that we used in the wind tunnel experiment is placed as shown in Figure 10. The computation is based on a finite volume method, in which the SIMPLE (Semi-Implicit Method for Pressure Linked Equations) algorithm and the RNG (Re-Normalization Group) k-ε model are used. The boundary condition is summarized in Table 4. The turbulence intensity obtained from the wind tunnel experiment is used (Table 5). The distributions of the wind force coefficients obtained from CFD1 for θ = 0° are shown in Figure 11. Figure 12 shows a comparison for the mean C_L and C_{My} values between experiment and CFD1, and the mean C_D value from CFD1. The values for the S1 model are corrected for the difference in the roof area. It is seen that the results of CFD1 capture the general trend of the experimental results.

Figure 11. Wind force coefficients obtained from CFD1 for the initial roof shape

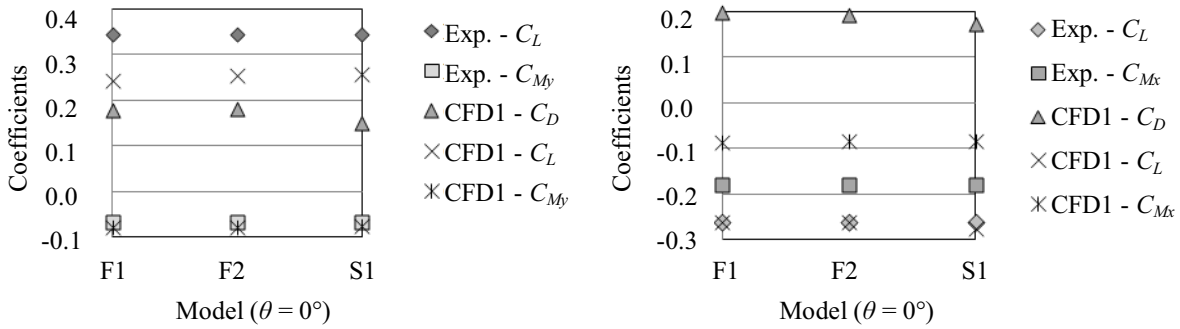

Figure 12. Comparison between experiment and CFD1 for the mean aerodynamic coefficients

6.2 *Effect of roof deformation on the wind forces*

The structural analysis is performed with the mean wind force coefficients obtained from CFD1 (hereafter "SA1"). The design wind speed is 31.5 m/s in the same way as Section 5.2. However, the value of G_f = 1.0 is used to obtain the time-averaged deformation. Then, CFD analysis is again performed for the deformed roofs obtained from SA1 (hereafter "CFD2"). The cross-sections of the roofs are shown in Figure 13. Figure 14 shows the distributions of the mean wind force coefficients on the deformed roofs. Comparing the results with those in Figure 11, it can be seen that the region of upward wind forces expands in the leeward division for the F2 and S1 models. This indicates that the roof deformation in the upward direction causes an increase in the wind force on the roof. Figure 15 shows a comparison for the mean C_D, C_L, and C_{My} values between CFD1 and CFD2. In the figure, the C_L and C_{My} values obtained from CFD2 for F2 and S1 models are approximately 4% to 18% larger than those from CFD1. These features may be caused by the expansion of the upward wind force region that is accompanied by the change of curvature of the membrane surface. Similar feature is observed for the wind direction θ = 90°.

The structural analysis is again made with the mean wind force coefficients obtained from CFD2 (hereafter "SA2"). Figure 16 shows the ratio of the maximum stress obtained from SA2 to that from SA1 for θ = 0°. It is seen that the stresses obtained from SA2 are generally larger than those from SA1. The ratios for the F1 model are up to 1.08, while those for the F2 and S1 models are up to 1.13. Similar feature is also observed for the wind direction θ = 90°. This feature may be related to the increase in the lift coefficient C_L, as shown in Figure 15. Moreover, the feature may be related to the arrangement and stiffness of the elements. From these results, a correction factor for the effect of roof deformation should be introduced in the proposed wind force coefficients.

7 CONCLUDING REMARKS

The application of the design wind force coefficients obtained from the wind tunnel experiments with rigid models of HP-shaped free roofs to membrane structures has been investigated numerically, based on structural and CFD analyses. Focus is on the supporting system and roof deformation. Three types of membrane structure are considered, i.e. two frame types and one suspension type. First, the structural analyses are performed with the previously proposed design wind force coefficients to investigate the effects of supporting systems on the load effects. The maximum stress ratios for the members are calculated to identify the critical condition providing the maximum load effects. The results suggest that the previously proposed design wind force coefficients should be improved so that they can be applied to membrane roofs. Then, the mean wind forces coefficients on the initial HP-shaped roofs are computed numerically. The structural analysis is made with the mean wind force coefficients obtained from the CFD analysis to predict the time-averaged deformation of the membrane roofs. The CFD analysis on the deformed roofs is performed again. Moreover, the structural analysis is made again with the computed mean wind force coefficients on the deformed roofs. Finally, the load effects obtained from the second structural analyses are compared with those of the first structural analyses. The results indicate that a correction factor for the effect of roof deformation should be introduced in the wind force coefficients.

ABSTRACT: Wind loads have a very severe effect on the stability of scaffolding, especially when is covered with sheets of 0% porosity, which significantly changes the wind forces acting on it. Wind tunnel experiments were carried out based on a prototype of scaffolding attached to a medium-height building, and covered with sheets of 0% porosity. Wind force characteristics of scaffoldings with sheets for different building opening ratios and scaffolding arrangements were studied. For most scaffolding arrangements, both maximum positive and minimum negative wind force coefficients tended to be smaller when the building opening ratio was increased. When scaffolding was arranged on one side or encompasses half the building, local wind force coefficients of the scaffolding sheets were more sensitive to changes of building openings.

Keywords: Scaffolding sheet; Wind force coefficient; Wind tunnel experiment; Building opening ratio; Scaffolding arrangement.

1 INTRODUCTION

Scaffolding is a temporary structure used to support people and material in the construction or repair of buildings and other large structures. It is usually a modular system of metal pipes or tubes. For safety, environmental and noise considerations, it is commonly net clad or sheet clad. On construction sites, scaffolding collapses sometimes occur due to strong wind when the scaffolding is covered with sheets of 0% porosity, which significantly increases the wind forces acting on it (Katsutoshi Ohdo, 2005). Furthermore, buildings of different structural types have different kinds of wall openings during construction stages, which also significantly affect wind forces (F. Yue, 2005; Yasumichi Hino, et al, 2005). Thus, the influence of building opening ratios should be considered in the design stage when estimating wind forces acting on scaffolding. For different construction sequences and engineering needs, for a common rectangular section building, scaffolding arrangements vary from one side to all four sides, which affect the wind flow between building and scaffolding (Yasumichi Hino, et al, 2005).

In this study, wind tunnel experiments were carried out based on a prototype of scaffolding attached to a medium-height building, and covered with sheets of 0% porosity. A systemic study of the influence of different building openings on wind forces acting on scaffolding covered with sheets was conducted, and scaffolding arrangements were also taken into account.

2 EXPERIMENT SETUP

The experiments were carried out in the Boundary Layer Wind Tunnel of the Tokyo Polytechnic University, Japan. Two scaffolding sheet models 5mm thick and 0.363m high were selected to

simulate 0% porosity sheets covering scaffolding, attached to a medium-height building with 1/75 geometric scale.

304 pressure taps were arranged on both outer and inner sides of the two sheet models (Sheet A and Sheet B). 4 building opening ratios and 6 scaffolding arrangements were considered. Building opening ratios ϕ_B for Models B0, B20, B40, B80 were 0%, 20% 40%, 80%, respectively, and two dummy models (no pressure taps) of sheets were used in some scaffolding arrangements. Fig. 1 shows experiment pictures. Fig. 2 shows building models and scaffolding arrangements.

Fig. 2 Building models and scaffolding arrangements

Reference wind pressures recorded by a pitot tube and pressure data were simultaneously collected at 781.25Hz for a sampling period of 20 seconds for each sample, corresponding to 26Hz and 10 minutes in full scale. Wind direction was changed at intervals of 5 degrees for each test case. The top wind speed, U_H, was used to obtain the wind pressure coefficients. A turbulent boundary layer with a power-law exponent, α, of 0.2 (U_H≈8.8m/s, $I_{u,H}$≈21%) was simulated (Fig. 3). Experimental cases are shown in Table 1.

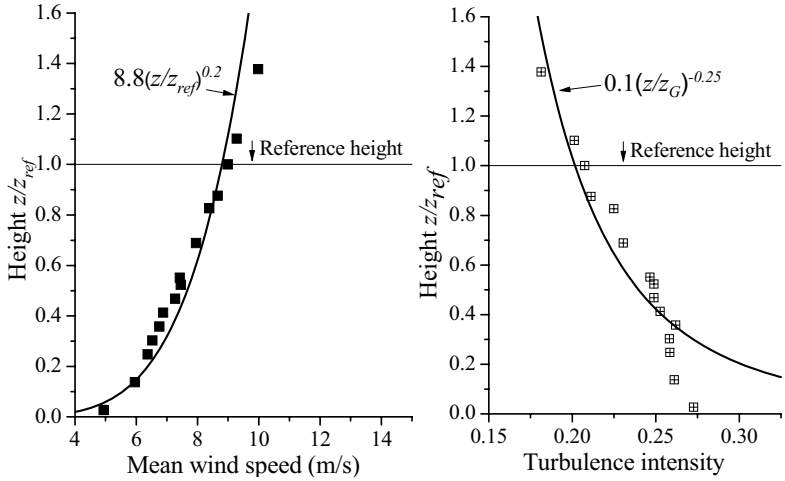

Fig. 3 Mean wind speed and turbulence intensity profile

Table 1 Experimental cases

Scaffolding arrange-ments	Building models	Wind directions
I1	Model B0, B20, B40, B80	0°~180°
I2	Model B0, B80	90°~270°
L	Model B0, B20, B40, B80	0°~360°
U1	Model B0, B20, B40, B80	0°~360°
U2	Model B0, B80	0°~360°
O	Model B0, B20, B40, B80	0°~360°

3 RESULT

Wind pressures measured on the models were expressed in the form of a non-dimensional pressure coefficient, defined as:

$$C_{p,\ outer} = \frac{P_{outer} - P_0}{0.5\rho U_H^2} \qquad C_{p,\ inner} = \frac{P_{inner} - P_0}{0.5\rho U_H^2} \tag{1}$$

where $C_{p,outer}$ and $C_{p,inner}$ are the wind pressure coefficients of the model's outer and inner surfaces, respectively, P_0 is the static reference pressure, U_H is the mean longitudinal wind speed at the reference height(model top) and ρ is air density. Wind force coefficient $C_f = C_{p,outer} - C_{p,inner}$, namely, net pressure coefficient. Thus, the positive wind force coefficient direction is from outside to inside. The maximum and minimum peak wind force coefficients are expressed as $C_{f,max}(i,\theta,\phi_B)$ and $C_{f,min}(i,\theta,\phi_B)$, respectively, where i and θ indicate the i-th pressure tap and the approaching wind direction, and ϕ_B is building opening ratio.

3.1 *Local mean wind force coefficient*

3.1.1 *Local mean wind force coefficient distribution*

The maximum local mean C_f usually occurs near wind direction 45 degrees for scaffolding arrangement I1. Fig. 4 shows the local mean C_f distribution of model Sheet A for scaffolding arrangement I1 and wind direction 45 degrees. The maximum local mean C_f occurs at the top corner of the model when ϕ_B (building opening ratio) increases, and the value of the maximum local mean C_f becomes smaller, from 2.6 decreasing to 1.8 at the corner of the model.

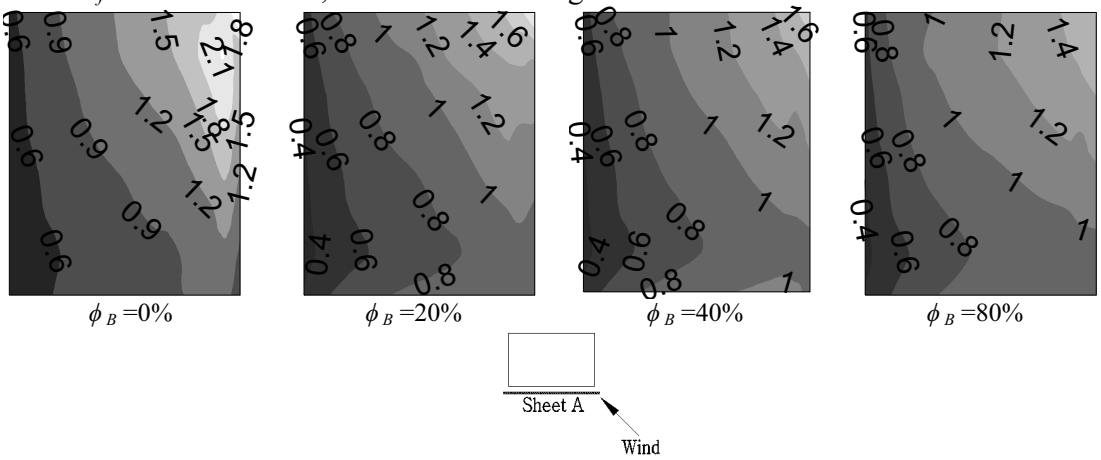

Fig.4 Local mean wind force coefficient distribution, arrangement I1, 45 degrees (Sheet A)

The minimum local mean C_f was found near wind direction 90 degrees, with wind flow almost parallel to the scaffolding sheet. When ϕ_B increased from 0% to 80%, local mean C_f became smaller, and was from -1.2 to -1.3 at the top corner. Thus, when ϕ_B increases, the changing tendencies of both the maximum and minimum local mean C_f are decrease.

Fig. 5 shows the distribution of mean $C_{p,outer}$ and $C_{p,inner}$ of Sheet A for different ϕ_B(0% and 80%). It shows almost the same distributions of $C_{p,outer}$, but for $C_{p,inner}$, they are quite different in both values and distribution. When ϕ_B increases from 0% to 80%, the mean $C_{p,inner}$ at the corner changes from -1.8 to around -0.8. When ϕ_B increases, the mean $C_{p,inner}$ increases and the mean $C_{p,outer}$ remains almost the same. Thus, the mean net pressure coefficients become smaller, namely, local mean C_f tend to be smaller.

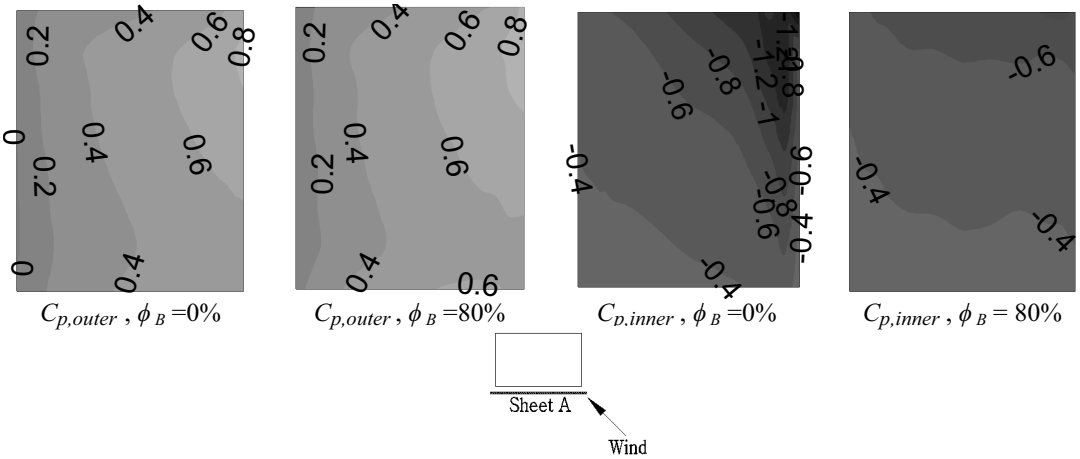

Fig.5 Mean wind pressure coefficient distribution of outer and inner surface, arrangement I1, 45 degrees (Sheet A)

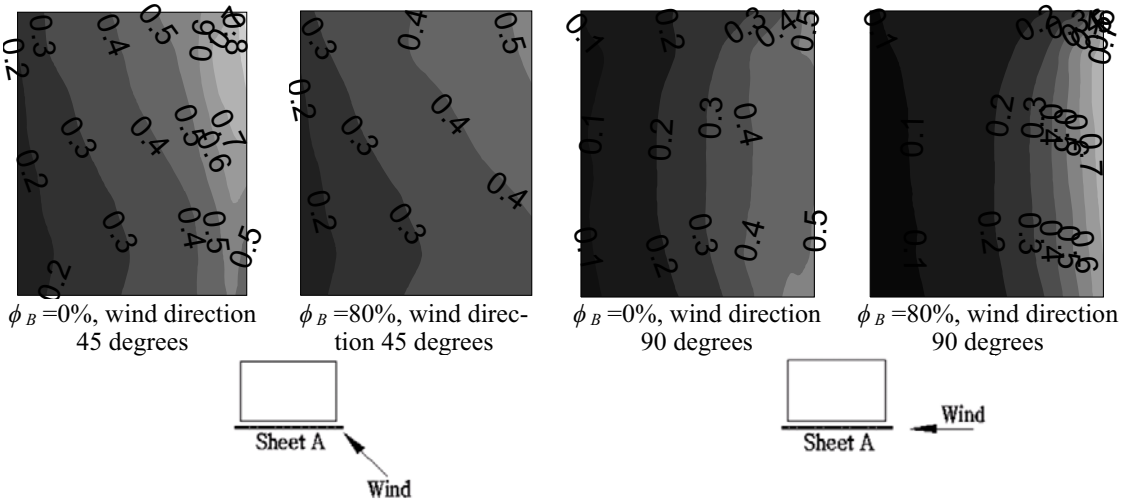
For other scaffolding arrangements, both the maximum and minimum local mean C_f positions are usually located on the top layer or side edge. From the experimental results, the distribution and tendency of local mean C_f on model Sheet B is similar to that on model Sheet A, except that the maximum value is smaller.

Unfavourable wind direction is the direction that causes a maximum or minimum local mean C_f on the models. When the scaffolding arrangement was I1, I2, L, or U1, the unfavourable wind directions changed within the range of ±25º for different ϕ_B. This means that the opening ratio of the building didn't greatly change the unfavorable wind direction for these arrangements. When the scaffolding arrangement was U2 or O, the unfavourable wind directions changed a lot within the range of ±80º for different ϕ_B.

3.1.2 *Local fluctuating wind force coefficients*

The standard deviation values show the fluctuating characteristic of C_f. Fig. 6 shows the local fluctuating C_f distribution of arrangement I1 of Sheet A. 45 and 90 degrees are unfavourable wind directions for the maximum positive and minimum negative local mean C_f, respectively. When ϕ_B changes from 0% to 80%, the maximum local fluctuating C_f becomes smaller (from 1.0 to 0.5) at wind direction 45 degrees but becomes larger (from 0.7 to 0.8) at wind direction 90 degrees. When ϕ_B=0%, maximum local fluctuating C_f occurs at wind direction 45 degrees, but when ϕ_B=80%, maximum local fluctuating C_f occurs at wind direction 90 degrees. Thus, building opening ratio significantly affects the fluctuating characteristic of C_f.



ϕ_B =0%, wind direction 45 degrees | ϕ_B =80%, wind direction 45 degrees | ϕ_B =0%, wind direction 90 degrees | ϕ_B =80%, wind direction 90 degrees

Fig.6 Local fluctuating wind force coefficient distribution, arrangement I1 (Sheet A)

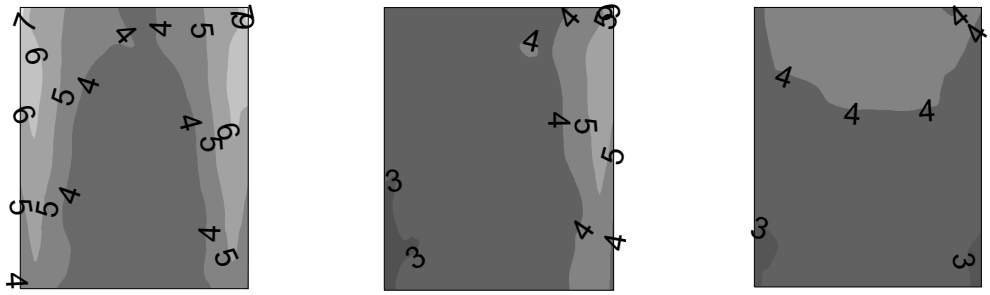
The maximum local fluctuating C_f usually occurs on the top layer or side edge of the model. When scaffoldings is in O arrangement, which all four sides of the building encompassed, the value of local fluctuating C_f is almost unchanged by the effect of ϕ_B.

3.2 *Local peak wind force coefficient*

An "Equivalent time averaging" method was used to determine the wind load acting on a finite area from point pressure. 0.0038s corresponding to 0.11s in full scale was, used for time averaging. The peak force coefficients were calculated by the "Cook-Mayne method" using the maximum values (for positive wind force coefficient) and minimum ones (for negative wind force coefficient) of 10 samples.

3.2.1 *Local peak wind force coefficient distribution*

Local $C_{f,max}$ and $C_{f,min}$ distribution was similar to local mean C_f distribution. Both maximum and minimum peak values usually occurred on the top layer or side edge of the model in most scaffolding arrangements. Usually, the maximum local $C_{f,max}$ occurred when ϕ_B =0% and the minimum local $C_{f,min}$ occurred when ϕ_B =80%. Fig. 7 shows the local $C_{f,max}$ distribution of Sheet A of all wind directions when ϕ_B =0%. Fig. 8 shows the local $C_{f,min}$ distribution of Sheet A of all wind directions when ϕ_B =80%. Scaffolding arrangements I1, L and O represent the conditions of a building single side clad, half clad and completely clad a building, respectively. The figures show that both maximum and minimum local peak values were smaller for arrangement O than for arrangements I1 and L. The maximum local $C_{f,max}$ of arrangement I1 is 7.6, larger than the value 6.2 for arrangement L, the minimum local $C_{f,min}$ for arrangements I1 and L are both -6.4.



Arrangement I1 Arrangement L Arrangement O

Fig.7 Local $C_{f,max}$ distribution, ϕ_B =0%, all wind directions (Sheet A)

Arrangement I1 Arrangement L Arrangement O

Fig.8 Local $C_{f,min}$ distribution, ϕ_B =80%, all wind directions (Sheet A)

3.2.2 *Effect of building opening ratio and scaffolding arrangement*

Fig. 9 compares the maximum local $C_{f,max}$ *(i,θ)* and minimum local $C_{f,min}$ *(i,θ)* of model Sheet A for different building opening ratios. For arrangement I1, when ϕ_B increases from 0% to 80%, the maximum local $C_{f,max}$ *(i,θ)* becomes smaller, changing from 7.6 to 5.3, and the minimum local $C_{f,min}$ *(i,θ)* also becomes smaller, from -5.4 to -6.4. For arrangement L, when ϕ_B increases from 0% to 80%, the maximum local $C_{f,max}$ *(i,θ)* becomes smaller, changing from 6.2 to 4.2, and the minimum local $C_{f,min}$ *(i,θ)* also becomes smaller, from -5.6 to -6.4. For arrangements U1 and U2, both the maximum local $C_{f,max}$ *(i,θ)* and minimum local $C_{f,min}$ *(i,θ)* are almost unchanged, within the range of ±0.3 for different ϕ_B. For arrangement O, when ϕ_B increases from 0% to 80%, the maximum local $C_{f,max}$ *(i,θ)* becomes smaller, changing from 4.4 to 4.2, but the minimum local $C_{f,min}$ *(i,θ)* becomes larger, changing from -4.6 to -4.

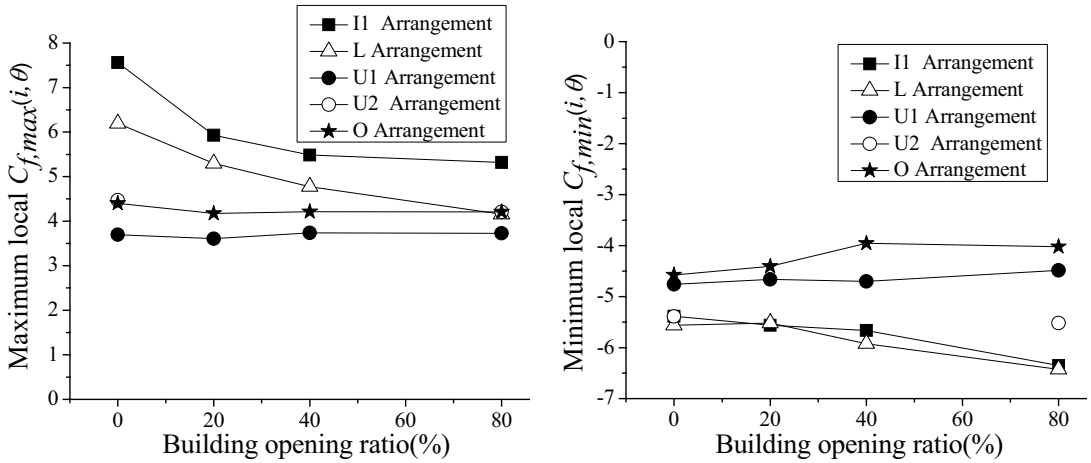


Fig. 9 Maximum local $C_{f,max}$ (i,θ) and minimum local $C_{f,min}$ (i,θ) for each building opening ratio (Sheet A)

From Fig. 10, it is clear that when ϕ_B increases from 0% to 80%, for arrangements I1 and L, the absolute values of both the maximum local $C_{f,max}$ (i,θ,ϕ_B) and minimum local $C_{f,min}$ (i,θ,ϕ_B) become significantly smaller, with a largest difference of 2.3. For arrangements U1, U2 and O, the maximum local $C_{f,max}$ (i,θ,ϕ_B) and minimum local $C_{f,min}$ (i,θ,ϕ_B) vary within the range of ±0.6 for different ϕ_B. Thus, for scaffolding arrangement I1 or L, the local peak $C_f(i,\theta)$ is more sensitive to building openings than for arrangements U1, U2 and O.

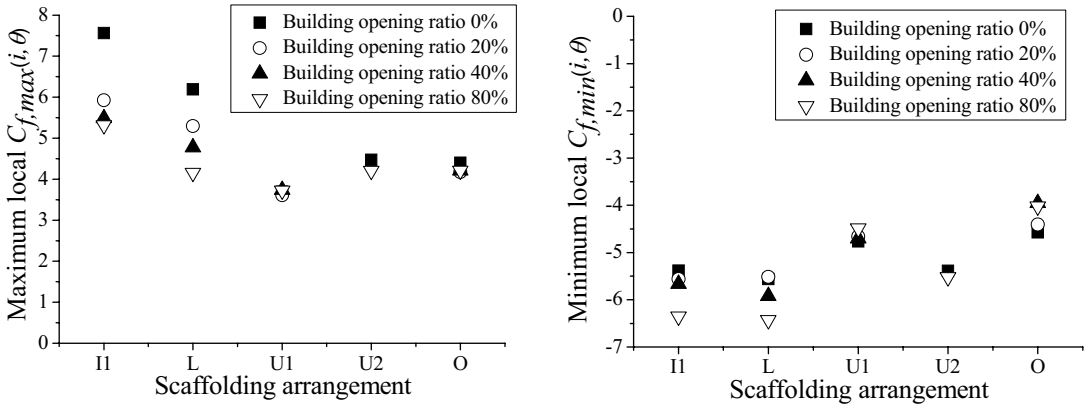

Fig. 10 Maximum local $C_{f,max}$ (i,θ) and minimum local $C_{f,min}$ (i,θ) for each scaffolding arrangement (Sheet A)

Fig. 11 shows local $C_{f,max}$ (i,θ) for wind direction ϕ_B= 0%. For scaffolding arrangements I1 and L, the maximum local $C_{f,max}$ (i,θ) are larger. For arrangement U1, the maximum local $C_{f,max}$ (i,θ) is smaller than those for the other arrangements. The maximum local $C_{f,max}$ (i,θ) of arrangements I1, L and U2 occur near wind direction 45 degrees. For scaffolding arrangements U1 and O, the maximum local $C_{f,max}$ (i,θ) were found near wind direction 0 degrees.

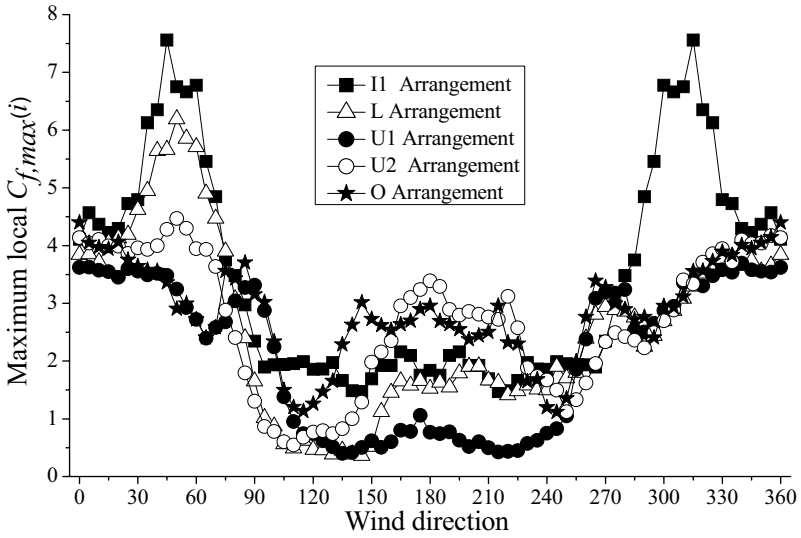

Fig. 11 Maximum local $C_{f,max}(i)$ for each wind direction, φ_B =0%(Sheet A)

3.2.3 *Comparison of model Sheets A and B*

The previous section discussed the characteristics of wind force acting on model Sheet A. This section compares model Sheets A and B. For scaffolding arrangements I(I1 or I2), L, and O, the distributions and changing tendencies of wind force on model Sheet B are similar to those on model Sheet A. Table 2 compares local $C_{f,max}(i,\theta,\phi_B)$ and $C_{f,min}(i,\theta,\phi_B)$ for model Sheets A and B. For arrangements I and L, the maximum local $C_{f,max}(i,\theta,\phi_B)$ value for Sheet A is larger than for Sheet B, but the minimum local $C_{f,min}(i,\theta,\phi_B)$ value is almost the same. For arrangement O, the absolute value of both maximum local $C_{f,max}(i,\theta,\phi_B)$ and minimum local $C_{f,min}(i,\theta,\phi_B)$ of Sheet B is smaller than of Sheet A, with a difference of around 0.5.

Table 2 Maximum local $C_{f,max}(i,\theta,\phi_B)$ and minimum local $C_{f,min}(i,\theta,\phi_B)$ of model Sheet A and Sheet B

Scaffolding arrangement	Maximum local $C_{f,max}(i,\theta,\phi_B)$		Minimum local $C_{f,min}(i,\theta,\phi_B)$	
	Sheet A	Sheet B	Sheet A	Sheet B
I1 or I2	7.6	6.6	-6.4	-6.5
L	6.2	4.6	-6.4	-6.4
U1	3.7	4.1	-4.8	-6.4
U2	4.5	4.1	-5.5	-4.2
O	4.4	4	-4.6	-4.1

For arrangements U1 and U2, the absolute values of both the maximum local $C_{f,max}(i,\theta,\phi_B)$ and the minimum local $C_{f,min}(i,\theta,\phi_B)$ of Sheet A is larger for arrangement U2 and that of Sheet B is larger for arrangement U1. For scaffolding arrangement U1, scaffolding sheets are located on both two adjacent sides of Sheet A, which diminish the absolute value of both the maximum local $C_{f,max}(i,\theta,\phi_B)$ and minimum local $C_{f,min}(i,\theta,\phi_B)$ of Sheet A. For Sheet B in arrangement U2, the absolute value of the minimum local $C_{f,min}(i,\theta,\phi_B)$ of Sheet B is also smaller due to the existence of the two adjacent side sheet models. Sheet A in arrangement U2 and Sheet B in arrangement U1 are the conditions with only one adjacent side scaffolding sheet model, which is similar to arrangement L.

3.3 *Total panel force coefficient*

For most wind load recommendations for scaffoldings, the resultant wind force F is calculated by a equation including three components: a velocity pressure, a reference area of scaffolding and a wind force coefficient C_f. C_f is usually used as a total panel C_f. In this study, the total panel C_f of each experimental case was calculated.

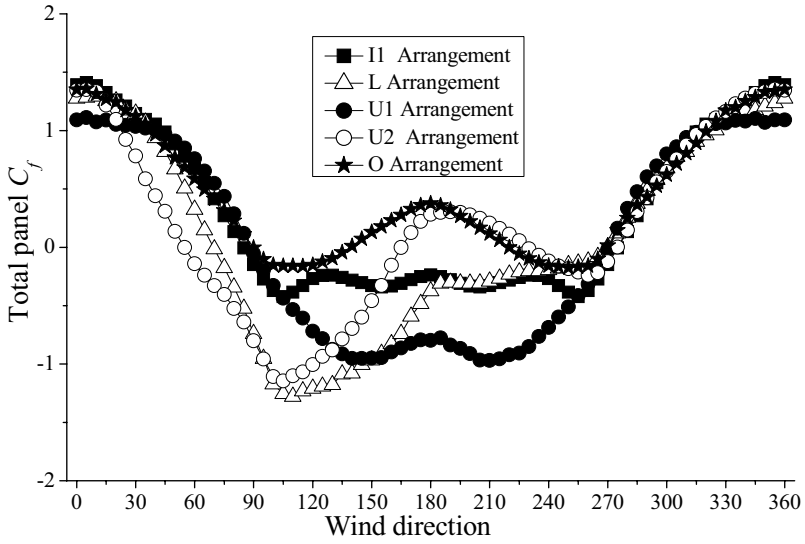

Fig. 12 Total panel C_f for each wind direction, φ_B =0%(Sheet A)

Fig. 12 shows the total panel C_f of model Sheet A for different scaffolding arrangements and each wind direction. Maximum positive total panel C_f occurs at wind direction near 0 degrees for each scaffolding arrangement, and its value is around 1.3 to 1.4, except for arrangement U1, which is 1.1. Minimum negative total panel C_f occurs at wind directions between 105 and 115 degrees for most scaffolding arrangements, except arrangement U1 at 150 degrees. The values are quite different. The minimum negative total panel C_f of arrangement L is the smallest, at around -1.3.

For other building opening ratios, the tendency of most scaffolding arrangements for both maximum positive and minimum negative total panel C_f become smaller when ϕ_B increases from 0% to 80%, but arrangement O has the inverse effect and becomes larger. Model Sheets B and A have the same tendencies as these results.

4 CONCLUDING REMARKS

Wind force characteristics of scaffoldings with sheets for different building opening ratios and scaffolding arrangements were studied from wind tunnel experiment results. The conclusions are:

(1) Local peak wind force coefficients usually occur on the top layer or side edge of a scaffolding sheet, and are significantly affected by building opening ratio. For most scaffolding arrangements, both maximum positive and minimum negative wind force coefficients tend to become smaller when building opening ratio increases.

(2) When scaffolding is arranged on one side or encompasses half a building, local wind force coefficients of scaffolding sheets are more sensitive to change of building openings. When scaf-

folding does not completely encompass a building, wind loads on the scaffolding sheet are larger.

ABSTRACT: A series of wind tunnels tests are presented on a cube, equipped with a permeable outer layer. The influences of cavity depth and opening width have been investigated. This research shows that a wind direction of 75 degrees with respect to the considered panel gives the highest differential pressures relevant for cladding. For smooth flow conditions uniform cavity flows are found, with local effects at the openings in the reattachment zones. Large gaps and small cavity depths have a positive effect on pressure equalization. However, the varied gap width and cavity depth in the current study show minimal effects. It is possible that measures leading to significant effects are outside the range of current practice.

KEYWORDS: Local wind loads, pressure equalization, building facades

1 INTRODUCTION

Rain screen facades are being applied frequently. The façade consists of an air tight inner layer, a cavity (usually partially filled with thermal insulation) and a permeable outer layer. This outer layer can be made of a variety of materials, e.g. natural stone, wood or metal. The permeability allows the pressures over the cladding to equalize. This minimizes the pressure difference over the cladding, thus preventing rain ingress, and reducing the local wind loads. As a result, relative lightweight solutions for the façade and its fixings can be applied. The extent of pressure equalization is sensitive to the detailing of the façade. A number of parameters, such as cavity depth, opening ratios, the extent to which compartments are realized in the cavity, and the complexity of the flow nearby the building influence the pressure distributions over the façade. The relation between these parameters and the pressure distributions are not explicitly known, which makes it difficult to accurately predict the differential pressure over individual façade elements.

The majority of research on pressure equalization has been carried out with respect to rain penetration. The relevant pressures in those studies is the pressure at the windward side of a building, which is the driving force for wind-driven rain. Brown et al. (1991) conclude that the cavity volume should be minimized to improve the speed of pressure equalization, since it reduces the amount of airflow required. Studies of Inculet & Davenport (1994) and Van Schijndel & Schols (1998) show that the higher frequency pressures (>0.1-1.0 Hz) are more damped than the lower frequency pressures.

For wind loads on permeable façades the pressure in the separation zones at the side faces of the building is of relevance. From wind tunnel tests, carried out by Gerhardt & Kramer (1983) and Gerhardt & Janser (1994), it was concluded that the detailing of the extremities, open or closed, has a major effect on the pressure equalization and the differential pressures near corners. The largest mean differential pressures are found at the reattachment point, where the mean external pressure has its minimum. For peak pressures, the largest differential pressure occurs near the

leading edge, where the flow is fully separated. Both for the means and peaks, smooth flow leads to the highest values. A good correlation between cavity flow and external flow is found for small gap widths where the gap flow resistance is high.

Cheung and Melbourne (1988) have performed an extensive wind tunnel study on permeable roofs where they varied the porosity of the roof and the cavity volume. The effect of the internal volume depends upon the distance from the leading edge and of the porosity. Except for regions very close to the leading edge (x/L<0.02), a combination of high porosity and small internal volume leads to the highest reduction in mean differential pressures. The effect of the internal volume on the peak differential pressures is small.

A simple test has been set up to separately investigate these parameters. This paper focusses on the effect of the cavity volume and opening width on the wind loading of façade elements.

2 EXPERIMENTAL SET-UP

A research project has been set up in the Netherlands, to understand the local wind loads of rain screen facades. A full scale, in-situ, test has been started on a 150 m high building in Rotterdam, and both CFD and wind tunnel work has been planned. This paper deals with a wind tunnel test in which parametric studies are carried out. The wind tunnel experiments were carried out in the open circuit atmospheric boundary layer (ABL) wind tunnel of TNO in the Netherlands. Pressure measurement have been performed on a floating cube with dimensions 60x60x60 cm positioned at half tunnel height (h_{ref}). Measurements were done with a smooth up-stream fetch and no roughness elements. The oncoming flow was measured above the center of the turntable with a one-component Dantec Dynamics hot wire anemometer. Ten measurements were performed with a 500 Hz sampling frequency for a total period of approximately 41 s. At a velocity of 15.16 m/s (+/- 0.04 m/s) the turbulence intensity was 0.38% (+/- 0.05%). The main flow properties are given Figure 1.

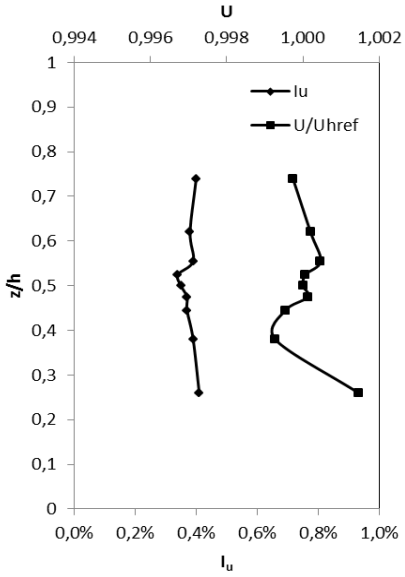

Figure 1. Main flow properties

The cube consists of an airtight inner cube and an outside layer. This layer consists of flat plates with open joints of 8 mm width. Figure 2 gives the outline of the cube. External pressures

and cavity pressures, and flow speeds in the cavity have been measured at different angles of attack. The reference dynamic pressure and oncoming flow velocity (U_{ref}=14.9 m/s) have been measured using a pitot static probe at half the height of the model. The pressures were simultaneously sampled at 20Hz. For every wind direction, 32 time series of 60 s each have been obtained.

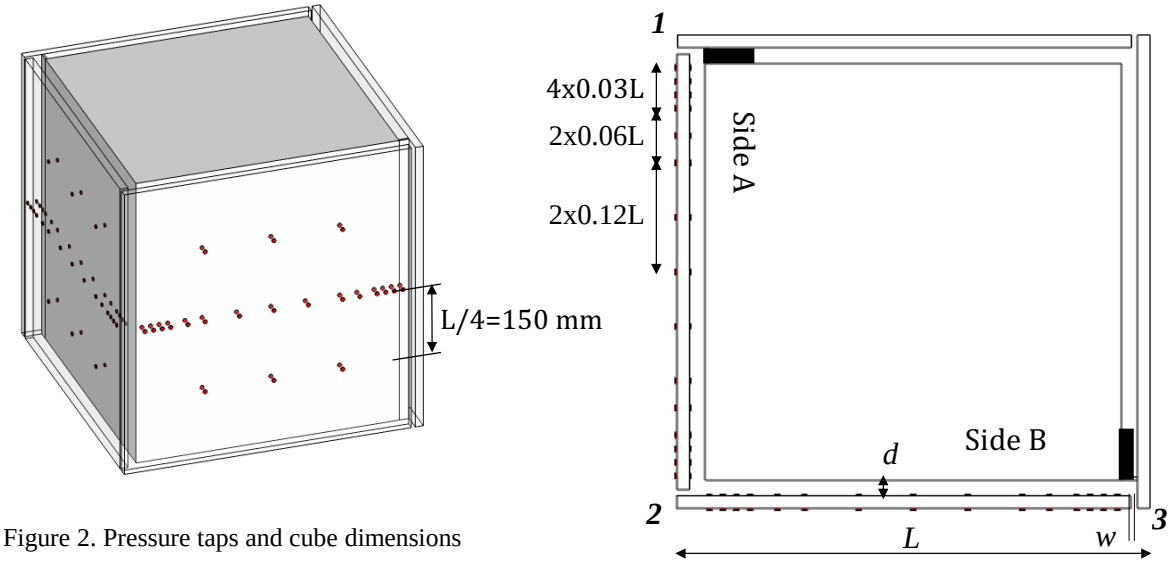

Figure 2. Pressure taps and cube dimensions

Mean, standard deviation and peak pressure coefficients are derived for each of these series according to:

$$C_p(\theta,t) = \frac{p(\theta,t) - p_a(\theta,t)}{\frac{1}{2}\rho U_{ref}^2} \quad (1)$$

Of which both mean values $\bar{C}_p$ and peak-values $\hat{C}_p$ are presented. Using the time signals of external p_e and cavity pressures p_c, time series of the differential pressure were derived. The resulting differential pressure coefficients C_{pdiff} are given by:

$$C_{pdiff}(\theta,t) = \frac{p_e(\theta,t) - p_c(\theta,t)}{\frac{1}{2}\rho U_{ref}^2} \quad (2)$$

Negative values correspond to a direction pointing outwards of the cube and positive values towards the cube.

The purpose of this paper is to show the effects of opening size and cavity width on the peak differential pressures. To study these effects, the configurations described in table 1 have been used. C0 consists of measurements of external pressures only on a closed cube. The basic configuration is C1A, with a gap width of 8 mm and a cavity depth of 20 mm. These sizes correspond on a 1:1 scale to measures found in current practice. The effects of the gap width and cavity depth are investigated by applying the other configurations of table 1.

Table 1. Configurations

Configuration	Gap width	Cavity depth	Outer dimensions	Opening 1	Opening 2	Opening 3
	w (mm)	*d* (mm)	*L*x*L* (mm)	*x*/*L* (-)	*x*/*L* (-)	*x*/*L* (-)
C0 (closed)	0	0	600x600	-	-	-
C1A (reference)	8	20	600x600	-0.97	-0.03	0.97
C1D	4	20	600x600	-0.97	-0.03	0.97
C1E	16	20	600x600	-0.96	-0.04	0.96
C1F	8	10	580x580	-0.97	-0.03	0.97
C1G	8	40	640x640	-0.97	-0.03	0.97

3 RESULTS

Results are presented for two sides of the cube (referred to as side A and side B, see figure 2), for approach flow directions towards those sides. This section starts with the external pressure distribution over C0, the closed cube. Subsequently, the pressure distributions over the outer layer and cavity are given for reference case C1A, followed by data obtained after varying the opening width and cavity depth.

3.1 *Cube without openings (C0)*

The mean external pressure coefficients of the closed cube are given in figure 3 for 4 angles of attack, zero being the direction perpendicular to side B. For the purpose of this study, the negative external peak pressure coefficients are of main interest. The mean peak external pressure coefficients are given in figure 4. The approach flow direction of 15 degrees give the largest external loads on side A. Note that these values correspond to approach flow direction of 75 degrees for side B, because of symmetry over the diagonal.

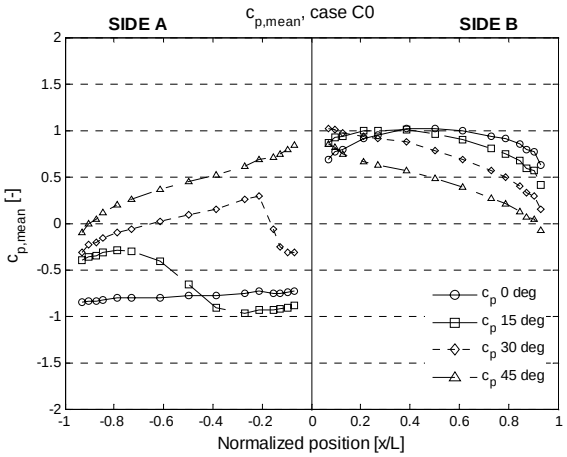

Figure 3: Mean pressure coefficient

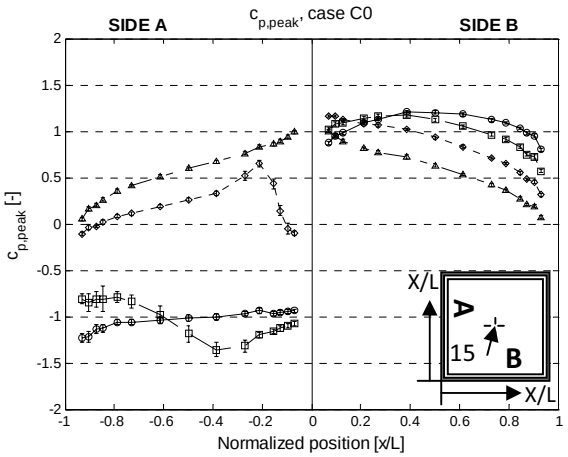

Figure 4: Peak pressure coefficient

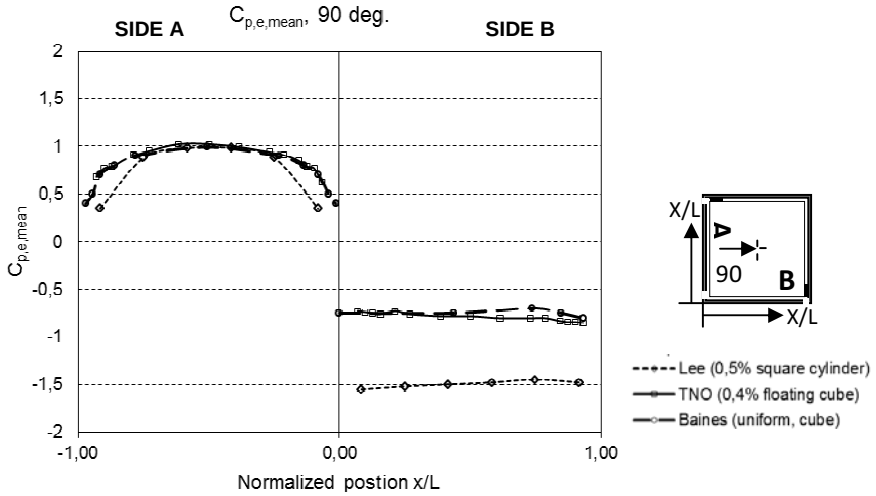
The mean pressure distributions show that the positive pressure coefficients decrease with increasing angle of attack, while simultaneously there is a shift of the maximum value towards the leading edge. At side A, the flow direction of 15 degrees show a clear separation zone, as well as reattachment. The mean peak pressure coefficients (0,1s peaks) are slightly higher, and have their maximum of -1.4 at x/L=-0.39 by 15 degrees angle of attack. At the reattachment zone high standard deviations are found, which affect the mean peak pressure coefficients of this flow direction.

The values for this cube have been compared with earlier reported values in literature. Unfortunately, no values for a non-surface mounted "floating" cube could be found by the authors. Data considered are surface mounted cubes and 2-dimensional cylinders with square cross-section. Measurements of the pressure distribution around square cylinders in turbulent flow have been presented by Lee (1975). A cube in uniform flow has been reported by Baines (1965).



The floating cube is best comparable with a surface-mounted cube in uniform flow field and end effects dominate the flow.

3.1 *Differential pressures over a permeable layer: the reference case*

The reference case has 3 openings (see figure 2): one at the leading edge of side A (2), one at the trailing edge of A (1) and one at the trailing edge of side B (3). Figure 5 shows the mean values of the external pressure coefficients and the cavity pressure coefficients for 4 angles of attack. The flow directions contain the highest pressures for side A (15 degrees) and B (75 degrees). The external pressure is not affected by the openings, resulting in the same external pressure coefficients as for the closed cube. At side A, the cavity pressures are dominated by opening 1, whereas at side B, the cavity pressures are determined by both openings (2 and 3). As expected the pressure in the cavity is uniform, except from local effects near the openings.

Figure 6 presents the mean peak pressure coefficients. Due to higher external pressures at the openings, the mean peak pressure coefficients of the cavities are higher than the mean pressure coefficients. Since the turbulence is low, the effect is rather small. As already concluded by Geurts (2000, 2005) pressure equalization is a very fast process and all external fluctuations are immediately followed by the cavity. The mean peak pressure coefficients of the separated flow near the leading edge (flow directions 15 degrees for side A and 75 degrees for side B) increase a bit more. The largest difference occurs where the flow is reattached and high standard deviations (not shown here) are found.

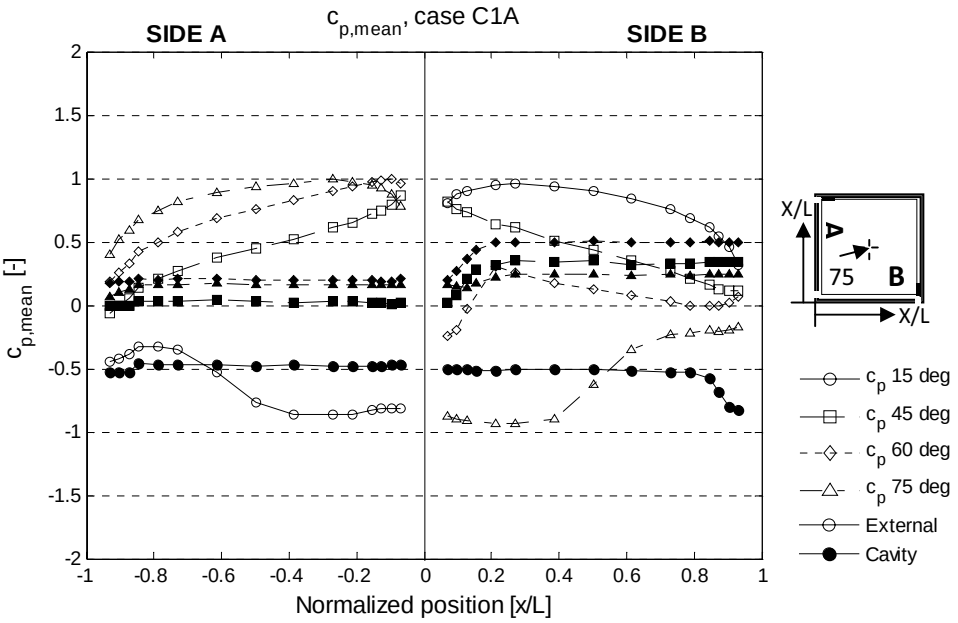


Figure 5: Mean pressure coefficients of reference case

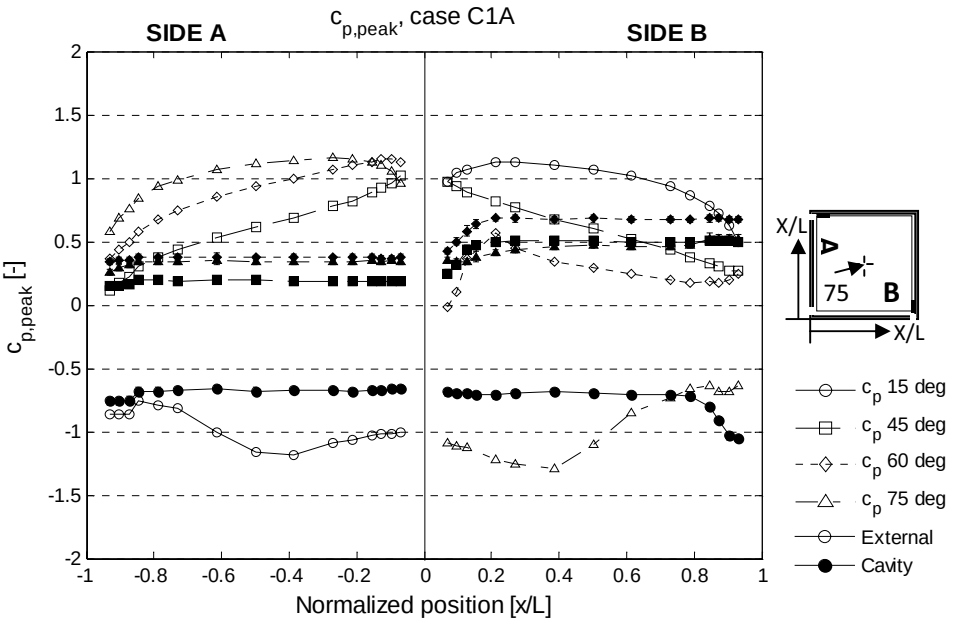

Figure 6: Mean peak pressure coefficients of reference case

For cladding the differential pressure is the most interesting one. The mean peak differential pressure coefficients are shown in figure 7. Negative values correspond to a direction pointing outwards of the cube and positive values towards the cube. On side A the cavity pressures have the same sign as the external pressures and lower differential pressures are found. On side B the opposite is true and the differential pressures are higher than the external pressures.

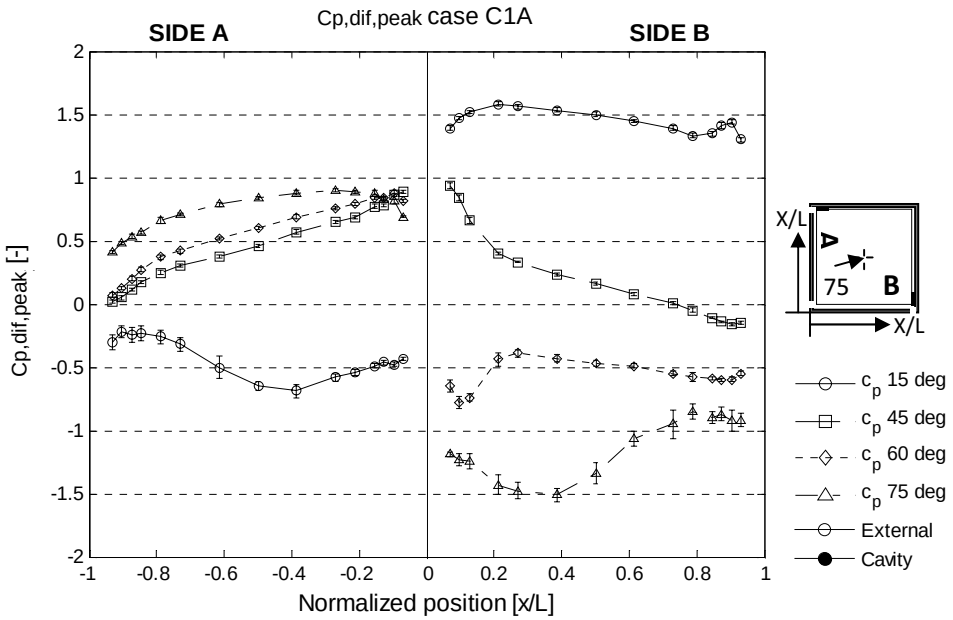

Figure 7: Mean peak differential pressure coefficients of reference case

Of the 4 considered wind directions, the highest outward pointing differential pressures are found for 75 degrees approach flow. On the leading edge the external pressure contributes for 2/3 in this pressure, on the trailing edge the cavity pressure and external pressure contribute equally.

3.2 *Effect of gap width (C1D, C1A, C1E)*

Three series of measurements have been conducted to investigate the effect of the gap width between de panels on the pressure distributions in the cavity. The gap width was varied between 4, 8 and 16 mm. Results are presented here for the approach flow direction of 75 degrees (figures 8 and 9). At this approach direction, the largest differential pressures have been measured in the reference case (with the 8 mm gap width).

Due to a higher flow resistance, the lowest pressures in the cavity and accordingly the highest differential pressures are expected with the smallest gap widths. Figure 8 does not show this effect: the smaller gap of 4 mm width gives similar values as the 8 mm gap at side A. However, it does show the opposite effect for the 16 mm gap where lower differential pressures are found. Side B results in higher mean differential pressure coefficients with increasing gap width. Since a wider gap leads to better pressure equalization at opening 2, a higher cavity pressure is present. The external underpressure combined with the cavity overpressure results in higher differential pressures over the outer layer.

The mean peak coefficients (figure 9) are even harder to compare for the different gap widths. Higher gap widths result in higher standard deviations in the cavity near opening 3 and near opening 2 to lesser extent. These local effects disturb the mean peak differential pressure coefficients and a trend is no longer visible. Figures 8 and 9 show that a more distinguished gap width difference is necessary to determine the gap width effect.

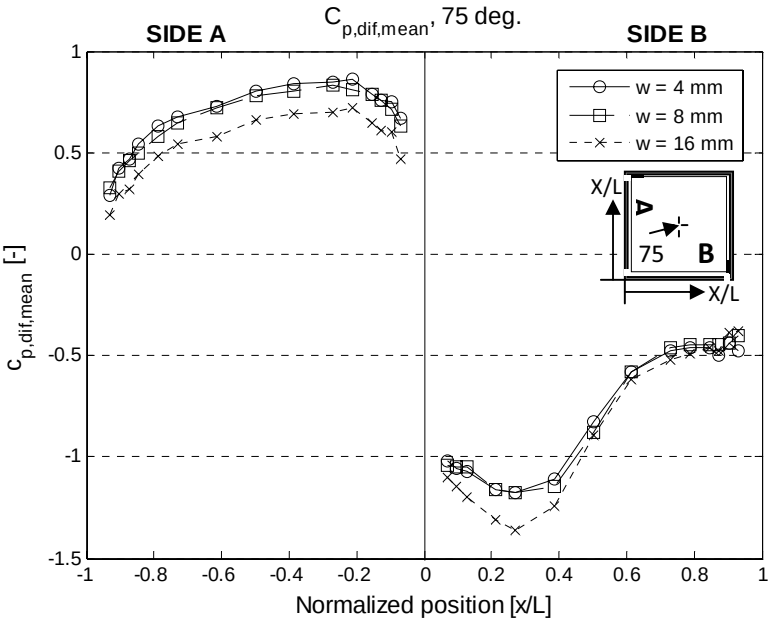

Figure 8: Mean pressure coefficient with varying gap width

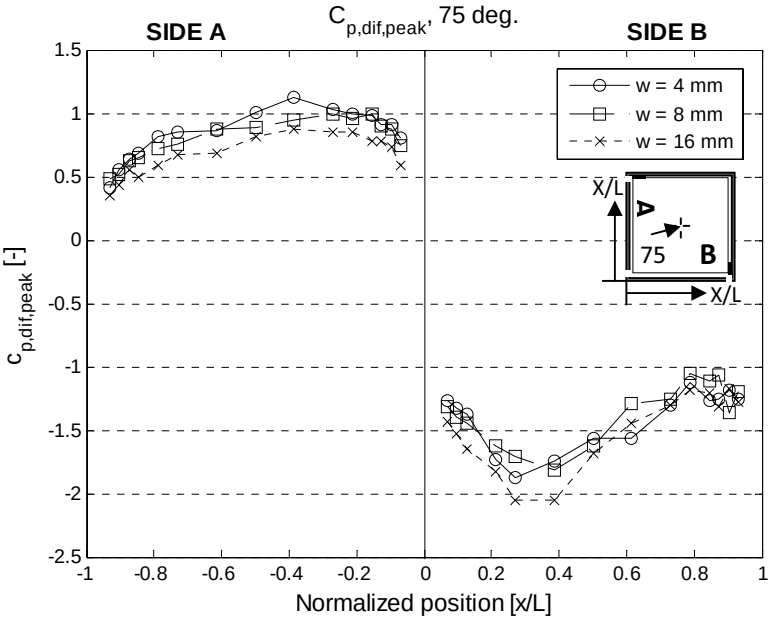

Figure 9: Mean peak pressure coefficient with varying gap width

3.1 *Effect of cavity depth (C1F, C1A, C1G)*

Again, three series of measurements have been conducted to investigate the effect of the cavity depth on the pressure distributions in the cavity. The cavity depth was varied between 10, 20 and 40 mm. Results are presented for the 75 degrees flow direction, that gave the highest differential

pressures for the reference case (with the 20 mm cavity depth). Unfortunately, also in this study the differences in cavity depth seem not distinguished enough to show clear effects. Brown et.al (1991) conclude that smaller cavity volumes, and thus smaller cavity depths, enhance pressure equalization and will lead to the smallest differential pressures. The mean pressure coefficients on the windward side show this trend, but very little (see figure 10). Side B shows the opposite effect due to the opposite sign of the pressures (externally and in the cavity).

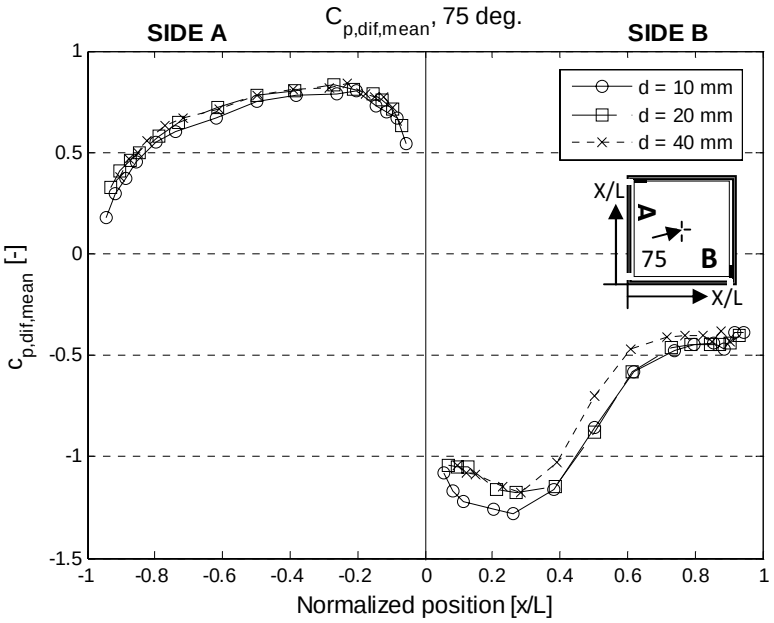

Figure 10: Peak pressure coefficient with varying cavity depth

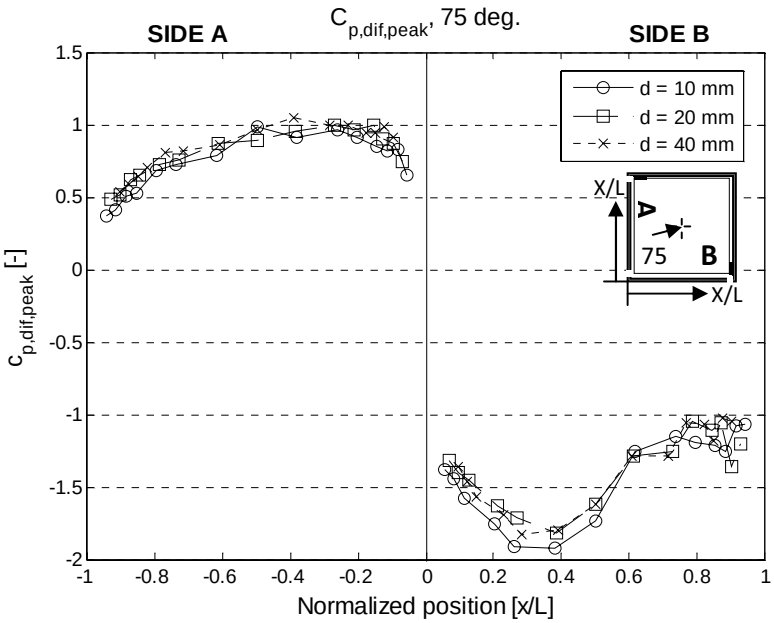

Figure 11: Peak pressure coefficient with varying cavity depth

The mean peak pressure coefficients show hardly any difference between the 3 cavity depths (figure 11). Like a large gap width a small cavity depth results in high standard deviations in the cavity near opening 3 and local effects disturb the flow pattern.

4 CONCLUSIONS

Measurements are performed on a cube with an airtight inner cube and an outside layer with open joints of 8 mm width and a cavity depth of 20 mm. These sizes correspond on a 1:1 scale to measures found in current practice. In smooth flow conditions a wind direction of 75 degrees with respect to the considered panel gives the highest differential pressures relevant for cladding. In general uniform cavity flows are found, with local effects at the openings in the reattachment zones. For unfavorable flow configurations, with overpressure in the cavity, the contribution of the cavity pressure to the total pressure difference is large. For the considered configurations between 1/3 and 1/2.

Large gaps and small cavity depths have a positive effect on pressure equalization. However the varied gap width and cavity depth in the current study are not distinguished enough to come up with final conclusions. It is possible that the measures for which the effects are clearly visible are outside the range of current practice. The tests in the next phase of this research should give an answer to that question.

Further research is ongoing, in which more configurations are being tested in turbulent flow conditions. Also upscaling to building level and validation with full scale measurements are part of the research program.

5 ACKNOWLEDGEMENTS

This research project is a collaboration of DHV, which took the initiative for the full scale measurements, Blitta, Centrum Natuursteen, Kenniscentrum Gevelbouw and TNO.

ABSTRACT: This paper investigates the characteristics of wind forces and wind induced vibrations on L-130x130x9 angle members used as members for large towers through wind forces tests and vibration tests in a wind tunnel using section models. It is thus clarified that unstable aerodynamic vibrations such as vortex induced vibrations, galloping and flutter occur in the angle member.

KEYWORDS: Angle cross-section member, Wind tunnel test, Wind force, Wind-induced vibration, Aerodynamic damping

1 INTRODUCTION

Angle-cross section members have been used in a lot of open structures such as transmission towers, radio towers and canopy roofs. Members of large open type structures in particular have large aspect ratios (ratio of length to width), so their natural frequencies are low and/or their critical damping ratios are small. For such members, vibrations induced by vortex shedding or self-exited vibrations may occur frequently under the design wind speed, which may cause fatigue damage or loosening of bolts at connections. To avoid these problems, characteristics of wind-induced vibrations need to be clarified and estimated in the design stage.

Cook[1], Modi et al.[2] and Okajima et al.[3] studied the relationship between the characteristics of mean wind forces on beams with angle sections and wind angles of attack (wind direction). However, there have been few studies on fluctuating wind forces in these members, and they did not provide enough information to estimate wind responses analytically.

Wardlaw[4], Modi et al.[2] and Okajima et al.[3] studied wind-induced vibrations in angle members. They suggested that vortex-induced vibration, galloping and/or flutter could occur in angle members. However, some of these vibration modes did not agree with the real vibration modes of angle members in open structures. Thus, the characteristics of real vibrations are not clarified by these results.

This paper discusses the characteristics of wind forces and wind induced vibrations on L-130x130x9 angle members usually used as members for large towers, through wind force tests and vibration tests in a wind tunnel.

2 OUTLINE OF WIND TUNNEL TESTS

2.1 *Wind force test*

An Eiffel type wind tunnel with a cross section 2.2m wide by 1.8m high was used.

The section of the model used in this study was L-130x130x9, which was the same as that of a full-scale member. The model was 1m long with end plates 0.5m in diameter, as shown in Figure 1(a). Wind forces were obtained from simultaneous wind pressure measurements at 37 points set on the center of the span (see Figure 1(b)). Approaching wind flow was generated by a turbulence grid. The mean wind speed profiles were almost constant. The wind turbulence intensity was about 5% and the turbulence scale was 0.12m. Wind direction was defined as shown in Figure 2. Wind tunnel tests were carried out for wind directions from 45^{o} to 225^{o} taking the section's symmetry into consideration. Wind speed was 4m/s. Sampling frequency of wind pressure was 500Hz and sampling length was 130seconds.

2.2 *Vibration test*

The wind tunnel cross section for the vibration test was 0.4m wide by 1.8m high. The model's section was the same as that of the wind force test model. The model was 0.4m long with end plates 0.45m in diameter. The model setting system is outlined in Figure 2. The vibration model was supported by 4 coil springs and vibration normal to the springs was fixed by long piano wires. It seemed that the effect due to the wires was negligible for target vibrations. Critical damping ratio was controlled by a damping system made up of a plate and silicon oil. The mass and mass inertia moment of the model were 17.9kg/m and $0.058 kgm^2/m$, respectively. These values were the same as those of the full-scale member.

The characteristics of the model's vibration modes were set according to those of the vibration mode obtained from the eigenvalue of a fixed beam of L-130x130x9 section and 8m span. The eigenvalues were calculated by the finite element method (FEM). Table 1 shows the obtained 1st to 4th mode eigenvalues. The 1st mode vibration swayed toward the weak axis and the 2nd mode one was coupled vibration between sway toward the strong axis and torsion. The 4th mode was also coupled vibration between sway toward the strong axis and torsion. The 3rd one swayed toward the weak axis with a node in the center of the span. The natural frequencies of the 3rd and4th modes were twice that of the 2nd mode, so it seemed that the 3rd and 4th mode vibrations did not occur within the design wind speed. In consequence, the target vibrations in the tests were the 1st and 2nd mode vibrations. The 1st and 2nd mode vibration tests were carried out respectively in order to clarify their vibration characteristics.

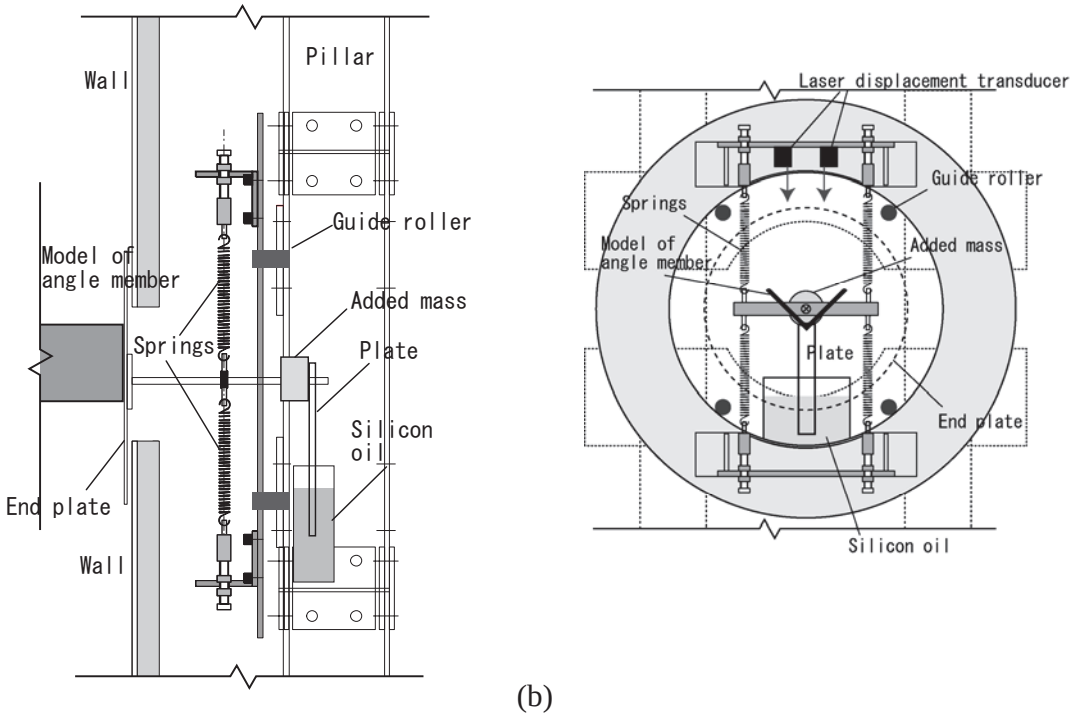

Figure 2. Wind vibration test system (a) View from leeward side, (b) Side view

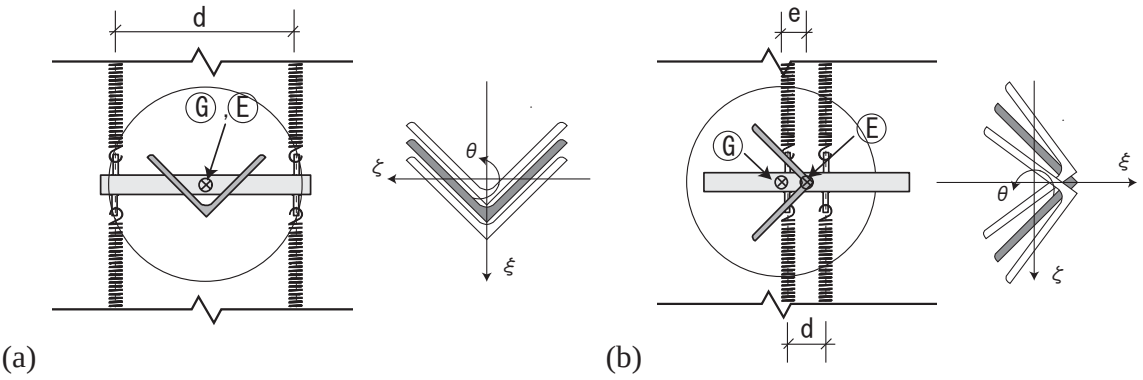

Figure 3. Set up of vibration model and vibration mode of model (a) 1st mode (b) 2nd mode

Table 1. Natural frequency and mode vector of FEM analysis and vibration model

Mode	Result of FEM analysis				Vibration test model			
	n_0 (Hz)	u_ξ	u_ζ	u_θ (rad/m)	n_0 (Hz)	u_ξ	u_ζ	u_θ (rad/m)
1st	7.7	1.0	0.0	0.0	6.5	1.0	0.0	0.0
2nd	11.7	0.0	1.0	8.8	6.2	0.0	1.0	5.2
3rd	21.3	1.0	0.0	0.0	-	-	-	-
4th	23.3	0.0	1.0	-22.0	-	-	-	-

The center of gravity of the model agrees with the center of stiffness for the 1st mode vibration model, supported with coil springs. The distance *d* between the coil springs was 0.28m, which was the maximum distance to produce high torsional frequency in the vibration system

(see Figure 3(a)). The resulting torsional frequency was 15Hz, being almost twice the 1st mode frequency. Therefore, it seemed that the effect of torsional vibration upon the 1st mode vibration was negligible.

The 2nd mode vibration test model was set such that the distance *e* between its center of gravity and center of stiffness was 0.042m, which was the same as the full-scale value. The distance *d* between coil springs was 0.061m (see Figure 3(b)).

Figure 3 and Table 1 show the characteristics of the 1st and the 2nd mode vibrations for the section model, where u_ξ, u_ζ and u_θ are the mode vectors for the weak axis, strong axis and rotation axis, respectively, and n_0 is the modal natural frequency. For the 2nd modal vibration, the vector for the rotation axis was smaller than the target value. However, the characteristics of coupled vibration were evaluated accurately enough by the model.

The critical damping ratio of the model was adjusted by silicon oil and the number of plates submerged in silicon oil (see figure 2). The critical damping ratios in the experiments were adjusted in the rage from 0.1% to 1%. The ratios were measured by free vibration tests in the no-wind condition. The experimental wind speed of the vibration tests were in the range from 3m/s to 20m/s. The model displacements were measured by two raiser displacement transducers at each end sides of the vibration system. The sampling frequency of displacement was 200Hz and the measurement time was 80 seconds for each case.

3 RESULTS OF WIND FORCE TEST AND DISSCUSSION

3.1 *Characteristic of mean wind force coefficient*

Figure 4(a) shows mean drag force coefficients C_{FD}, mean lift force coefficients C_{FL} and mean torsional moment coefficients C_{MZ} at the middle span of the section model, as defined by Equation 1.

$$C_{FD} = \frac{F_D}{qB}, C_{FL} = \frac{F_L}{qB}, C_{MZ} = \frac{M_Z}{qB^2} \tag{1}$$

where F_D is mean drag force; F_L is mean lift force; M_Z is mean torsional moment; q is dynamic pressure; and B is reference width 0.13m.

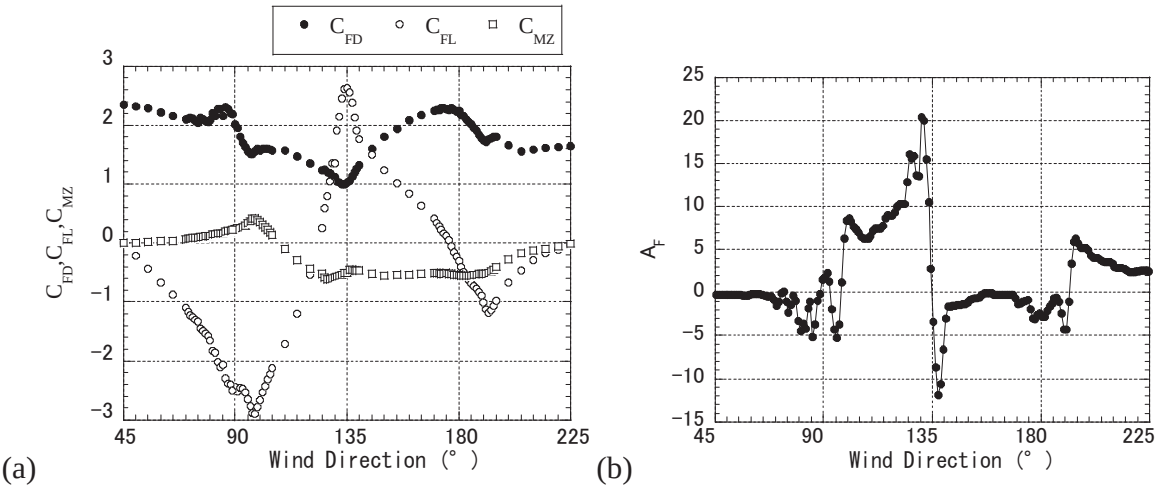
The mean drag force coefficients were large, being about 2.2 for wind directions of about 45°, 85° and 180° The minimum value was about 1.0 for a wind direction of about 135°. The mean lift force coefficients varied widely with change of wind direction. The maximum value was about 3 for a wind direction of 135 ° and the minimum value was about -3 for a wind direction of about 100°.

The mean drag force coefficients agreed with the values obtained by Modi et al. [2] and Okajima et al. [3], except for wind directions in the range from 45° to 80°, where the values obtained from this study were smaller. This difference is probably due to the difference of sectional edge shape of the model, arising from the difference of back pressure.

Figure 4(b) shows the values of Den Hartog's criterion obtained from Equation 2, which showed large negative values of about -12 for a wind direction of 137°. This direction is normal to the weak axis, so galloping may occur in this case.

$$A_F = C_{FD} + \frac{\partial C_{FL}}{\partial \alpha} \tag{2}$$

where α is the wind direction.



(a) (b)

Figure 4 Mean wind force (a) Mean wind force coefficient (b) Den Hartog's criterion

3.2 *Characteristics of modal fluctuating wind force coefficient*

The characteristics of modal fluctuating wind force coefficients derived from Equation 3 and 4 are discussed.

Figure 5 shows the modal fluctuating wind force coefficients of the *i* th mode C'_{Fi} versus wind direction.

$$C'_{Fi} = \frac{\sigma_{Fi}}{qB} \tag{3}$$

$$\sigma_{Fi} = \sqrt{\overline{F_i(t)^2}} = \sqrt{\overline{\left(F_\xi(t)u_{\xi i} + F_\zeta(t)u_{\zeta i} + M_Z(t)u_{\theta i}\right)^2}} \tag{4}$$

where $F_i(t)$ is modal wind force and subscript *i* is modal number; and $F_\xi(t)$, $F_\zeta(t)$ and $M_Z(t)$ are the fluctuating wind forces for the weak axis, the strong axis and torsion, respectively.

The 1st and 2nd modal fluctuating wind force coefficients showed large values for wind directions of 85° and 140° to 180° .

The 1st modal fluctuating wind force coefficients show the same values as the 2nd ones for wind directions of about 85°, but the 1st modal fluctuating wind force coefficients are larger than the 2nd ones for wind directions of 140° to 180°.

Figure 6 shows the power spectral densities of modal fluctuating forces.

The power spectral densities of the 1st and the 2nd modal fluctuating forces for wind directions of 85° and 175° show a dominant peak at a non-dimensional frequency of 0.12. These peaks are due to vortex shedding from the model. The peak value of the 2nd modal fluctuating force is larger than the value of the 1st one for a wind direction of 85°, and the peak values of the 1st and the 2nd modal fluctuating forces show almost the same values for wind direction 175°. Judging from these power spectral densities, vortex induced vibration may occur for wind directions of about 90° and 150° to180°.

Modi et al. [2] and Okajima et al. [3] indicated that across-wind vibrations due to vortex occurred for wind directions of 45°, 75° and 165° in vibration tests. The result for the wind direction of 165° is the same as the result foreseen from this study. However, the peaks of power spectral densities are not dominant for wind directions of 45° and 75° in this study, so there are

few possibilities of across-wind vibration due to shedding vortex. These differences between the results obtained from this study and those obtained from Modi et al. [2] and Okajima et al. [3] seem to be due to the shape difference of the model's edge.

Figure 6(c) and (d) shows the modal fluctuating forces for wind direction of 95° and 135° where large displacements occurred in the vibration tests. The power spectral densities of the 1st and the 2nd modal fluctuating forces for a wind direction of 95° show a blunt peak at a non-dimensional frequency of 0.12, unlike the peaks for a wind direction of 85°. The power spectral densities of the 1st modal fluctuating force for a wind direction of 135° show a blunt peak at a non-dimensional frequency of 0.2, which is about twice those for wind directions of 85° and 175°.

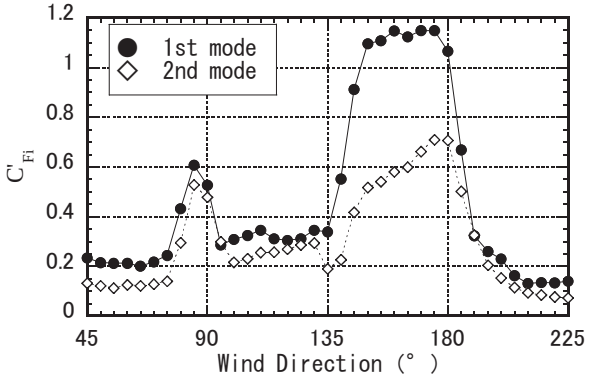


Figure 5. Modal fluctuating wind force coefficient

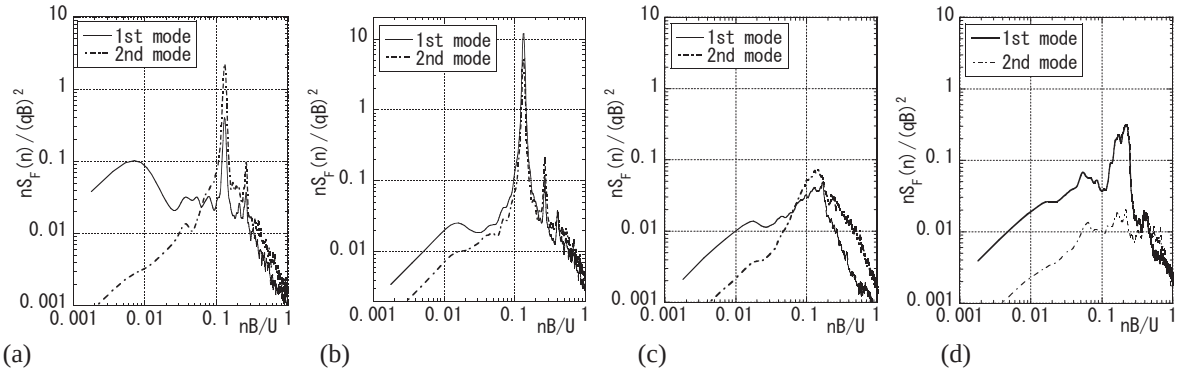

Figure 6. Non-dimensional power Spectral Densities of modal fluctuating wind force (a) Wind Direction 85° (b) Wind Direction 175° (c) Wind Direction 95° (d) Wind Direction 135°

4 RESULT OF VIBRATION TEST AND DISCUSSION

4.1 *Measurement result of response displacement*

Figure 7 shows some examples of standard deviations of response displacement obtained from vibration tests. The test results shown in Figure 9 are selected for the following reasons: (1) Wind directions are 85° and 175° where the power spectral densities have dominant peaks due to shedding vortex in the force tests and vortex-induced vibration occurs clearly in the vibration tests. (2) Wind direction is 135° , which is normal to weak axis, where the Den Hartog's criterion

had negative and large values in the force tests and galloping occurred in the vibration tests. (3) Wind direction is 95° where the 2nd vibration mode occurred divergently in the vibration tests.

Standard deviations of response displacement obtained from the force vibration theory, Equation 5, 6 and 7, by using fluctuating modal forces are also shown in Figure 7.

$$\sigma_i = \sqrt{\int_0^\infty S_{Fi}(n) \mid H_i(n) \mid^2 \, dn} \tag{5}$$

$$\mid H_i(n) \mid^2 = \frac{1}{(2\pi n_i)^2 M_i \left[\left\{ 1-(n/n_i)^2 \right\}^2 + 4h_i^2 (n/n_i)^2 \right]} \tag{6}$$

$$M_i = M(u_\xi^2 + u_\zeta^2) + Iu_\theta^2 \tag{7}$$

where $S_{Fi}(n)$ is the ith modal power spectral density; $|H_i(n)|^2$ is the ith mechanical admittance; M_i is the ith modal mass; n_i is the ith natural frequency; h_i is the ith modal critical damping ratio; M is the mass of the model; and I is the mass moment of inertia of the model.

In the 1st modal vibration test, large displacements occurred at non-dimensional wind speed 7 for wind direction 175°. The values obtained from the vibration tests were larger than the estimated values by the aforementioned theory for critical damping ratio 0.23%. However, for critical damping ratios larger than 0.49%, the two displacements were almost the same. The same characteristic of displacements was indicated for wind directions of 150° to 180°, where the power spectral densities of the 1st modal fluctuating forces had dominant peaks. On the other hand, the power spectral density of the 1st modal fluctuating force also had a dominant peak for wind direction 85°. However, self-excited vortex vibration did not occur.

The displacements of the 1st mode for wind direction 135°, where the Den Hartog's criterion had negative and large values, increased suddenly with increasing wind speed for non-dimensional wind speeds more than 15, so this vibration was galloping. This tendency was clearer where the critical damping ratio was less than 0.42%. The critical galloping non-dimensional wind speed was larger than about 9, as obtained from Equation 8 where A_F is -5 and h_1 is 0.2%.

$$U_C = \frac{4M\omega_1 h_1}{\rho B \mid A_F \mid L} \tag{8}$$

where ω_1 is the 1st modal angular frequency; h_1 is the 1st modal critical damping ratio; ρ is air density; and L is model length.

In the 2nd modal vibration test, the displacements for wind direction 85° were larger than the estimated values from the force vibration theory regardless of critical damping ratio values. For critical damping ratio 0.18%, the vibration translated into divergent vibration from self-excited vortex vibration. For critical damping ratio 0.4%, displacements at non-dimensional wind speeds more than 15 increase rapidly with increase of wind speed. Taking the 2nd mode shape into consideration, self-excited vortex vibration and flutter could occur for wind direction 85°.

On the other hand, displacements are almost the same as the estimated values for wind direction 175°.

Flutter occurred without regard to critical damping ratio values for wind direction 95°. The critical flutter wind speed was non-dimensional wind speed 10 for critical damping ratio 0.1% and as the critical damping ratio became larger, the critical flutter wind speed became higher.

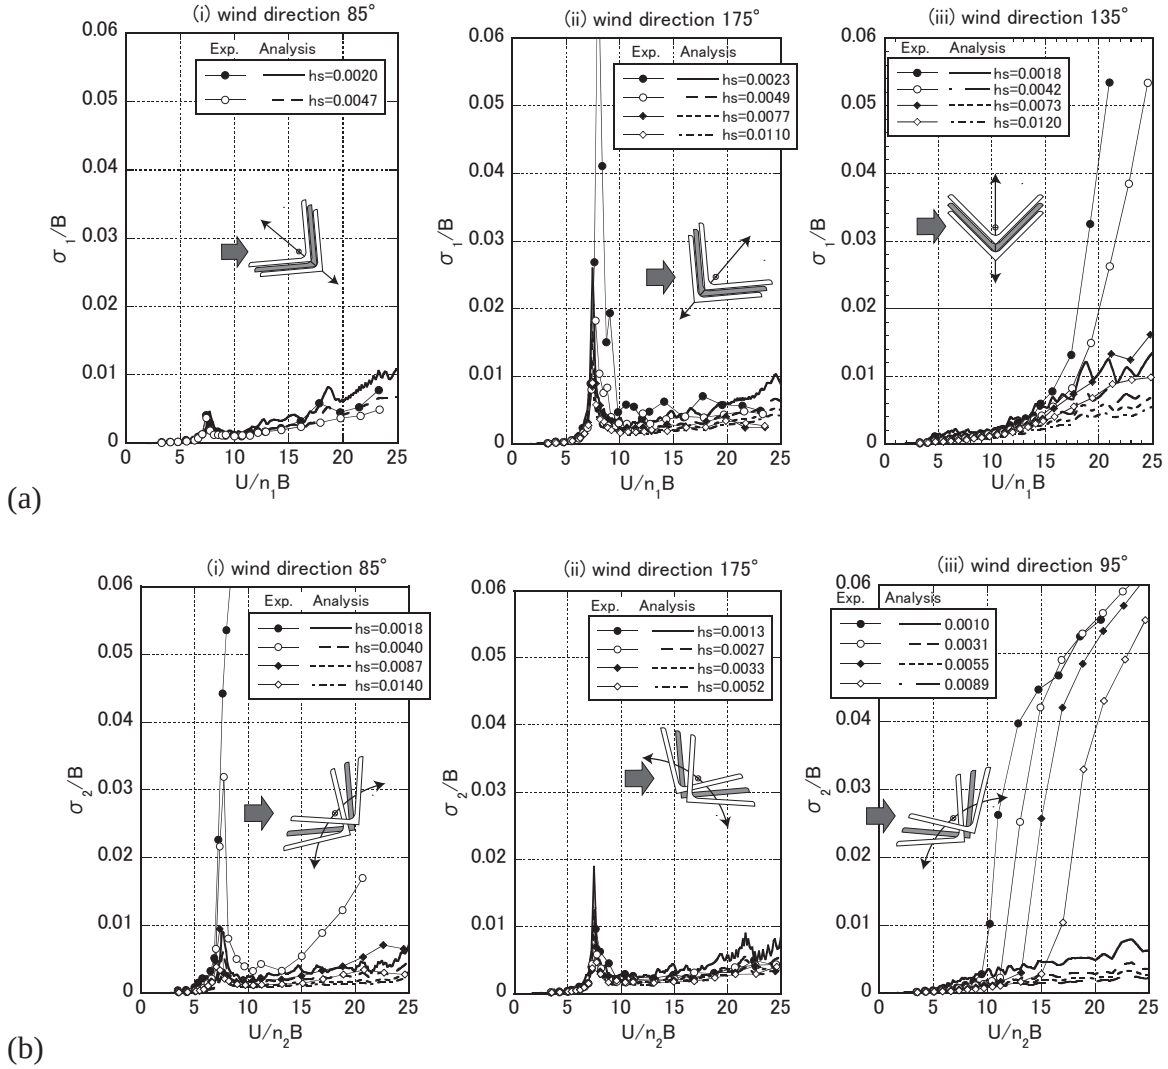

Figure 7. Results of standard deviations of response displacement form vibration test (a) 1st mode vibration, (b) 2nd mode vibration

4.2 *Aerodynamic damping ratio*

The vibration test suggested that galloping for wind direction 135° in the 1st mode occurred and flutter for wind direction 95° in the 2nd mode occurred. We discuss aerodynamic damping ratios estimated by the random decrement method (RD method) for these wind directions. However, these power spectral densities of fluctuating wind forces had a peak because the shedding vortex added a peak of components of natural frequency. Therefore, the time series obtained from the RD method is approximated by Equation 9. Equation 9 gives equivalent modal damping ratio, so aerodynamic damping ratio was one that was deducted from the critical damping ratio of the model from the equivalent modal damping ratio.

$$C(\tau) = a_I \exp(-h_{eqI}\omega_I\tau)\cos(\omega_I\tau + \varphi_I) + a_{II} \exp(-h_{eqII}\omega_{II}\tau)\cos(\omega_{II}\tau + \varphi_{II}) \quad (9)$$

where h_{eq} is equivalent critical damping ratio; and a and φ are constants.

Figure 8 shows aerodynamic damping ratio.

For the 1st mode for wind direction 135°, aerodynamic damping ratios are negative at non-dimensional wind speeds more than 17. The aerodynamic damping ratio derived from Equation 10 is also shown in Figure 8(a) where A_F was -5. Galloping can be estimated over non-dimensional wind speed 20 by quasi-steady theory.

$$h_a = \frac{\rho B |A_F| UL}{4M\omega_1} \quad (10)$$

For the 2nd mode for wind direction 95°, aerodynamic damping ratios are negative at non-dimensional wind speeds more than about 10 and the vibration is a coupled one. So, this vibration seems a flutter which is mainly controlled by aerodynamic forces subjected to the one side plate almost parallel to the wind direction. In this connection, the aerodynamic damping ratios for the 2nd mode were calculated from the result obtained from forced vibration tests for 2-dimensional rectangular cylinders[5].

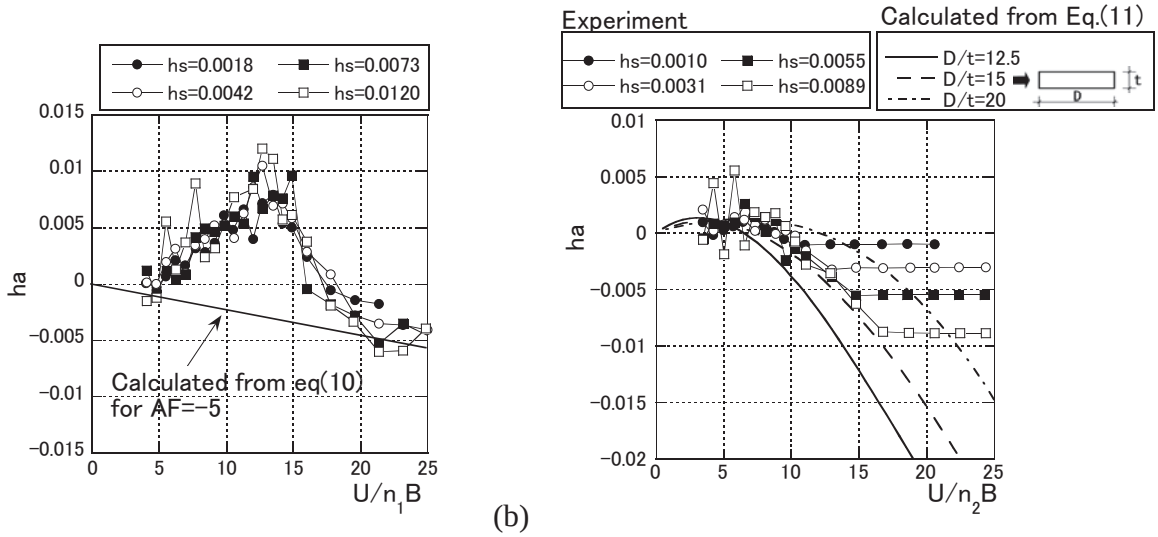

Figure 8. Estimated results of aerodynamic damping ratio (a) 1st mode vibration for wind direction 135°, (b) 2nd mode vibration for wind direction 95°

$$\begin{aligned} h_a &= -\frac{1}{16}\frac{\rho}{\rho_b}U^{*2}C_{FI} \\ &= -\frac{1}{16}\frac{\rho}{\rho_b}U^{*2}\left[C_{LCI}u_\zeta + C_{MCI}u_\theta\right] \\ &= -\frac{1}{16}\frac{\rho}{\rho_b}U^{*2}\left[(2H_1^*u_\zeta + H_2^*u_\theta)u_\zeta + (A_1^*u_\zeta + \frac{A_2^*}{2}u_\theta)u_\theta\right] \end{aligned} \quad (11)$$

where C_{FI} is out-of-phase component of unsteady aerodynamic force coefficient (motion-induced force coefficient); C_{LCI} and C_{MCI} are unsteady lift force coefficient and unsteady torsional moment coefficient during coupled vibration, respectively; H_1^*, H_2^*, A_1^* and A_2^* are aerodynamic derivatives[5]; $U^*=U/\omega_2 b$; $b=D/2$; and D is depth of rectangular cylinder.

Figure 8(b) shows the aerodynamic damping ratio obtained from vibration tests and the result derived from Equation 11. The test result is in good agreement with the values obtained from Equation 11 where the ratio of width to thickness of a plate is 15. The ratio of width to thickness(t:see Figure 1) of one side plate of the angle model is 14.4. Therefore, it seems that the vibrations are due to the same factor as that causing plate flutter.

5 CONCLUSIONS

This study investigated the characteristics of wind forces and wind-induced vibrations on L-130x130x9 angle member usually used as members for large towers, through wind force tests and vibration tests in a wind tunnel.

(1) In the 1st mode vibration, the self-excited vortex vibration occurs at non-dimensional wind speed 7 for wind direction 175°. For wind direction 135°, galloping occurs in the case of low critical damping ratios at non-dimensional wind speed over 15.
(2) In the 2nd mode vibration, the self-excited vortex vibration occurs at non-dimensional wind speed 7 for wind direction 85°. For wind direction 95°, flutter occurs for more than non-dimensional wind speed 10 without regard to critical damping ratio values.

ABSTRACT: For low Mach number flow around a bluff body, the far-field sound pressure is mainly dominated by dipole sources. The dipole sources are induced by the unsteady surface pressure distributions due to the presence of a turbulent boundary layer in the vicinity of the solid body. The far-field sound pressure can be calculated by integrating the time derivative of the wall-pressure fluctuations at the surface of the rigid body. Recent development in computational fluid dynamics (CFD) brings a powerful tool for predicting unsteady turbulent flow fields and the generation mechanism of aerodynamic noise. The present study investigates the use of an improved CFD method to accurately simulate the flow fields near a solid body. In particular, a large eddy simulation technique is adopted to predict the unsteady surface pressure fluctuation. The influences of various subgrid-scale models and near-wall treatments are investigated. The information of the flow field is then used to calculate the far field sound pressures. Extensive computations have been conducted to calculate the noise induced by the flow over a circular cylinder and an automobile's rear view mirror. The calculated sound pressure levels have been shown to agree well with published experimental results.

KEYWORDS: Low Mach Number Flow, Dipole, CFD, Aerodynamic Noise, Subgrid-scale model, Near-wall Treatment.

1 INTRODUCTION

For low Mach number flow around a solid body, the far-field sound pressure is dominated by dipole sources and quadrupole components play little role in the total sound field [1][2]. The dipole sources are created by unsteady surface pressure distributions due to the presence of a turbulent boundary layer in the vicinity of the solid body. The far-field sound pressure can be calculated by integrating the time derivative of wall-pressure fluctuations at the surface of the rigid body [3][4]. Recent developments in the field of computational fluid dynamics (CFD) have provided a powerful tool for predicting unsteady turbulent flow fields and the generation mechanism of aerodynamic noise. The direct numerical simulation (DNS) approach [5] solves the Navier–Stokes equation "exactly" in the temporal-spatial domain (resolving to the smallest scale). To avoid the extremely high computational cost associated with DNS, temporal development of averaged field parameters can be assessed using unsteady Reynolds-averaged Navier–Stokes (U-RANS) equations. Appropriate turbulence closure models are then required to close these equations. Different turbulence closure models, ranging from simple algebraic models to more complicated ones involving multiple equations [6], are applied to simulate flow-induced aerodynamic noise [7]-[9].

An alternate approach is to apply the large eddy simulation (LES) methodology [10] where large energy-containing scales of the flow fields are computed numerically and flow parameters

in unresolved subgrid scales are modeled by a subgrid-scale (SGS) model. Among the various proposed SGS schemes[10]-[12], the most popular model is the eddy-viscosity type developed by Smagorinsky [13], where the model constant can either have a static value or be determined dynamically (see detailed discussion in section 2). LES generally provides better accuracy than U-RANS for flows that feature unsteady components and large-scale eddies. When LES is used to simulate a flow field for analyzing flow-induced noise, it is very important to select an appropriate SGS model. This is because mid-to-high frequency noise is generated by turbulent structures of a very fine resolution at the subgrid scale, and the energy contained in the SGS eddies may be comparable to the acoustic energy.

The performance of SGS models can usually be appraised by a priori or a posteriori tests, as suggested by Piomelli et al. [14]. The validity of static and dynamic Smagorinsky-type SGS models for LES simulations has been well established using either numerical simulations or experimental results on homogenous isotropic turbulence [10][12]. LES simulations show that the dynamic Smagorinsky model gives better prediction results as compared to the static Smagorinsky model for predicting aerodynamic noise generated by an automobile's rear-view mirror [15]. However, a priori tests on SGS models of a homogenous but less complicated, time-evolving, anisotropic, turbulent flow field show that the dynamic Smagorinsky model, as well as several other advanced SGS models, do not always yield numerical results that are better than those predicted by the static Smagorinsky model [16]. It is therefore important to examine the performance of a number of SGS models and establish guidelines for their use in studying flow-induced noise at low Mach numbers.

The current study is also motivated by the need to reduce the cabin noise level in automobiles operating at cruising speeds. The aerodynamic noise inside the cabin increases considerably with the vehicle's speed. This type of flow-induced noise has broadband spectral content ranging from tens of Hertz at low frequencies to a few hundreds or thousands of Hertz at mid-to-high frequencies. This is attributed to time-varying flow separations and the breaking of large vortical structures into fine turbulent structures. The low frequency noise is generated by periodic convection of large-scale vortices over the open cavities where an unsteady shear flow exists, e.g., buffeting noise due to an open sunroof or window. The high frequency noise is induced by the shedding of unsteady vortices due to the interaction between body details, e.g., the flow interaction between the outside rear-view mirror and the A-pillar. This type of aerodynamic noise is a major contributor to the total noise levels inside the passenger cabins of vehicles. It can cause passenger discomfort, and more importantly, it may lead to driver fatigue. Therefore, it is crucial for the success of automobile development to predict the aerodynamic noise at the design stage and control it within an acceptable level. In the past few years, some researchers have incorporated the boundary element formulation in Curle's analogy [17]–[19] to predict aerodynamic noise for a non-compact solid body interacting with flow at low Mach numbers. However, we adopt a different route by examining the accuracy of the flow fields to address the weakness of the traditional approach at high Helmholtz numbers. We note that the first requirement for predicting the sound fields accurately is to develop an effective and precise numerical scheme to simulate the unsteady flow fields.

This paper aims to assess the effectiveness of combinations of SGS models and near-wall treatments in predicting aerodynamic noise. We conduct LES simulations on 2D and 3D canonical problems. The simulations are configured in such a way that the results can be directly compared with well-documented acoustic measurements. This evaluation is expected to aid the selection of effective simulation tools at the design stage for predicting flow-induced noise. The paper is organized as follows. A brief review of LES is given in section 2. Following that, the simulation results of flow over a 2D cylinder and 3D generic side-view mirror model are discussed in sections 3 and 4; comparisons of the experimental data are also presented therein. Conclusions and future prospects are presented in the final section.

2 UNSTEADY FLOW SIMULATION BY LES FOR PREDICTING FLOW-INDUCED NOISE—A REVIEW

In LES, a filtering operation is applied initially to field variable $g(\mathbf{x},t)$ to obtain its resolved component $\tilde{g}(\mathbf{x},t)$ in the spatial domain$D$:

$$\tilde{g}(\mathbf{x},t)=\int_D g(\mathbf{x}-\mathbf{x}',t)G_\Delta(\mathbf{x}')\,d\mathbf{x}' \tag{1}$$

where $\mathbf{x}=(x_1,x_2,x_3)$ denotes the coordinates, t is time, and $G_\Delta(\mathbf{x})$ is the filtering kernel with a characteristic length scale Δ. The representative flow variable $g(\mathbf{x},t)$ can be either the flow velocity $u_i(\mathbf{x},t)$ or the instantaneous pressure$p(\mathbf{x},t)$. For low Mach number (incompressible) flow, $\tilde{u}_i(\mathbf{x},t)$ and $\tilde{p}(\mathbf{x},t)$ can be solved using the filtered incompressible Navier–Stokes equations [20]:

$$\begin{cases}\dfrac{\partial\tilde{u}_i}{\partial x_i}=0\\[2ex]\dfrac{\partial\tilde{u}_i}{\partial t}+\tilde{u}_j\dfrac{\partial\tilde{u}_i}{\partial x_j}=-\dfrac{1}{\rho}\dfrac{\partial\tilde{p}}{\partial x_i}+\nu\dfrac{\partial^2\tilde{u}_i}{\partial x_j\partial x_j}-\dfrac{1}{\rho}\dfrac{\partial\tau_{ij}}{\partial x_j}\end{cases} \tag{2}$$

where ρ is the fluid density and τ_{ij} is the subgrid-scale stress given by

$$\tau_{ij}\equiv\widetilde{u_iu_j}-\tilde{u}_i\tilde{u}_j, \tag{3}$$

and the subscripts *i*, *j* = 1, 2, 3 (free indexes of index notation) represent the respective components along the coordinate axes x_1,x_2, and x_3. Once the SGS stress given in equation (3) is modeled properly, e.g., using the resolved parameters $\tilde{u}_i(\mathbf{x},t)$ and $\tilde{p}(\mathbf{x},t)$, it can be solved using equation (2). Then, the instantaneous flow fields are approximated by their resolved counterparts, namely,

$$u_i\simeq\tilde{u}_i(\mathbf{x},t) \tag{4a}$$

and

$$p\simeq\tilde{p}(\mathbf{x},t) \tag{4b}$$

The predominant influence of the SGS stress on the resolved flow field parameters is reflected in the transport of kinetic energy from large resolved scales to the small unresolved subgrid scales [20],[21]. As a result, accurate modeling of the SGS stress is crucial for the success of LES in predicting the flow fields. Among the various SGS models that have been proposed [10]-[12], the most popular model is the eddy-viscosity type wherein the deviatoric part of the SGS stress is given by

$$\tau_{ij}-\frac{1}{3}\tau_{kk}\delta_{ij}=-2\nu_r\tilde{S}_{ij} \tag{5a}$$

where, δ_{ij} is the Kronecker delta function, ν_r is the subgrid-scale eddy viscosity, and the resolved strain is given by

$$\tilde{S}_{ij}=\tfrac{1}{2}(\partial\tilde{u}_i/\partial x_j+\partial\tilde{u}_j/\partial x_i) \tag{5b}$$

where the repeated subscript *k* in the tensor represents the sum of the respective components from 1 to 3 (summation index of index notation).

The Smagorinsky model [13] is typically used for this class of approximations for the SGS stress, in which the eddy viscosity is

$$\nu_r=\left(C_S\Delta\right)^2\tilde{S} \tag{6a}$$

where C_S is the Smagorinsky coefficient, and the magnitude of the resolved strain, $\tilde{S}$, is calculated as

$$\tilde{S}=\sqrt{2\tilde{S}_{ij}\tilde{S}_{ij}} \tag{6b}$$

In the traditional (static) Smagorinsky–Lilly model, C_S usually takes a static value of 0.16 in

many practical situations simulated using scale invariant models [22]. However, the value of this Smagorinsky coefficient is questionable in highly complex flow problems [12]. A dynamic approach is proposed to determine the local value of C_S by applying a second filtering operation at a scale of $\alpha\Delta$ where α is usually taken as 2 [23],[24]. This approach is referred to as the (standard) dynamic Smagorinsky model. Other approaches to model C_S and τ_{ij} have been proposed [10] - [12]. Some of these advanced models have been incorporated into commercial CFD programs. Users may choose a specific SGS model to simulate different flow problems.

Once the unsteady flow field is determined from LES, the Ffowcs Williams–Hawkings (FW-H) acoustic analogy [25] can be applied to compute the far-field sound pressure for flow over the rigid body, where the dipole term is dominant over the monopole and quadrupole terms. Then, the FW-H equation can be simplified as follows [26]:

$$p'(\mathbf{x},t)=\frac{1}{4\pi c_0}\int_S \frac{(x_i-y_i)n_i}{r^2}\frac{\partial p(\mathbf{y},\tau)}{\partial t}dS(\mathbf{y})+\frac{1}{4\pi}\int_S \frac{(x_i-y_i)n_i p(\mathbf{y},\tau)}{r^3}dS(\mathbf{y}) \tag{7}$$

where c_0 is the speed of sound in air, τ is the emission time ($\tau = t - r/c_0$), r is the distance between the source and the receiver, and $\mathbf{y}$ is the source on the surface of the rigid body S.

An accurate prediction of surface pressures in an unsteady flow field is crucial for the successful prediction of the far-field aerodynamic noise [15]. Flow fields in the viscous near-wall regime must be treated properly because of the distribution of dipole-type sources located on rigid surfaces. The presence of small but dynamically important eddies in the near-wall region demands that LES meets a number of challenging requirements. The computational grid must be sufficiently fine to resolve at least 80% of the energy-containing flow eddies. In addition, grid cells of high aspect ratio in the near-wall regime should be avoided [27]. Estimation suggests that an extremely fine grid is needed to accurately predict the surface pressure fluctuation, and the number of required grid points is proportional to the second power of the flow Reynolds number, which is comparable to the grid requirement in DNS [28]. It is evident that LES becomes increasingly impractical for fully resolving the near-wall regime in high Reynolds number flows.

To extend the applicability of LES at high Reynolds number flows, the dynamic effects of a semi-viscous near-wall layer can be estimated by means of a simple model that leads to an approximate boundary condition for LES at the outer regions; thus, the need to construct very fine grid points near the wall surface is avoided [29]-[31]. Among the various options proposed, the "wall-function" (WF) method uses an assumed instantaneous velocity profile between the nodes closest to the wall and the wall surface. A commonly used velocity profile is the Werner–Wengle wall function [32], which assumes a 1/7th power law outside the viscous sublayer interfaced with the linear profile within the viscous sublayer,

$$u^+(y^+)=\begin{cases} y^+ & \text{if} \quad y^+ < 11.8 \\ 8.3(y^+)^{1/7} & \text{if} \quad y^+ > 11.8 \end{cases} \tag{8a}$$

Here, $u^+ = u/u_\tau$, and u is the resolved velocity tangential to the wall at the nearest point. The non-dimensionalized distance y^+ measured from the wall is given by

$$y^+ = u_\tau y/v \tag{8b}$$

where u_τ is the friction velocity, y is the normal distance measured from the cell centers, and v is the kinematic viscosity of the fluid. The tangential velocity can be related to the wall shear stress by integrating the velocity profile given in equation (8a) over the distance between the first cell and the wall surface. A detached eddy simulation (DES), which matches U-RANS simulation for the near-wall layer and is equivalent to LES in the outer region, is also frequently used. The LES-WF combination and the DES method have been used to study unsteady separated flows in channels and over cylinders at high Reynolds numbers [29]-[31],[33].

3 FLOW OVER CIRCULAR CYLINDER

Flow over a 2D circular cylinder is a canonical problem for studying the unsteady effect of flow over a solid body and the induced aerodynamic noise. We simulate air flow with a free stream velocity $U_0 = 69.2$ m s^{-1} over a cylinder with diameter $D = 19$ mm; Reynolds number $Re = U_0 D / \nu \approx 90{,}000$. These parameters are set such that they are identical to the values in the experimental study conducted by Revell et al. [34]. The computational domain extends from $-8.5D$ (upstream) to $+20.5D$ (downstream) with the origin set at the center of the cylinder. As suggested by Kim [35],[36], the distance between the top and the bottom of the computational domain is $21.0D$. An O-mesh topology is applied around the cylinder for better quality mapping of computational results. Thus, a fine mesh of 94,651 quadrilateral cells are employed, with a total of 360 mesh nodes in the circumferential direction and 80 mesh nodes in the radial direction. Numerical accuracy is checked by having a finer mesh consisting of 162,543 quadrilateral cells and a coarser grid consisting of 47,449 quadrilateral cells. Surface pressure and skin friction coefficient of the circular cylinder on different computational grids are compared in figure 1 and figure 2. As shown in figure 1 and 2, the fine and finer grid results are in good agreement, proving that the resolution is sufficient for an LES [47]. An additional comparison of the results between different meshes is presented in Table 1, where drag coefficients are compared. The difference in drag coefficient between fine and finer grids is approximately 0.4%. Thus, fine computational grid is used for the entire analysis.

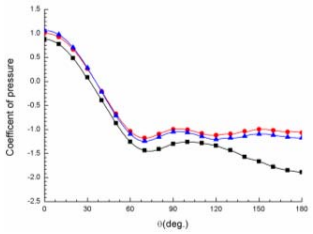

Figure 1. Distribution of average coefficient of pressure C_p over surface of circular cylinder ($\theta = 0^\circ$ is leading edge and $\theta = 180^\circ$ is trailing edge). Square: coarse grids; Triangle: fine grids; Circle: finer grids.

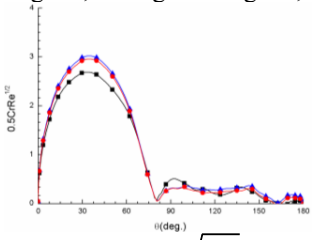

Figure 2. Distribution of scaled skin-friction coefficient $Cr\sqrt{Re}\ /\ 2$ (where $Cr{=}2\tau_w / (\rho U_0^2)$ and τ_ω is local wall shear stress) over circular cylinder. Square: coarse grids; Triangle: fine grids; Circle: finer grids.

	Number of cells	LES SLM+WF $\overline{C}_d$
Coarse	47,449	0.82
Fine	94,651	1.26
Finer	162,543	1.265

Table 1. Comparisons of drag coefficient on different computational grids.

In this set of numerical simulations, the boundary conditions are (i) no-slip and no-penetration conditions on the cylinder surface, (ii) a uniform free stream velocity with no perturbations at the inlet boundary, (iii) a constant free stream pressure on the outlet boundary, and (iv) free-slip conditions on the upper and lower boundaries of the computational grids. To predict the sound pressure, an implicit pressure-based finite volume method is used to solve the incompressible Navier–Stokes equations (equation 2) on the unstructured grids. The numerical solver in Fluent

CFD software is used for the present study. The discretized transport equations are advanced in time using the non-iterative time-advancement (NITA) algorithm. In addition, the fractional-step method (FSM) is chosen so that the momentum equations are decoupled from the continuity equation. To avoid numerical diffusion, the convection terms in all transport equations are discretized using bounded central-differencing schemes (BCD). Thus, this methodology preserves the non-dissipative properties of the fluid flow and avoids possible unbounded solutions and non-physical oscillations caused by other central-differencing schemes. Furthermore, the diffusion terms are discretized using a central-differencing scheme of second-order accuracy. The unsteady pressure is interpolated using PRESTO (PREssure STaggering Option), available in Fluent.

In LES the timescale of the smallest resolved eddies determines the time step needed. According to Kim and Mohan [35], the smallest resolved eddy, ℓ, should be set approximately at $\ell = 0.05D$ and the corresponding characteristic velocity, u', at $0.2U_0$. A non-dimensional time step, $U_0 \Delta t / D = 0.0036$ (Δt~1×10^{-6} s), is used to ensure that the maximum local Courant-Friedriches-Lewy (CFL) number does not exceed 1.5 in most grid points of the computational domain. Although using this time resolution to predict sound pressure is a second-order approach, it has been demonstrated that the numerical solutions are as accurate as those directly computed by a sixth-order compressible flow solver in the frequency range in which the numerical method accurately resolves the flow structures [15].

To obtain converged results, it is essential that the CFL criterion is met. In fact, the CFL number reflects the portion of a cell that a fluid traverses by advection in one time step. The Courant number should preferably be chosen to be less than 1.5 in order to reduce oscillations and numerical dispersion and improve accuracy. In general, each cell in the computations has a different CFL number. A summary of statistical data used in our numerical simulations shows that over 95% of cells have CFL numbers that are less than 1.5.

In the present study, we investigate the importance of simulation methods in efficiently and accurately predicting the aerodynamic noise in low Mach number flows. In particular, a variety of SGS models are used in LES and DES to obtain the time histories of flow fields over a circular cylinder. Predictions from the following models are compared: (i) Smagorinsky–Lilly model (SLM, equation (6) with $C_S = 0.16$), (ii) wall-function equation (8) along with Smagorinsky–Lilly model (SLM+WF), (iii) dynamic kinetic energy subgrid-scale model (DKESM), (iv) wall-adapting local eddy-viscosity model (WALEM), (v) renormalization group model (RNGM) [37], (vi) dynamic Smagorinsky–Lilly model (DSLM) [37], and (vii) DES with Spalart-Allmaras RANS model and Smagorinsky–Lilly model [37].

The prediction results are evaluated by comparing them with the experimental data obtained by Cantwell and Coles [38]. As shown in figure 3, the pressure coefficients predicted by DKESM, WALEM, and RNGM are less than the measured data in most angular positions. On the other hand, DSLM performs better than DKESM, WALEM, and RNGM. DSLM underpredicts as compared to the experimental data when $\theta < 120^\circ$ but overpredicts when $\theta > 120^\circ$. DES predictions are generally less accurate than those of LES when θ is small, but DES yields improved results near the trailing edge when $\theta > 110^\circ$.

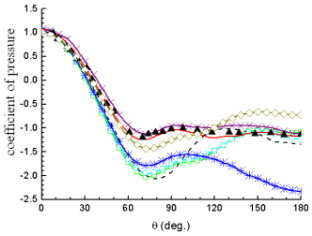

Figure 3. Distribution of average coefficient of pressure C_p over surface of circular cylinder ($\theta = 0^\circ$ is leading edge and $\theta = 180^\circ$ is trailing edge). Solid triangle: experimental data [Ref. 38]; solid line: SLM+WF; cross: SLM; square: DKESM; circle: WALEM; asterisk: RNGM; diamond: DSLM; dashed line: DES.

The remaining two models, SLM and SLM+WF, both give excellent predictions C_p, although the predictions of SLM+WF are marginally better than those of SLM. However, it is interesting to note that SLM alone does not yield better predictions for the coefficient of mean skin friction (figure 4). Thus, SLM+WF out of all the methods tested is the best numerical model for accurately predicting the coefficient of skin friction. Both DKESM and WALEM agree closely with the experimental data. The prediction of RNGM is of the same order of accuracy as that of SLM. DSLM performs marginally better than RNGM and SLM and generally underpredicts the coefficient of mean skin friction at the leading edge.

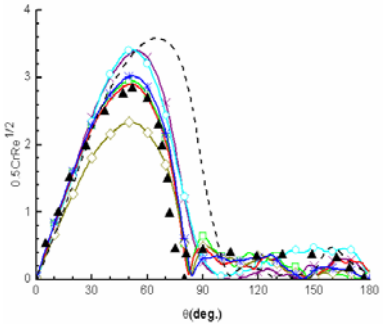

Figure 4. Distribution of scaled skin-friction coefficient over circular cylinder. Solid triangle: experimental data [Ref. 39]; solid line: SLM+WF; cross: SLM; square: DKESM; circle: WALEM; asterisk: RNGM; diamond: DSLM; dashed line: DES.

The Strouhal number ($St = fD/U_0$) for the shedding frequency of vortices, mean and r.m.s. drag coefficients ($\overline{C}_d$ and $\sqrt{C_d^2}$), lift coefficients ($\sqrt{C_l^2}$), and angle of flow separation (θ_s) are also used as benchmark parameters for evaluating the quality of the CFD results. The predicted values of these parameters are listed in table 2 for comparison with the experimental data. Except for the r.m.s. drag coefficient, the SLM+WF model agrees better with the measured data. All other models give comparable results for these parameters. The predictions according to LES with different subgrid models are consistently better than the DES predictions in all parameters except the Strouhal number. However, the computational cost for LES is generally higher than that for DES.

		St	$\overline{C}_d$	$\sqrt{\overline{C_d^2}}$	$\sqrt{\overline{C_l^2}}$	θ_s
Experimental Data		0.18-0.19 [Ref. 40]	1.0-1.4 [Ref. 38]	0.18 [Ref. 41]	0.45-0.60 [Ref. 40]	78° [Ref. 39]

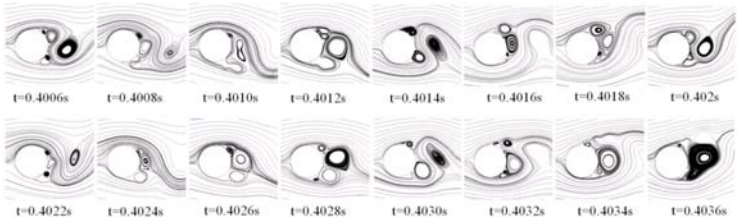
DES		0.205	0.8	0.21	0.35	99°

Table 2: Comparisons of simulation results with experimental data.

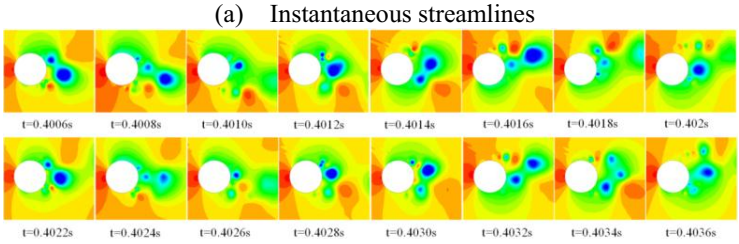
The comparisons indicate that SLM+WF shows better agreement between the predictions and the experimental data. The SLM differs from SLM+WF only in terms of the respective near-wall treatments. As shown in the computational results, the interaction between the flow and the solid surface greatly affects the accuracy of the numerical model. This result indicates the superior performance of the analytical integration of the power law in the velocity distribution for the near-wall treatment in dealing with separating flows.

Thus, in light of the comparisons described above, SLM+WF is suitable for performing LES to compute unsteady lift and drag forces on a circular cylinder as well as to predict the surface

pressure and mean drag and the point of flow separation on the cylinder's surface. Furthermore, by substituting pressure into equation (7), the flow-induced noise can be calculated for an observer located at the far field. Before we proceed, it is of interest to demonstrate the correlation between the flow fields and acoustic field by examining snapshots of flow fields. Figure 5(a) and (b) shows the instantaneous streamlines and pressure distribution in the vicinity of the circular cylinder, where a periodic flow pattern is identified. This repeated alternate shedding of vortices suggests that the frequency of the far-field sound pressure can be characterized by the Strouhal number of the flow (corresponding to a frequency of 625 Hz and period of 0.0016 s).



(a) Instantaneous streamlines



(b) Instantaneous static pressure

Figure 5. Predictions of instantaneous flow field from LES simulations (SLM+WF). (a) Instantaneous streamlines; (b) instantaneous static pressure.

To further support the above observation, time histories of the lift coefficient and the surface pressure at selected points on the cylinder's surface are analyzed (results not shown here for brevity). It is noted that the magnitudes of the lift force and surface pressures vary sinusoidally with a dominant period of approximately 0.0016 s, which is consistent with the change in flow patterns observed in figure 5. However, the phase angles of the surface pressures at different locations differ because the surface pressures change both spatially and temporally. In figure 6, we plot the power spectral density of the lift coefficient of the cylinder versus Strouhal number, and a distinct peak is observed at $St = 0.173$. Figure 7 shows spectra of relative surface pressure levels, L, at three azimuthal locations of 10°, 90°, and 160°, where L is defined as

$$L = 20 \log \; p / p_{ref} \tag{9}$$

with the reference pressure $p_{ref} = 2 \times 10^{-5}$ Pa. Figures 6 and 7 show the broadband characteristics of the lift force and surface pressure. These are largely due to the presence of a turbulence field in the flow around the cylinder.

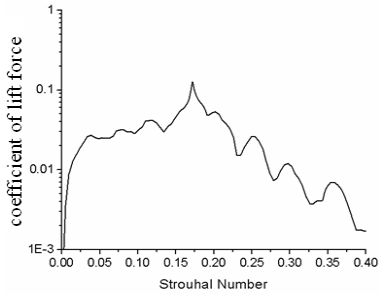


Figure 6. Lift coefficient of 2D cylinder versus Strouhal number.

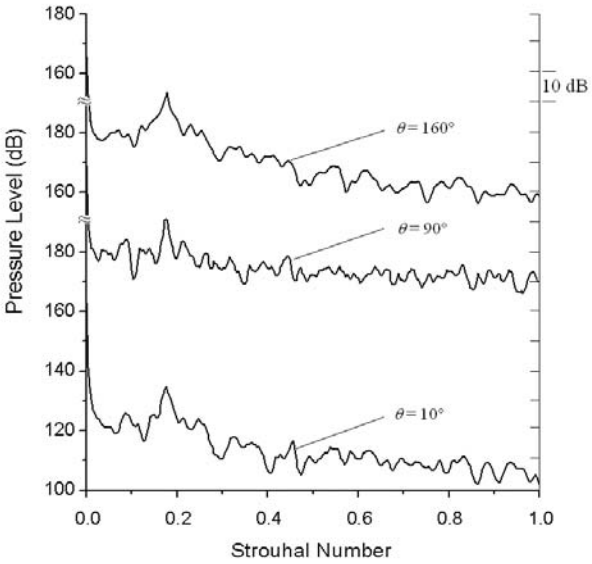

Figure 7. Spectra of relative surface pressure levels at three selected locations on surface of circular cylinder. Results are from LES predictions using SLM+WF.

Next, we compare the predictions of noise induced by this flow over a 2D circular cylinder with experimental results. The data is from Revell et al. [34], where a microphone is used to measure a sound field $128D$ away from the longitudinal axis at an angle $\theta = 90°$ in an acoustic wind tunnel. The tests are conducted at a Mach number of 0.2 ($U_0 \approx 69.2$ m s^{-1}) and Reynolds number of 89,000. The flow simulations and acoustics analysis are repeated under identical conditions. The numerical results are presented in terms of the overall sound pressure level (OASPL):

$$\mathrm{OASPL} = 10\log\left[\sum_i 10^{SPL_i/10}\right] \tag{10}$$

where SPL_i represents the far-field sound pressure level at the receiver location for the ith frequency band.

The relative sound pressure level SPL is represented by equation (9) where p is replaced with the far-field acoustic pressure in the time domain, which is computed via equation (7) using the time histories of the surface pressure predicted by CFD. The narrow-band acoustic pressures in the frequency domain can then be computed from the time-domain data by means of fast Fourier transform (FFT). Summing contributions from all frequency bands leads to the OASPL given in equation (9). Recall that the integration given in equation (7) is performed over a 3D surface. Hence, a further assumption is needed to compute the sound fields based on the 2D input data. To allow a reasonable comparison between numerical and experimental results, a source correction length (SCL) is introduced where the sound sources are assumed to be perfectly correlated within the SCL region but uncorrelated outside it. Based on the strategy employed by Cox et al. [42], the SCL region can be adjusted for evaluating its effect on the predicted OASPL. For a Reynolds number of 90,000, Norberg [40] suggests that the SCL can be set experimentally as $3.16D$. Here, according to the conclusion of Orselli et al. [8], the SCL of $5.0D$ provides the best agreement with the experimental results for 3D flow over a long cylinder of length $25.3D$. The OASPLs obtained from the LES using SLM+WF and DES are 101.9 dB and 102.09 dB, respectively, compared to the experimental data 100 dB obtained by Revell et al. [34]. This further supports the notion that, in order to predict flow-induced noise at a far-field location, accurate predictions of the near-field unsteady flow fields are essential.

4 FLOW OVER CIRCULAR CYLINDER

In the previous section, the 2D simulation results suggest that LES with SLM+WF agrees better with the experimental data. In this section, this approach is extended to a 3D model problem. In particular, we consider the noise induced by flow over a generic side-view mirror mounted on a flat plate. The flow has a free stream velocity U_1=39 m s^{-1} and a Reynolds number Re =5.2×10^5. As shown in figure 8, the generic side-view mirror consists of a half-cylinder of diameter D=0.2 m and height H=0.2 m. A quarter sphere is placed on top of a half-cylinder, making the total height $1.5D$. The mounting plate has a width of $8D$ and a length of $12D$. The side mirror is located centrally at $4.5D$ downstream of the plate's leading edge.

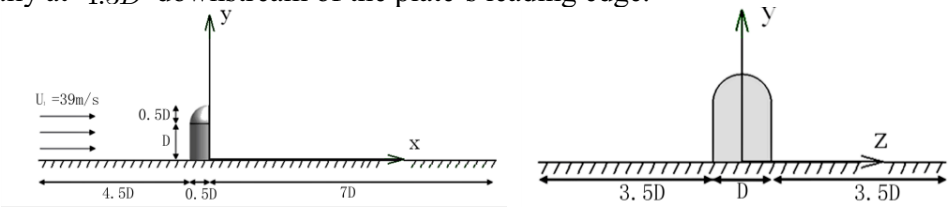

Figure 8. Geometry of generic side-view mirror.

The numerical solver is set similar to the 2D case described in section 2. The computational mesh is composed of a structured grid with a multi-block arrangement. A total of three different computational grids are created using ICEM-HEXA software [43]. The purposes of having three different computational grids (Coarse, Fine, and Finer) are to ensure that the results obtained are grid independent. There are 2.3million of nodes in the coarse computational domain, 5.2million of nodes in the fine computational domain and 7.2million of nodes in the finer computational domain. Figure 9 shows the surface pressure coefficient at different sensor position for coarse, fine and finer meshes. Fine and finer mesh produce similar results, meaning that the results obtained is converged and is grid independent. Thus, fine mesh is be used throughout the entire analysis. The height and circumferential direction of the cylinder surface in the fine grid computational domain are discretized by 100 nodes, and the first off-wall node is located 2×10^{-4} m away from the solid surface along the normal direction, n, of the local wall. A fine mesh is extended in the wake of the mirror for a distance of $10D$ as measured from the mirror's rear face. The mesh is progressively coarsened from the vicinity of the mirror to the domain boundary, where the mesh size is set from 0.01 m to 0.1 m.

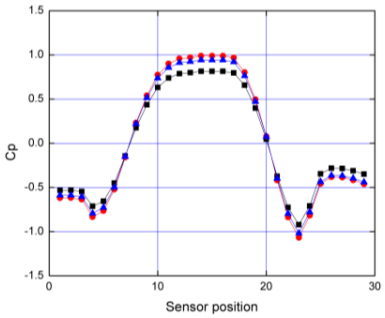

Figure 9. Comparison of time-mean pressure coefficient on three different computational grids. Square: coarse grids; Triangle: fine grids; Circle: finer grids.

The boundary conditions are as follows: (i) no-slip and no-penetration conditions on the generic mirror and the flat plate, (ii) a uniform free stream velocity with no perturbations at the inlet boundary, (iii) a constant free stream pressure at the outlet boundary, and (iv) free-slip conditions at the top and two lateral sides of the computational domain. The flow fields and fluctuating pressures are computed by SLM+WF. To improve numerical efficiency, a steady RANS approach is first employed to initialize the transient computations. The pressure time histories are then calculated and recorded after an initial transient period ($\sim 90D/U_1 = 0.46s$) with a time step

of 5×10^{-5} s for a period of 0.85 s, i.e., the recording time period is between $90D/U_1$ and $255D/U_1$. The time-domain pressures are then converted to frequency-domain pressures by standard FFT numerical routines. These results are then compared later with the published experimental data [44] and DES predictions [45].

For ease of comparison, figure 10 gives the locations of multiple pressure transducers for measuring surface pressures. The measured mean surface pressures (circles) from transducers 1 to 34 are presented in figure 11. The predictions of LES with SLM+WF and DES, also shown in figure 11, show reasonable agreement with the measurement results. The predicted mean pressure from LES and DES over the mirror front side (locations 10–25) shows good agreement with the measured results. Sensors at locations 1–9 and 30–34 are deployed downstream of the separation line where the flow has complex temporal-spatial characteristics, and thus, it is difficult to obtain ideal agreement with the experimental data. DES underpredicts the mean pressure at these locations, whereas LES (with SLM+WF) overpredicts. At locations 5 and 28 the underprediction from DES is more pronounced, which is attributed to a misrepresentation of the separation zone, as highlighted by Ask and Davidson [46]. LES with SLM+WF provides accurate predictions at these two locations.

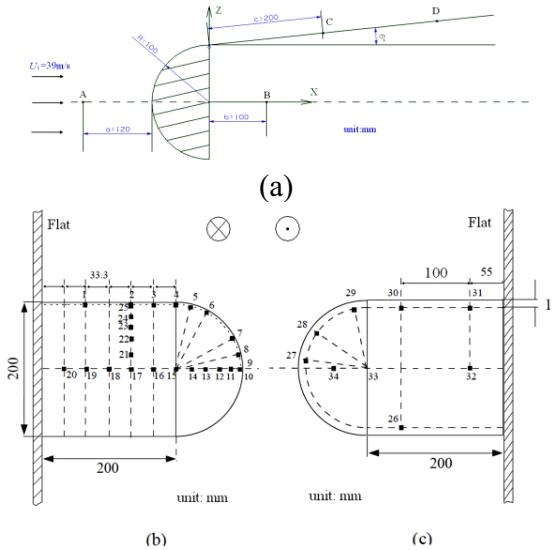

Figure 10. Locations of pressure measurements on plate surface (A, B, C, and D) and mirror surface (1–34) of generic side-view mirror model: (a) top, (b) front, and (c) rear view.

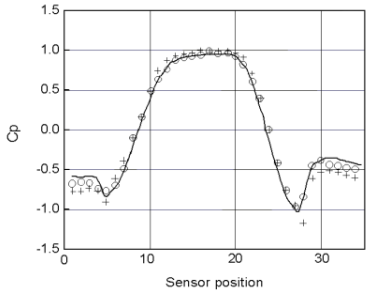

Figure 11. Comparison of predicted and measured time-mean pressure coefficient. Circle: experimental; solid line: LES + wall function; cross: DES.

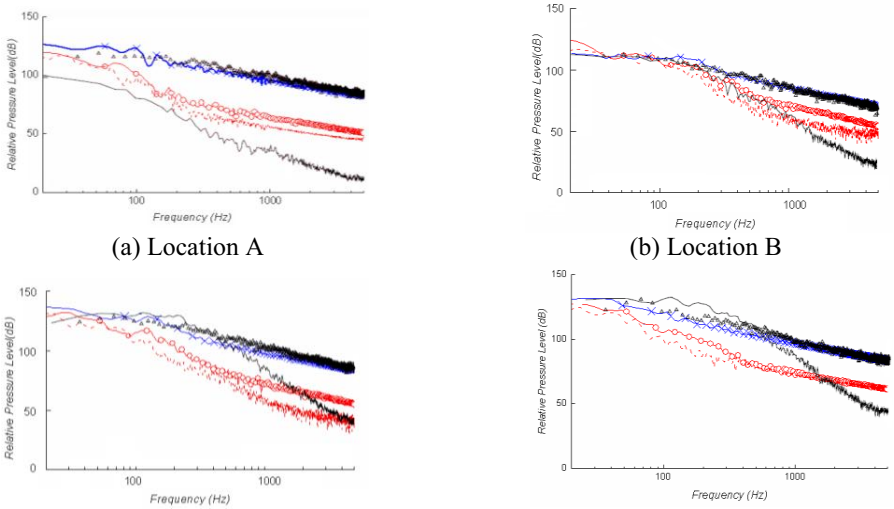
The breaking vortex behind the side mirror will induce air noise and may trigger vibration of the exterior structure. Thus, it is necessary to evaluate the capacity of a variety of simulation schemes to accurately predict surface pressure fluctuation. The simulation results are compared with the experimental data [43] and the numerical results from DES [45]. Again, the relative

pressure level, which is defined in equation (9), is used for the presentation of data. Figure 12 shows comparisons of experimental measurements with numerical predictions at four selected locations (A–D, figure 11). Predictions of the surface pressures according to SLM+WF agree well with the experimental data for all these locations. At the upstream location A, numerical predictions according to DES provide the worst results, with discrepancies in excess of 40 dB even at low frequencies. Numerical predictions according to SLM and DSLM are somewhat better than those of DES, but the errors are typically more than 25 dB at high frequencies.



(a) Location A (b) Location B

(c) Location C (d) Location D

Figure 12. Predicted and measured relative pressure levels [equation (9)] at various locations. Cross: SLM+WF; circle: SLM; solid line: DES; dashed line: DSLM; triangle: experimental [Ref. 44].

The propagation of sound is computed at four receiver locations, shown in figure 13. The far-field acoustic pressures at the same locations are measured by Rung et al. [45], and the comparison is shown in figure 14. It is evident that the LES with SLM+WF offers the best predictions at these four locations. DES significantly underpredicts SPL, particularly at high frequency range (>300 Hz), which may contribute to the underprediction of unsteady pressure level (thus dipole strength in equation (7)) at high frequency (figure 14). LES with DSLM overpredicts SPL at the same high frequency range, which further demonstrates the inadequacy of the dynamic Smagorinsky SGS model in simulating unsteady surface pressure fluctuation.

5 CONCLUSIONS

In this study, the implications of various SGS models and near-wall treatment schemes used in LES of low Mach number flows are investigated for the accurate prediction of unsteady flow fields and far-field acoustic fields. The unsteady LES predicts surface pressure fluctuations, which gives a distribution of the dominant dipole source. The far-field acoustic fields are assessed using the FW-H analogy. Benchmark studies are conducted on flow over a 2D cylinder and a generic side-view mirror model. Numerical predictions of various schemes are compared with the measured surface pressure and far-field acoustic data. It is identified that LES combined with the Smagorinsky–Lilly SGS model ($C_S = 0.16$) and the Werner–Wengle wall function provides the best predictions in a wide frequency range (10–1000 Hz). On the other hand, the DES approach (a combination of RANS in the near-wall regime and LES in the outer regime) considerably underpredicts the unsteady surface pressure and acoustic field at high frequencies (>300 Hz). Advanced SGS models such as the dynamic Smagorinsky model show no superiority over the other models in predicting surface pressure fluctuations. These results aid the selection of appropriate CFD techniques for accurately simulating low Mach number flows. The technique identified in the present study is currently being applied to investigate the aerodynamic noise of automobiles operating at cruising speeds, including low frequency buffeting noise due to flow over open cavities and high frequency noise associated with the breaking of large-scale vortical structures.

ABSTRACT: In this paper a novel approach for bridge deck flutter assessment is introduced. The classical forced oscillation technique was updated by using advanced three-dimensional CFD simulation instead of 2D sectional studies. The whole bridge deck wall boundary was given a forced oscillation in airflow according to the relevant rotational and bending modes. The advanced CFD modeling required the development of the modal derivatives that can be used to calculate the critical wind speed as by using the classical flutter derivatives. An aeroelastic wind tunnel model was constructed, specially dedicated to the validation of the numerical solution. Good agreement between the measured and simulated results was found. After the validation the technique was applied on a footbridge with a main span of 120m.

KEYWORDS: Three-dimensional study, CFD, modal derivatives, bridge flutter

1 INTRODUCTION

In classical flutter prediction of bridges the flutter derivatives theory is applied mainly. These derivatives are calculated by considering a section of the bridge deck. Nowadays, however, really complex bridges are built in geometry, therefore their simplification into a section is not easy to make in some cases. Therefore, the authors of this paper have invested a lot into the application of three-dimensional flutter simulation [2], in which a fluid-structure interaction (FSI) simulation of a three-dimensional bridge deck was studied. Such work can mainly be found for aircraft wings [1]. As a thee-dimensional FSI simulation requires tremendous amount of computational time, a new approach was developed for flutter study of complex structures. In this approach the three-dimensional flow field around the oscillating bridge deck can be taken into account and the niceties of the forced vibration method can be kept too. The forced oscillation of the 3D bridge deck leads to new derivatives that will be referred to as modal derivatives later.

2 DEVELOPMENT OF THE MODAL DERIVATIVES

In this chapter the development of the modal flutter derivatives will be presented. First of all a full aeroelastic wind tunnel model is shown as a validation for the novel method. A three-dimensional CFD model and the necessary parameters of the simulation will be shown that are necessary for calculating the modal derivatives. The formulation of these modal derivatives as well as their application in the critical wind speed evaluation will be finally presented.

2.1 *Full aeroelastic wind tunnel model*

In Figure 1 the fully aeroelastic wind tunnel model is shown that was constructed in order to validate the numerical solutions. This model is an individual mechanical system for validation

only and is not a scaled model of any real bridge structure. The bridge is made up by using an aluminum core beam on which balsa elements are fixed. The cross section can be seen in Figure 2. The contour of the model represents an idealized streamlined boxed bridge deck cross section. This section was chosen because it was believed to be handled properly with simpler turbulence models and coarse CFD mesh. The core beam is fully constrained at both ends. There are six steel wires working like stay cables. These wires were softened by introducing spring elements (stiffness is 230N/m) in order to make the bridge more flexible. The model can be seen in Figure 3. The elastic modulus of the aluminum is 2.06E10 N/m², the density is 2500kg/m³. The density of the balsa coating is 123kg/m³.

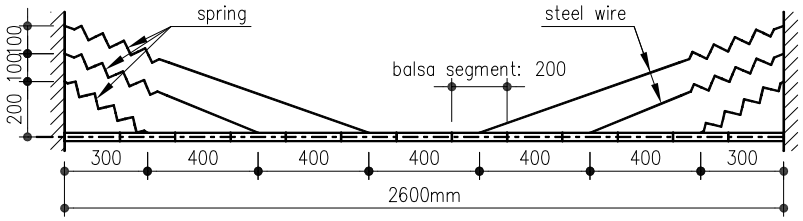

Figure 1. Side view of the aeroelastic wind tunnel model.

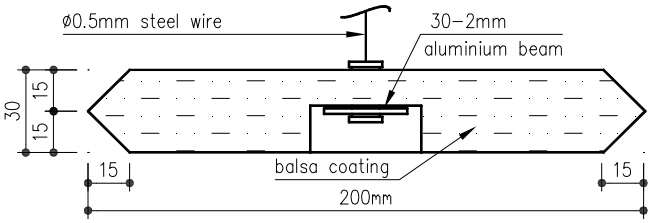

Figure 2. Cross section of the aeroelastic model.

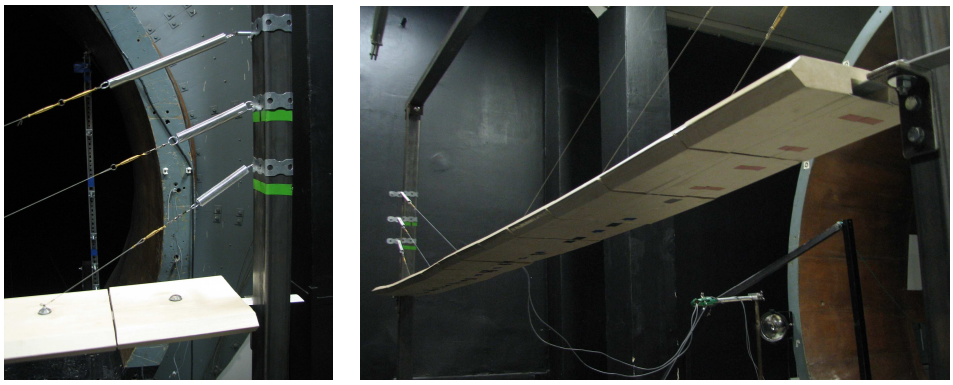

Figure 3. Bridge model mounted in the wind tunnel.

At the middle balsa element of the bridge, at both sides of the segment two piezoelectric accelerometers were fixed for monitoring the vertical motion. For the wind-off case the natural frequencies and logarithmic decrement values were measured. The first vibration mode was a symmetrical heave motion of the bridge deck with a natural frequency of 1.62Hz. For the flutter analysis the first torsion mode is dominant, which was the fifth one with a natural frequency of 5.55Hz. The logarithmic decrement for this mode was δ=0.02. These parameters were used for tuning the mechanical FEM model. During the measurement the wind speed was incrementally increased. The high frequency vibrations caused by the vortex shedding were ignored and the flutter phenomenon was only considered. The tests were done under low turbulence level. The critical wind speed was 9.7m/s with a coupled flutter motion.

2.2 *Three-dimensional CFD model*

The aerodynamic characteristics of the bridge deck were modeled by using CFD. The mesh and the domain is show in Figure 4. The ANSYS-CFX was utilized. The computational mesh was carefully optimized in order to save computational time and maintain the accuracy of the results. The number of cells used is 49.816, where the in-plane cell number is 958 and there are 52 divisions along the bridge axis.

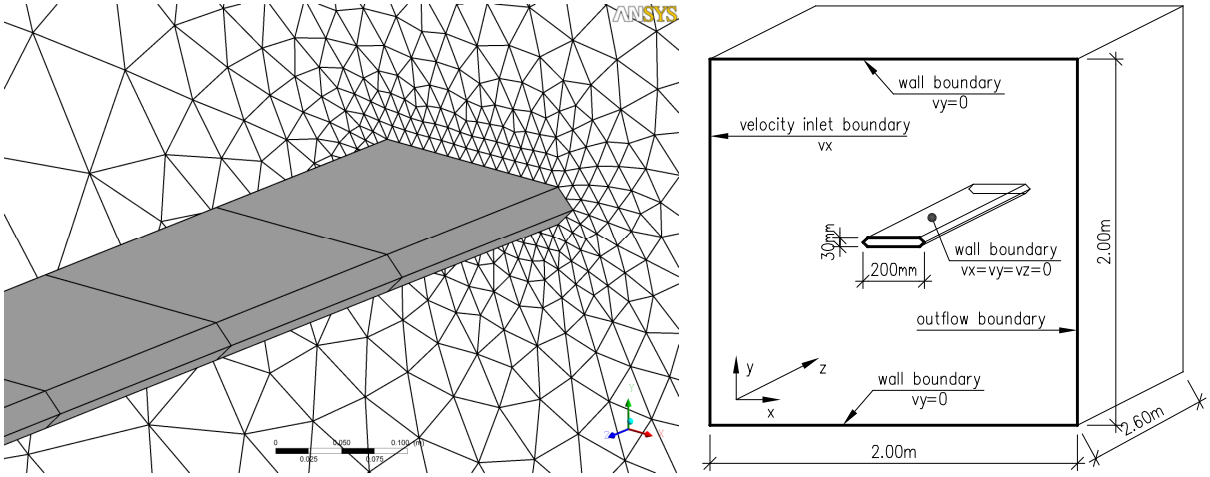

Figure 4. CFD mesh around the aeroelastic bridge model with the boundary conditions.

The novel approach requires the arbitrary motion of the bridge deck that is feasible by using user defined functions. Every cell node position of the bridge boundary can be defined as a function of time, therefore any kind of three-dimensional shape can be defined. In Figure 5 a rotated bridge shape in illustrated. The mesh deformation is solved by the software by using spring stiffness analogy. The initial (no deformed) mesh quality can be preserved by defining increased spring stiffness in the vicinity of the bridge boundary. In case of a section model the forced oscillation is performed with translational and rotational degrees of freedoms. In case of a 3D boundary, however, the relevant heave and torsion mode shapes are used that will be shown later. As usual, a reduced inflow velocity range (4, 8, 12, 16 and 20) is considered. The oscillating frequency was 6.00 Hz in each case. The time step was chosen as 0.0008 s. In Figure 6 the flutter derivatives are shown. The flutter derivatives were determined with an ordinary 2D section model with 12590 cells that is not shown here. The derivatives were also determined using the result of the 3D mesh; the lift force and moment signals of the middle section along the bridge axis were considered where the motion amplitudes reach their maximal values.

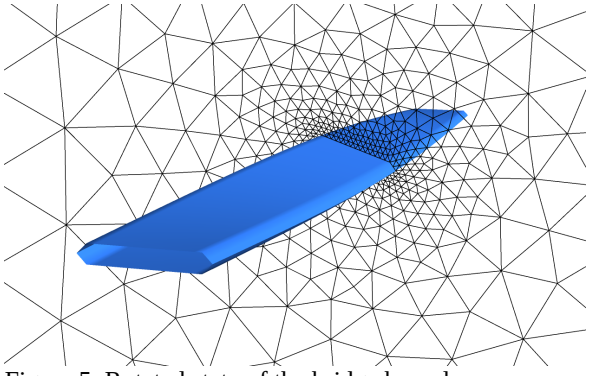

Figure 5. Rotated state of the bridge boundary.

In Figure 6 the flutter derivatives belonging to the 2D and 3D meshes can be seen. Although the 3D mesh is much coarser than the 2D one, it succeeds to provide accurate flutter derivatives. Therefore, the 3D mesh is considered to be appropriate for the novel technique. As a streamlined cross section is investigated the derivatives of the flat plate theory are also illustrated.

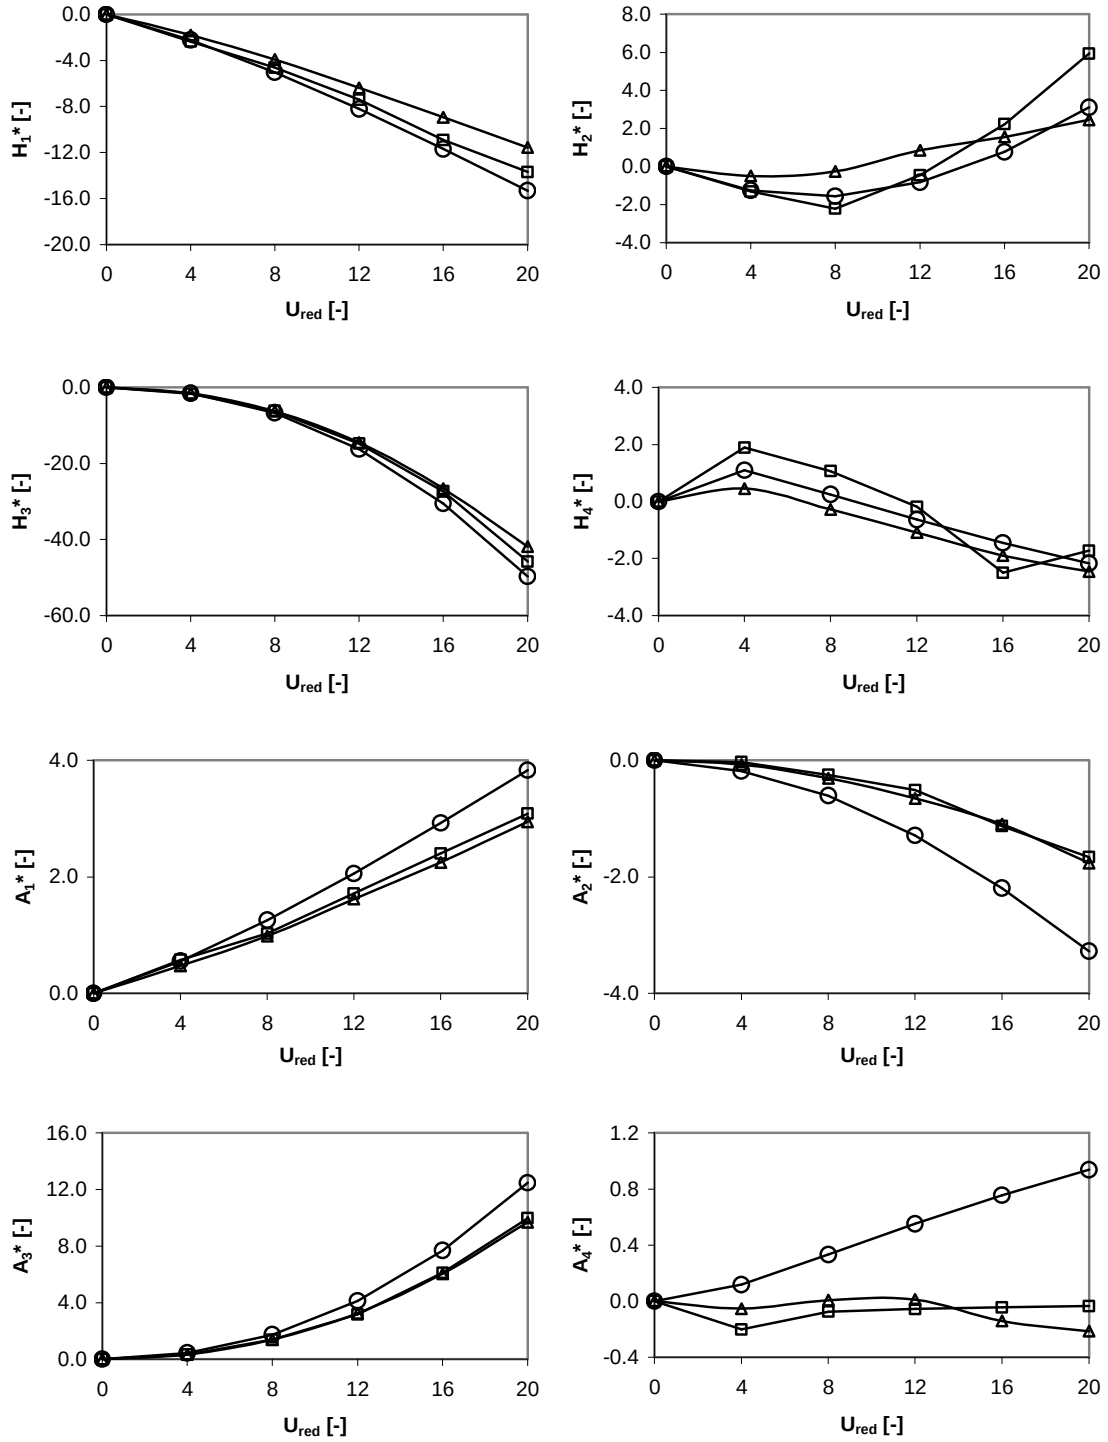

Figure 6. Flutter derivatives of the bridge (Circle: Flat plate theory, Rectangle: CFD_2D, Triangle: CFD_3D).

2.3 *Mathematical background of flutter prediction*

In classical flutter prediction the following eigenproblem is to be solved (1). In case of a 2DOF system the problem can be solved according to [3]. If the system is considered as a system with a series of segments (see Figure 7), the (1) solution can be extended.

$$\left|(1+\mathrm{i}\gamma)\mathbf{K}-\omega^2\left[\mathbf{M}+\mathbf{L}(U_{red})\right]\right|=0 \tag{1}$$

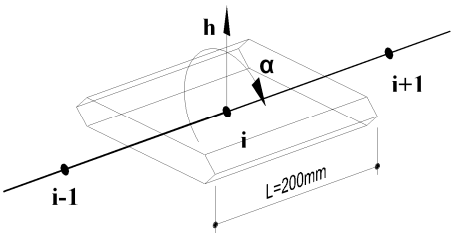

Figure 7. A 200mm long segment of the aeroelastic bridge model.

The aeroelastic wind tunnel model can be regarded as a system with 13 nodes, as 13 balsa segments are attached to the main beam. The load matrix in (1) can be rewritten in (2).

$$\mathbf{L}=\pi\rho b^2\begin{bmatrix} c_{hh} & bc_{h\alpha} & & & & & & n=1 \\ bc_{\alpha h} & b^2c_{\alpha\alpha} & & & & & & n=1 \\ & & \ddots & & & & & \vdots \\ & & & \ddots & & & & \vdots \\ & & & & c_{hh} & bc_{h\alpha} & & n=13 \\ & & & & bc_{\alpha h} & b^2c_{\alpha\alpha} & & n=13 \end{bmatrix} \tag{2}$$

In (2) the aeroelastic bridge is considered as a bridge deck with 13 nodes, with a lift force and a moment at each node. Therefore the size of the **L** matrix is 26x26 in this case. By seeking the solution in the form (3) according to the modal analysis, and using expressions in (4), the (5) eigenproblem is to be solved now.

$$\tilde{\mathbf{x}}=\mathbf{V}\tilde{\mathbf{y}} \tag{3}$$

$$\mathbf{V}^{\mathrm{T}}\mathbf{L}\mathbf{V}=\mathbf{A},\quad \mathbf{V}^{\mathrm{T}}\mathbf{M}\mathbf{V}=\mathbf{E},\quad \mathbf{V}^{\mathrm{T}}\mathbf{K}\mathbf{V}=\left\langle\omega_{0r}^2\right\rangle \tag{4}$$

$$\left|(1+\mathrm{i}\gamma)\left\langle\omega_{0r}^2\right\rangle-\omega^2\left[\mathbf{E}+\mathbf{A}(U_{red})\right]\right|=0 \tag{5}$$

In (5) **V** contains two column vectors belonging to the chosen mode shapes. In (4) **E** is the unity matrix, ω_{0r} is the r_{th} natural circular frequency of the bridge structure. The solution process of the (5) system is the same as in case of a 2DOF system. On top of all, the size of the (5) equation in case of two mode shapes is also the same as that of the 2DOF system. In [3] similar approach can be found for involving the bridge deck as a three-dimensional spatial system. It can be seen that if the flutter derivatives as functions are known for a certain bridge shape, the critical wind speed can be calculated for the bridge structure. This can be done by reducing the bridge into a 2DOF system or by using the mode shapes and natural frequencies in the framework of the modal analysis. The main shortcoming of the above described method is that the three-dimensional flow field is reduced into a set of two-dimensional flows that is the flow parallel

with the bridge axis is neglected. On top of all if the cross section is not constant along the bridge axis for instance, the flutter derivatives have to be determined at several cross sections, resulting in a tedious calculation process.

2.4 *Formulation of the modal derivatives*

In this section the advantages of the flutter derivatives theory and the three-dimensional CFD modelling are combined in order to develop a novel technique. The flutter condition is assumed to show harmonic motion; therefore the analysis is obvious to carry out in the frequency domain as in case of the classical flutter calculation. In (5) matrix **A** can be compiled easily, as **L** and **V** matrices are known for a certain fixed U_{red} value. In order to replace the two-dimensional CFD simulations with the advanced three-dimensional simulation, the **A** matrix should be examined in detail; after multiplying the **L** matrix by **V** matrix, **A** reads (6).

$$\mathbf{A} = \pi\rho b^2 \begin{bmatrix} \sum_i v_{hi}^2 \cdot c_{hh} & b \cdot \sum_i v_{hi} \cdot v_{\alpha i} \cdot c_{h\alpha} \\ b \cdot \sum_i v_{hi} \cdot v_{\alpha i} \cdot c_{\alpha h} & b^2 \cdot \sum_i v_{\alpha i}^2 \cdot c_{\alpha\alpha} \end{bmatrix} \tag{6}$$

The elements of the **A** matrix are terms c_{ii} multiplied by the elements of the mode shape vectors. The main goal is to compile the **A** matrix based on the result of the three-dimensional CFD simulation instead of the 2D ones. As mentioned earlier the ANSYS-CFX enables the user to define arbitrary motion of the bridge deck. The 3D CFD model was tested and the flutter derivatives were extracted by defining translational and rotational spatial deformation of the bridge boundary (see Figure 6). The ways of prescribing this motion is explained here in detail. Obviously the first translational and rotational mode shapes were used, as these contribute to the flutter motion.

In Figure 8 the two relevant mode shapes are shown with the corresponding natural frequencies. The calculation of the mode shapes and frequencies were done by using FEM model of the aeroelastic wind tunnel model.

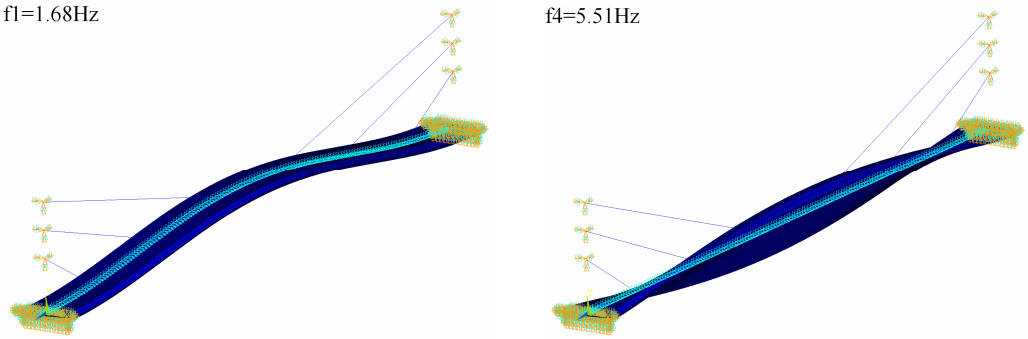

Figure 8. The two relevant dynamic mode shapes.

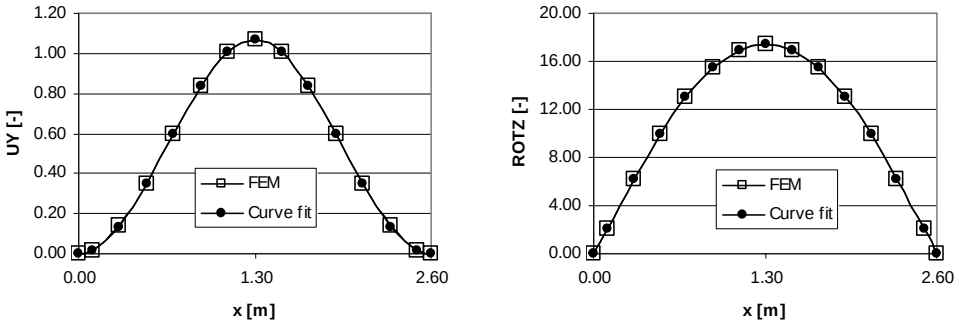

Figure 9. Heave (UY) and torsion (ROTZ) mode shape values used for the calculation.

It is necessary that the bridge boundary is given a predefined motion as a function of time and space. In Figure 9 the discrete mode shape values of the FEM model are fitted by analytical functions. The motion in time is written by using harmonic function. The translational function of the bridge deck is written in (7), where the vertical position of every point (h) is defined at location (z) and at time (t). Likewise the rotation can be written (8), from which vertical and horizontal components can be derived. The maximal translational amplitude at the middle of the deck is h_0=20mm, the maximal rotational amplitude is α_0=0.1744 (10°).

$$h(z,t) = \left[1 - \cos(z\,2\,\pi/L))\right] \cdot h_0 / 2 \cdot \sin(\omega\, t) \tag{7}$$

$$\alpha(z,t) = \left[\sin(z\,\pi/L))\right] \cdot \alpha_0 / 2 \cdot \sin(\omega\, t) \tag{8}$$

When the three-dimensional bridge deck is oscillated according to the certain mode shapes, the aerodynamic forces belonging to the i_{th} node (see Figure 7) can be calculated. There are 13 moment and 13 lift force signals at each simulation case. In Figure 10 the moment functions are shown (U_{red}=8) at i=1,4 and 7 sections.

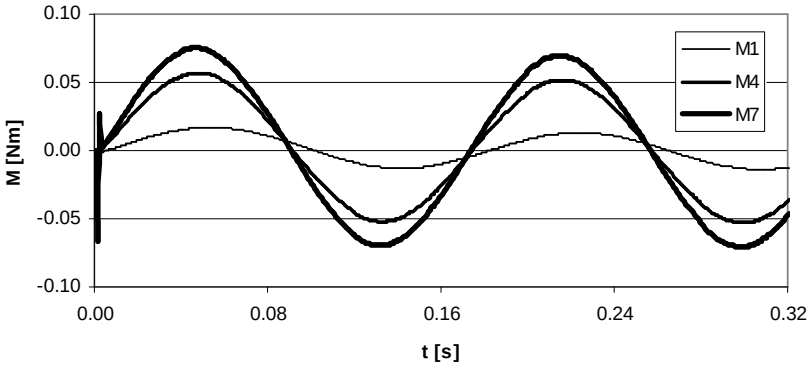

Figure 10. Moment signals at deck element 1, 4 and 7 (U_{red}=8).

Based on the aerodynamic forces and moments in relation with the modal oscillation, (6) equation can be rewritten as (9). The over hat denotes that the $\hat{\mathbf{A}}$ matrix is written by using the mode shape vectors.

$$\hat{\mathbf{A}} = \pi\rho b^2 \cdot \begin{bmatrix} \hat{c}_{hh} & b \cdot \hat{c}_{h\alpha} \\ b \cdot \hat{c}_{\alpha h} & b^2 \cdot \hat{c}_{\alpha\alpha} \end{bmatrix} \tag{9}$$

The elements of matrix $\hat{\mathbf{A}}$ can be compiled analogously as shown in [3], but instead of using the flutter derivatives of a 2D section of the bridge new terms are to be used. In (8) these new flutter derivatives are introduced, that are extracted based on the results of the modal oscillation of the 3D CFD model, therefore can be called as modal (flutter) derivatives. As the 3D bridge is oscillated according to the selected mode shape vectors, the resulting force and moment signals at each i_{th} element of the bridge deck can be assumed to be proportional to the mode shape values at the same locations. Thus, the force and moment signals are to be multiplied by the mode shape values only at once, contrary to the case of the **A** matrix in (6). The summation in (6), thus, can be substituted by summing up the forces and moments multiplied by the relevant mode shape values at the i_{th} location.

$$\hat{H}_1^* = -U_{red}^2 \cdot \frac{\max\left[\sum_i v_{hi} \cdot F_{hi}(t)\right]}{q \cdot B \cdot (2\pi)^2 \cdot (h_0/\hat{h})/B} \sin(\beta) \qquad \hat{H}_2^* = -U_{red}^2 \cdot \frac{\max\left[\sum_i v_{hi} \cdot F_{\alpha i}(t)\right]}{q \cdot B \cdot (2\pi)^2 \cdot (\alpha_0/\hat{\alpha})} \sin(\beta)$$

$$\hat{H}_3^* = U_{red}^2 \cdot \frac{\max\left[\sum_i v_{hi} \cdot F_{\alpha i}(t)\right]}{q \cdot B \cdot (2\pi)^2 \cdot (\alpha_0/\hat{\alpha})} \cos(\beta) \qquad \hat{H}_4^* = U_{red}^2 \cdot \frac{\max\left[\sum_i v_{hi} \cdot F_{hi}(t)\right]}{q \cdot B \cdot (2\pi)^2 \cdot (h_0/\hat{h})/B} \cos(\beta)$$

$$\hat{A}_1^* = -U_{red}^2 \cdot \frac{\max\left[\sum_i v_{\alpha i} \cdot M_{hi}(t)\right]}{q \cdot B^2 \cdot (2\pi)^2 \cdot (h_0/\hat{h})/B} \sin(\beta) \qquad \hat{A}_2^* = -U_{red}^2 \cdot \frac{\max\left[\sum_i v_{\alpha i} \cdot M_{\alpha i}(t)\right]}{q \cdot B^2 \cdot (2\pi)^2 \cdot (\alpha_0/\hat{\alpha})} \sin(\beta)$$

$$\hat{A}_3^* = U_{red}^2 \cdot \frac{\max\left[\sum_i v_{\alpha i} \cdot M_{\alpha i}(t)\right]}{q \cdot B^2 \cdot (2\pi)^2 \cdot (\alpha_0/\hat{\alpha})} \cos(\beta) \qquad \hat{A}_4^* = U_{red}^2 \cdot \frac{\max\left[\sum_i v_{\alpha i} \cdot M_{hi}(t)\right]}{q \cdot B^2 \cdot (2\pi)^2 \cdot (h_0/\hat{h})/B} \cos(\beta) \qquad (8)$$

Finally, the maximum values of these functions are taken, as in case of the extraction of the classical flutter derivatives. If necessary, the summed force and moment functions can be filtered in order to remove the high frequency components that are irrelevant in flutter analysis. In (8) $\hat{h}$ and $\hat{\alpha}$ are the maximum values of the mode shape vectors (Figure 8 and 9), respectively, β is the phase shift between the force or moment functions and the translational or rotational oscillations, $q = 0.5\rho U^2$ is the dynamic pressure, where U is the flow speed, ρ is the air density. In Figure 11 the logarithmic decrement of damping can be seen by using the classical and the novel methods. The flutter speed is 8.7m/s with the classical method, and 9.2m/s using the novel one.

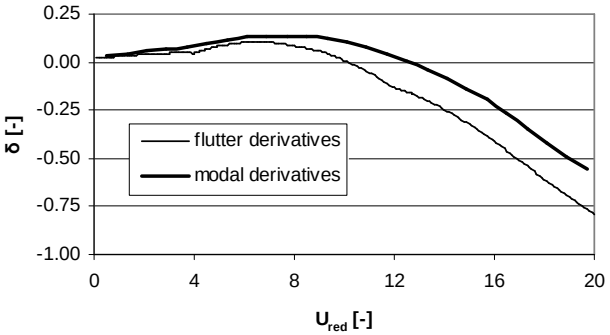

Figure 11. Logarithmic decrement damping versus reduced wind speed.

3 APPLICATION OF THE MODAL DERIVATIVES

3.1 *Introduction of the investigated footbridge*

The previously introduced modal derivatives method is applied on a footbridge with a main span of 120m, which was completed in 2011 at Szolnok city, Hungary. The bridge structure is shown in Figure 12. The stiffening girder is a truss structure with two upper and one bigger lower chord. The stiffening girder is supported by two steel arches that are tilted outwards. The modeling process is completely the same as in case of the previously detailed case study. The FEM model provided the natural frequencies and the mode shape vectors. The heave frequency is 1.67Hz, the rotational is 2.02Hz.

Figure 12. Picture of the investigated bridge structure and the two relevant mode shapes.

The CFD mesh can be seen in Figure 13. The CFD modelling required simplification of the stiffening girder. The spatial trusses were substituted with an equivalent longitudinal object, enabling the CFD mesh be simply extruded. The vertical elements of the handrails were also replaced with longitudinal elements. The cell number was limited to 775300. The in-plane cell number is 38765 and there are 20 divisions along the bridge axis.

In accordance with the modal derivatives method, the forced vibration method was used according to the two relevant mode shapes. The reduced velocity range was 4-20 with a step of 4. The oscillation frequency was 2.00 Hz in each case. The inflow velocity was varied from 4.80 up to 24.00. The reference width was 0.60 m. The rotational oscillation shape with the streamlines at U_{red}=8 can be seen in Figure 14. The heave mode shape is also asymmetrical as the rotational one.

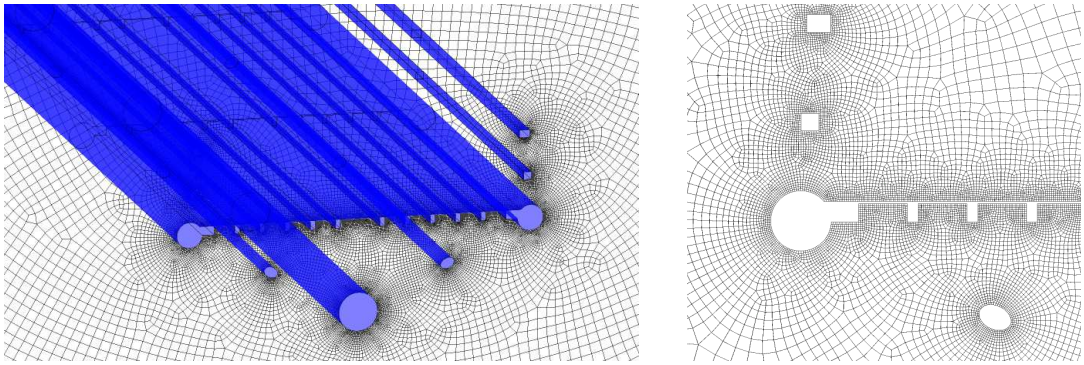

Figure 13. CFD mesh of the bridge structure.

The critical wind velocity was determined by using the classical approach according to expressions (2) and (5) giving a critical wind speed of 146m/s. The novel approach provided a value of 171m/s, which is higher by 17 percent than the classical one.

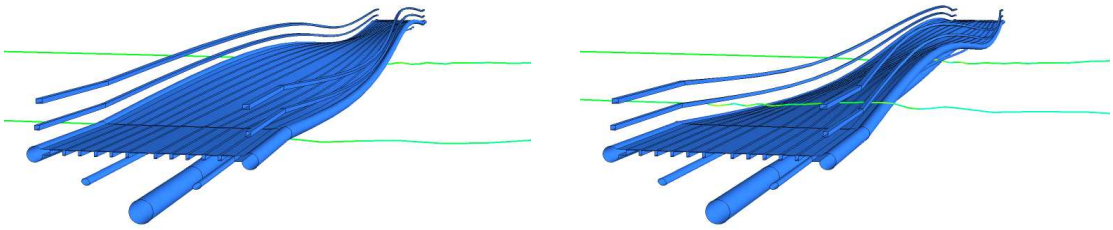

Figure 14. Streamlines around the rotated bridge deck (U_{red}=8).

4 CONCLUSIONS

In this paper a novel technique for flutter prediction of bridge decks has been shown. The method is strongly based on the ANSYS-CFX CFD code, in which arbitrary three-dimensional motion can be defined as a function of time. The 3D bridge deck is considered as a series of segments, on which the lift force and moment signals can be collected. These time functions were properly multiplied by the corresponding elements of the dynamic mode shape vectors and summed up, giving the modal derivatives. The modal derivatives can be used in the framework of the classical procedure of the critical wind speed. The modal derivatives were tested in a case study; a full aeroelastic wind tunnel model was considered. The critical wind speed by using the modal derivatives (9.2 m/s) was closer to the measured one (9.7 m/s) than by using the classical method (8.7 m/s). The method was also tested on a completed pedestrian bridge. The critical wind speed by using the modal derivatives was higher than that of the classical method, as in case of the case study. To conclude, the modal derivatives approach can be a tool in bridge flutter study of structures with complex geometry. In our future work the effects of turbulence will be taken into consideration.

ABSTRACT: Previous researches found that the moment method is on the unsafe side for structural reliability evaluation compared with the result using Monte Carlo (MC) method for low failure probability events such as flutter instability. In this paper a quadratically asympototic integral method based on the direct calculation of probability density was proposed in probabilistic evaluation of four parameters of flutter failure mode which was compared with MC method. The fourteen domestic long-span bridges were utilized to validate the proposed algorithm. The results showed that the flutter failure probability based on the proposed method is more reliable and safer than that based on MC method. Of course, this method proposed here involves the calculation about the first-order and second-order derivatives of logarithm of probability density function (PDF) for random variables so that it is not fit in those situations such as unknown PDF of random variables or very complex derivatives.

1 INTRODUCTION

Probability and statistics design method is more reasonable than empirical coefficient design method used in the estimation of flutter failure probability for long-span bridges. Since most of these parameters involved in the prediction are physically uncertain variables and/or subjectively assumed values because of a lack of complete knowledge, it would make more sense to carry out a probabilistic reliability analysis to determine a probability of the bridge flutter failure. Over the years various reliability theories have been proposed for the study of failure probabilities of complex systems, since in many cases an exact numerical calculation is not possible. The first paper, in which approximate methods were proposed, is Freudenthal (A.N. Freudenthal, 1956). The basic idea in this article is to approximate the probability content of a failure region by linearizing the boundary of the region at a point, where the "local" failure probability is maximal. This method is described there only for normal and lognormal random variables, but in principle it is applicable for arbitrary distributions with continuous probability densities.

Hasofer and Lind (A.M. Hasofer and N.C. Lind, 1974) proposed for the case of standardized independent random variables a so-called reliability index β for the failure domains. This index β is the distance of the failure domain to the origin and is not an extimate for the failure probability. But, in consequence of that paper, many papers were published, where approximations for the failure probability were derived by linearizing the failure boundary at the points with minimal distance to the origin, giving $\Phi(-\beta)$ as approximation in the case of normal random variables. Later, also quadratic approximations for the boundary were proposed (B. Fiessler, H.J. Neumann and R. Rackwitz, 1979). All these methods were based on heuristic arguments and no clear mathematical justification was given.

When these approximation methods can not provide ideal probability density distribution, the failure probability of structure can be calculationed by directly integral of PDF of random variables in failure margin. Then Breitung (K. Breitung, 1984) showed with methods of asymptotic analysis that for certain methods a mathematical basis can be found. He proved that the asymptotic relative error of quadratic approximations converges to zero, i.e. these approximations are asymptotically exact and the problem of convergence would not be easy to occur.
In the present paper, a reliability analysis model is formulated by considering four random variables, which are mutually indepent, and the safety margin which is also a random variable and depends only on the stochastic nature of these variables. Though the probability of failure from the safety margin may be efficiently determined by some approximate reliability methods or by applying simulation techniques such as the MC method, the quadratically asympototic integral method is applied here and extensively explained through some sample calculations of 14 long-span bridges in China compared with MC method.

2 FLUTTER FAILURE EVALUATION METHODS

2.1 *Limit state function of flutter failure*

For the sake of comparing and analysising, a flutter reliability model established by Prof. Ge Yaojun was utilized in this study. The corresponding limit state function is represented by the critical flutter speed U_{cr} minus the extreme wind speed U_c (Y.J. Ge, H.F. Xiang, H. Tanaka, 2000)

$$f(U_{cr}, U_c) = U_{cr} - U_c \tag{1}$$

the probability model of the critical flutter speed U_{cr} and the extreme wind speed U_c can be expressed respectively as

$$U_{cr} = C_w U_f \tag{2}$$

$$U_c = G_s U_b \tag{3}$$

where U_f = basic flutter speed which is experimentally determined with some uncertainties of the structural properties; C_w = wind conversion factor from a scaled model to the prototype structure; U_b = basic wind speed at the bridge deck location; and G_s = gust speed factor for taking account of the influence of wind gust speed and its horizontal correlation.
Substituting Eqs.(2) and (3) into Eq.(1), the safety margin Z is now defined as a function which denpends on the stochastic nature of a basic variable vector $X = (C_w, U_f, G_s, U_b)$ as

$$Z = f(X) = C_w U_f - G_s U_b \tag{4}$$

where the above four random variables may be described as normal distribution, log-normal distribution, log-distribution and Gumbel distribution respectively. Since f is a non-linear function and the random variables are not all distributed normally, the failure probability can not be gained directly by using PDF of normal distribution. So many algorithms are applied such as a first-order reliability method (FORM) and a second-order reliability method(SORM) etc. Here the probability was calculated by applying both quadratically asympototic integral method and MC method.

2.2 *The MC method*

A procedure based on th MC method was implemented to allow for the direct numerical estimation of the probability without first-order reliability approximation. Standard algorithms for MC statistical analysis were considered (C. Bucher, 2009). A standard MC procedure was employed and a large sample of computer generated events (1×10^6) was used to estimate probabilities.
A fatal deficiency existing in the MC method is the enormous simulation number when the failure probability of structure is less than 1×10^{-3}. Therefore, the MC method is usually used to validate those proposed methods.

2.3 *The quadratically asympototic integral method*

The general procedure of quadratically asympototic integral method can be resolved into three parts. Firstly, it considers direct integral of probability density function (PDF) in failure region so that non-convergence of calculation can rarely happen. Secondly, it considers direct integral nearby most probable point of structural failure mainly contributes to the evaluation of failure probability. Finally, its direct integral is in fact an asympototic integral by Taylor series quadratical development for logarithm of PDF of random variables and performance function. The derived quadratic hypersurface is applied in approximating practical failure surface. And then the integral is finished by use of the definition of first-order and second-moment and second-order and second-moment methods.
A likelihood function h(x) of PDF is defined by

$$h(x)=ln(f(x)) \tag{5}$$

The performance function of structure is defined as $Z = g_X(X)$ and the random variables $X = (X_1, X_2, \cdots, X_n)^T$'s joint PDF is defined as $f_X(x)$, then the probability of failure by flutter can be written in the form (K. Breitung, 1984,1989)

$$p_f = \int_{g_X(x)\le 0} f_X(x)dx = \int_{g_X(x)\le 0} \exp[\ln f_X(x)]dx = \int_{g_X(x)\le 0} \exp[h(x)]dx \tag{6}$$

h(x) is expanded into Taylor series at x^*, which is a poin on limit state surface and taken to the quadratic term as

$$\begin{aligned} h(x) &\approx h(x^*) + (x-x^*)^T \nabla h(x^*) + \frac{1}{2}(x-x^*)^T \nabla^2 h(x^*)(x-x^*) \\ &= h(x^*) + \frac{1}{2}\nu^T B\nu - \frac{1}{2}(x-x^*-B\nu)^T B^{-1}(x-x^*-B\nu) \end{aligned} \tag{7}$$

where

$$\nu = \nabla h(x^*) \tag{8}$$

$$B = -[\nabla^2 h(x^*)]^{-1} \tag{9}$$

Substituting Eq. (7) into Eq. (6), the failure probability p_f is now given as

$$p_f \approx f_X(x^*)\exp\left(\frac{\nu^T B\nu}{2}\right) \times \int_{g_X(x)\le 0}\exp\left[-\frac{1}{2}\left(x-x^*-B\nu\right)^T B^{-1}\left(x-x^*-B\nu\right)\right]dx \tag{10}$$

Applying the Chokesky decomposition, the matrix B can be defined as $B=AA^T$ and then defining $X-x^*-B\nu=AY$, the failure probability p_f is now defined as

$$p_f \approx \sqrt{\det B}\, f_X(x^*)\exp\left(\frac{\nu^T B\nu}{2}\right)\int_{g_Y(y)\le 0}\exp\left(-\frac{y^T y}{2}\right)dy \tag{11}$$

Corresponding performance function Z at x^* can be defined as

$$\begin{aligned} Z_Q &= (AY+B\nu)^T\nabla g_X(x^*) \\ &\quad +\frac{1}{2}(AY+B\nu)^T\nabla^2 g_X(x^*)(AY+B\nu) \\ &= \left(Y+A^T\nu\right)^T A^T\nabla g_X(x^*) \\ &\quad +\frac{1}{2}\left(Y+A^T\nu\right)^T A^T\nabla^2 g_X(x^*)A\left(Y+A^T\nu\right) \end{aligned} \tag{12}$$

Let be unit vector

$$\alpha_X = -\frac{A^T\nabla g_X(x^*)}{\left\|A^T\nabla g_X(x^*)\right\|} = -\frac{A^T\nu}{\left\|A^T\nu\right\|} = -\frac{A^T\nu}{\beta_L} \tag{13}$$

By structuring an orthogonal matrix $H=[H_1,H_2,\cdots,H_{n-1},\alpha_X]$ using α_X, Y space is orthogonally transformed into U space in the form

$$Y=HU \tag{14}$$

Z_Q can be expressed as

$$\begin{aligned} Z_Q &= \left\|A^T\nabla g_X(x^*)\right\|\left(\beta_L-U_n-\frac{1}{2}\tilde{U}^T H^T QH\tilde{U}\right) \\ &\approx \left\|A^T\nabla g_X(x^*)\right\|\left[\beta_L-U_n-\frac{1}{2}V^T\left(H^T QH\right)_{n-1}V\right] \end{aligned} \tag{15}$$

where $\tilde{U}=(U_1,U_2,\cdots,U_n-\beta_L)^T=\left(V^T,U_n-\beta_L\right)^T$.

Substituting Eq. (14) into Eq. (11), the quadratic failure probability p_{fQ} is derived as

$$\begin{aligned} p_{fQ} &= \sqrt{\det B}\, f_X(x^*)\exp\left(\frac{\nu^T B\nu}{2}\right)\int_{g_U(u)\le 0}\exp\left(-\frac{u^T u}{2}\right)du \\ &= (2\pi)^{1/2}\sqrt{\det B}\, f_X(x^*)\exp\left(\frac{\nu^T B\nu}{2}\right)\int_{g_U(u)\le 0}\varphi_n(u)du \end{aligned} \tag{16}$$

Then, the quadratically asympototic integral failure probability applying directly the result of SORM in Gauss space is expressed as

$$p_{fQ} = \frac{p_{fL}}{\sqrt{\det\left[I - \beta_L \left(H^T Q H\right)_{n-1}\right]}} \tag{17}$$

where p_{fL} is first order asympototic integral failure probability (K.M. Breitung, 1994)

$$p_{fL} = (2\pi)^{n/2} \sqrt{\det B}\, f_X(x^*) \exp\left(\frac{v^T B v}{2}\right) \Phi(-\beta_L) \tag{18}$$

3 FLUTTER PROBABILITY FOR 14 LONG-SPAN BRIDGES

The results of the numerical simulations for 14 bridges are summarized in Table 1. In this table the flutter failure probability computed by both the quadratically asympototic integral method and MC method was compared. The minimum failure probabilities is less than 1×10^{-7} . Most result using the quadratically asympototic integral method is larger than that using MC method. That is the result using the quadratically asympototic integral method emphasis on safety compared with that using MC method.

Table 1. Flutter failure probability of 14 Long-span bridges using two methods

Serial number of bridges	Quadratically asympototic integral		MC		Relative error of failure probability
	Reliability index β	Failure probability Pf	Reliability index β	Failure probability Pf	%
1	3.05	1.16E-03	3.03	1.21E-03	-4.87

4 CONCLUSIONS

For very small probability case, a quadratically asympototic integral method has been presented for the consideration of flutter failure of long-span bridges compared with MC method. The proposed method gives asymptotic approximations for failure probabilities without using any transformation of the probability space and any cumulative distribution function of random variable. Some sample calculations using 14 long-span bridges were introduced to demonstrate its effectiveness. It was found that most of failure probabilities using the proposed method were generally larger than that using MC method. The approximation may emphasis on safety compared with that using MC method.

ABSTRACT: The effects of local vibrations of cables on flutter behaviors of cable-stayed bridges are investigated by using the 3D flutter analysis method. The cables are treated as multi-link model, instead of single link model, and therefore can show the lateral degrees of freedom along the cables. After simulating the structural damping, the flutter behaviors including local vibration effects of cables for an example bridges, Yangpu Bridge in China, are investigated based on the 3D flutter analysis method. The calculated results show that for the Yangpu cable-stayed bridge with a 602m main span, the flutter critical wind velocity can be increased by 20.2% with the consideration of local vibration effects of cables and the aerodynamic forces acting on cables. The mechanisms of the local vibration effects of cables are also discussed in this paper.

KEYWORDS: cable-stayed bridges; flutter analysis; single-link model; multi-link model; lateral vibrations of cables

1 INTRODUCTION

The aeroelastic interaction between the flowing air and the cables of the cable-stayed bridges must exist and will exhibit some influences on the flutter behaviors of the bridge structures. The aeroelastic effects of cables include the aerodynamic forces acting on cables, the local vibrations of cables, and their interaction. The aerodynamic forces on cables are generally neglected due to the belief of their insignificant effects. For a long-span cable-stayed bridge, the effects of cable local vibrations on flutter should be investigated because the dense cable system of a cable-stayed bridge can form one or more powerful wind-resisting cable planes. The local vibrations of these cables as tightly tensioned chords can significantly impact the bridge-and-wind interaction. This interaction can be taken into account by using the flutter analysis method with the cable model which can show the local vibration shapes of cables.

The three-dimensional (3D) flutter analysis of bridges is based on structural 3D finite element (FE) models and the action of self-excited aerodynamic forces (Ge, 2008) [1]. Many researchers have contributed to the bridge 3D flutter analysis. Xie and Xiang (1985) [2] proposed the state apace method. Agar (1989) [3] treated the flutter as a 2M-order eigenvalue problem. Chen (1994) [4] proposed a multi-mode search method based on the modal analysis method. Namini, et al (1992) [5] presented the pK-F method, to solve the flutter equations. Ge (2000) [6] proposed a full mode method to abstract the eigenvalues and eigenvectors without the need to select the participating modes. All these methods treated the cable as a single-link model and therefore cannot consider the local vibrations of cables.

Cheng (1999) [7] took the aeroelastic effects of cables into account by using a finite strip model (Lau, et al, 2000) [8] of the deck and the pK-F solving method. The lateral degrees of

freedom of cables are represented by sinusoidal generalized coordinates. However, since the modes representing the local vibration of cables are usually far away from the principal modes of bridges and cannot be selected by the pK-F method, the pK-F method cannot take into account of the effects of cable local vibrations very well.

If a method intends to take into account the cable lateral vibration effects, the method has to both include the degrees of freedom reflecting the cable local vibrating shapes and have the ability to abstract the modes of cable local vibrations as well as the bridge principal modes. Yang (2005, 2011)[9, 10], Hua (2007)[11] separately proposed a method to conduct the bridge 3D flutter analysis by using the commercial FE software (ANSYS)[12], which is based on the existing functions of the software. This method could model the cable as a multi-link model with consideration of the geometric stiffness to show the lateral degrees of freedom along the cable and therefore make it possible to take the lateral vibration effects of cables into account. By taking an actual cable-stayed bridge with a middle span length of 602m as an example, this paper focuses to calculate the effects of local vibrations of cables on flutter critical state by the 3D finite element method for the flutter analysis.

2 3D FLUTTER ANALYSIS OF CABLE-STAYED BRIDGE

An example bridge needs to be employed to illustrate the 3D flutter analysis of cable-stayed bridges (Yang 2005, 2011) [9, 10]. The Yangpu Bridge, opened to traffic in 1993, in Shanghai, China, has twin towers, twin cable planes and composite girders. The bridge spans over the Huangpu River by its main span of 602m. It was the longest span of cable-stayed bridges in the world when it was completed and opened to traffic. It has a span length pattern of 99+144+602+144+99 m. The cross section of the deck applies an open-style composite girder. It has two separate steel boxes of 2.67m deep and 1.5m wide each with a composite precast prestressed concrete deck slab of 0.26m deep. The overall width of the bridge deck is 32.5m. The FE model was established using the structural data used by Ding (2001, 2002) [13, 14]. The structural FE model is shown in Figure 1.

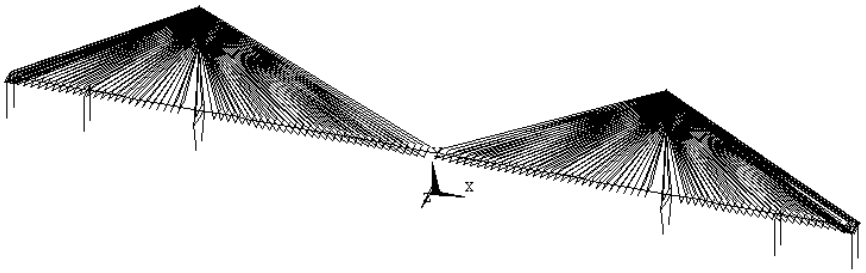

Figure 1. FE model of Yangpu Bridge with span pattern of (99+144+602+144+99) m

The mode damping ratio of the Yangpu cable-stayed bridge can be simulated by 1%. The two-parameter Rayleigh damping (Clough 1993) [15] can cover two main participative modes. After the damping is simulated, the structural natural modes with the designed damping can be obtained. Using the data of flutter derivatives of the Yangpu Bridge deck, as same as in Ding 2001, 2002 [13, 14], the flutter analysis can be carried out, in which each cable with the top end connecting to the tower and the bottom end to the girder, is simulated as a single link model. The calculated results without local vibration shapes of cables (single-link model) and without aerodynamic forces acting on cables are listed in Table 1. The flutter mode is initiated from the

structural inherit mode of the first symmetric torsion and companied with the second symmetric vertical deck bending. The mode shape of the flutter critical state is shown in Figure 2.

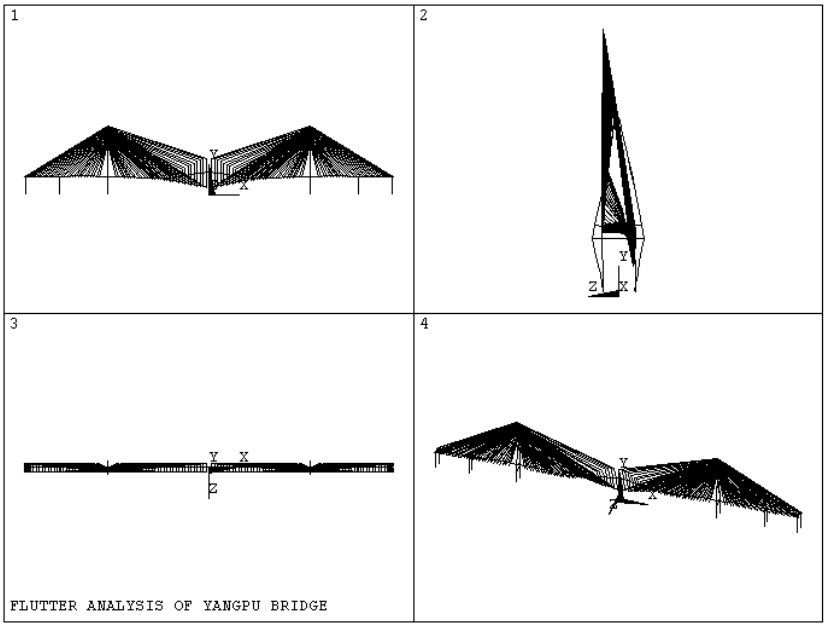

Figure 2. Mode shape of flutter critical state for Yangpu Bridge
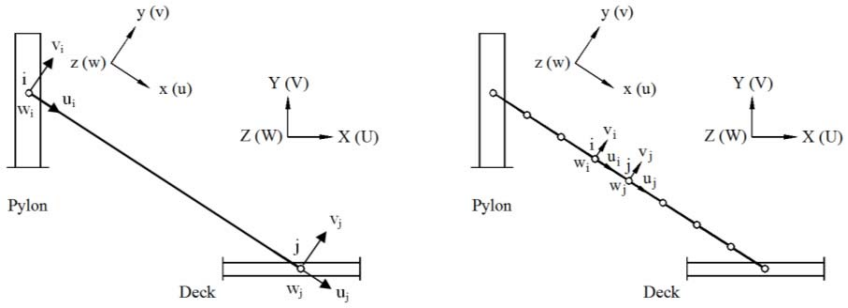
(single-link model, 1st symmetric torsion complex mode)

3 MULTI-LINK MODEL OF CABLES

When a cable-stayed bridge is vibrating, each cable vibrates locally and laterally as a tensioned chord in addition to the vibration as a straight link member along with the movement of the 3D spatial bridge structure. The single-link model, as shown in Figure 3 (a), cannot reveal the behavior of the local vibrations of cables. Instead, it can only reflect the global movement as a straight member connecting with the tower and the deck of the bridge structure. The multi-link model, as shown in Figure 3 (b), which includes the degrees of freedom reflecting the local vibrations of cables, can be introduced to take into account the lateral vibrations of cables. The geometric stiffness must be included for the multi-link model in order to avoid the zero lateral stiffness of intermediate nodes of a cable.



(a) Single-link model (b) Multi-link model

Figure 3. Single-link and multi-link models of a cable

It is the lower local vibrating modes of cables that impact the dynamic behaviors of the whole bridge including the flutter behaviors. The model with 8 links in a cable can well reflect two half-sinusoids with 4 links in each. For the first mode, it is more perfect to display a half-sinusoid with 8 links. So, the 8-link model for a cable is appropriate.

4 EFFECTS OF LOCAL VIBRATIONS OF CABLES

Take the Yangpu Bridge as an example again. The flutter analysis is carried out based on the multi-link model. The earliest flutter critical state is still the vibration shape dominated by the first symmetric deck torsion. The calculated results by using the multi-link model are listed in Table 1. This table also shows the results of the single-link model and as well as the results considering of aerodynamic forces on cables for comparison. Figure 4 shows the mode shape of the flutter critical state of the first symmetric torsion of the Yangpu Bridge by using multi-link model which considers the aerodynamic forces acting on cables.

Table 1 Effects of cable local vibrations and cable aerodynamic forces on flutter critical state of Yangpu Bridge

Critical Wind Velocity (m/s) / Frequency (Hz)		Local Vibrations of Cables	
		Without (Single-Link Model)	With (Multi-link Model)
Aerodynamic Forces Acting on Cables	without	76.33 / 0.49044	84.36 / 0.50877
	with	77.88 / 0.48963	91.74 / 0.50104

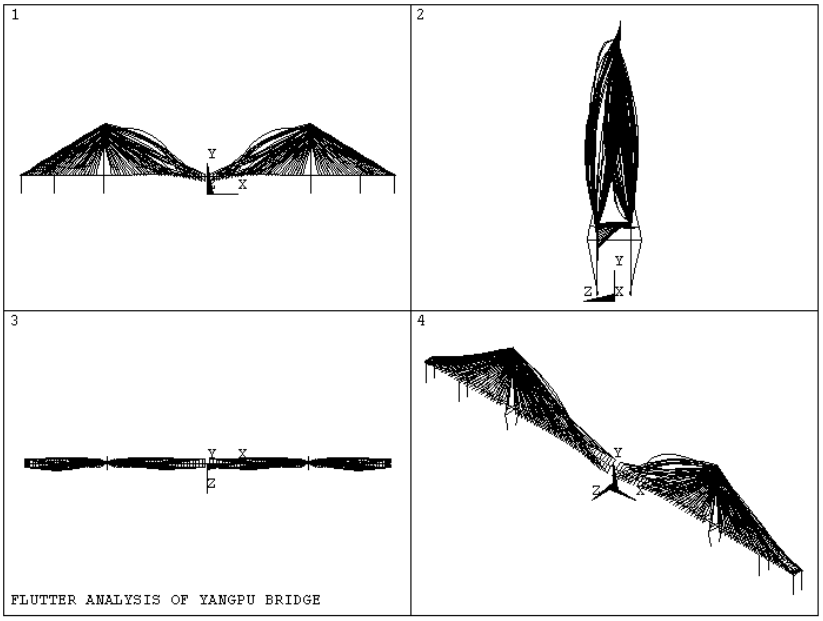


Figure 4. Mode shape of flutter critical state of 1st symmetric torsion of Yangpu Bridge (multi-link model, 8-link for each cable)

From Table 1, without the aerodynamic forces on cables but with the lateral vibrations of cables, the flutter critical wind velocity is increased by 10.5%. Without the lateral vibrations of cables but with the aerodynamic forces on cables, it is increased by 2.0%. When both the aerodynamic forces and the lateral vibrations of cables are considered, the flutter critical wind velocity is increased by 20.2%, from 76.33 to 91.74 m/s. It can be seen there exists an interaction

between the aerodynamic forces and the lateral vibrations of cables. The emergence of the cable lateral vibration shapes intensifies the action of the aerodynamic forces on cables, and therefore intensifies the absorption of the aerodynamic positive damping for cables.

5 EXPLANATION FOR MECHANISM

The mechanism of the effects of local vibrations of cables on the flutter characteristics of cable-stayed bridges can be further explained as follows.

After the introduction of the multi-link model, the increase of the flutter frequency is caused by the increase of the certain structural natural mode frequency since the flutter mode is originated from a certain structural natural mode.

The increase of the flutter frequency will generally cause the increase of the flutter critical wind velocity since the flutter derivatives, which represent the aerodynamic forces between the structure and the flow around it, are related to the reduced wind velocity defined as the actual wind velocity over the vibrating frequency. Therefore, the flutter with a higher vibrating frequency needs a higher wind velocity to activate.

However, the increasing extents in the wind velocity and the frequency should match each other according to the definition of the reduced wind velocity. But in this example, the increasing extent of the critical wind velocity predicted by the multi-link model is far more than that by the single-link model.

In fact, the flutter vibration shape of the first symmetric torsion in the multi-link model is much different from that in the single-link model in addition to the difference of the flutter frequencies. In the flutter vibration shape of the multi-link model (Figure 4), many first-order cable lateral vibration shapes emerge. Consequently, the component of the deck torsional displacement is decreased and is submerged in the lateral vibration shapes of stay cables. On the other hand, the flutter vibration shape in the single-link model is represented by simple torsional displacements of the deck. It is known that the aerodynamic negative damping should be absorbed by the deck torsional displacements, while the lateral vibration shapes of cables can only absorb aerodynamic positive damping. This is the very reason why the flutter critical wind velocity is much increased in the multi-link model.

In summary, the increase of the flutter critical wind velocity due to the effects of the aerodynamic forces on cables is limited. Only when the multi-link model is employed and the lateral vibration shapes emerge as a result, can the increase extent be significant due to the decrease of the component of the deck torsional displacements. The change of the critical wind velocity due to the change of the critical frequency is secondary. The decreasing extent of the deck torsional displacements is related to the participating extent of lateral vibration shapes of cables, namely the coinciding extent of lateral vibrating primary frequencies of cables as tension chords and the fundamental deck torsion frequencies of bridge structures.

6 CONCLUSIONS

Based on the developed method, the aeroelastic effects of cables on flutter behaviors are investigated by using the actual bridge examples. According to the analysis results, some conclusions can be summarized as follows:

(1) With the aerodynamic forces acting on cables but without the consideration of the local vibrations of cables, the flutter critical wind velocity can be increased by 2.0% for the cable-stayed bridge with a 602m middle span. This is because the cable aerodynamic forces only

include the positive aerodynamic damping but do not include the aerodynamic stiffness.

(2) Without the aerodynamic forces but with the local vibrations of cables, the flutter critical wind velocity can be increased by 10.5%. The participation of the cable vibrations weakens the component of torsional displacements of the deck in flutter mode. The emergence of local vibration shapes of cables increase the ability for the bridge to absorb positive damping; while the weakening of the deck torsional displacements decreases the ability for the bridge to absorb the negative damping.

(3) With both the aerodynamic forces and the lateral vibrations of cables, the flutter critical wind velocity can be increased by 20.2%, which is remarkable and much larger than the sum of both separate effects. The apparent impact reveals the interaction relationship between the aerodynamic forces and the local vibrations of cables.

ACKNOWLEDGEMENTS

The research described in this paper was partially supported by Natural Science Foundation of China, under the Grant No. 51178367. Dr. Q.S. Ding provided the ANSYS command flow of structural FE model and the data of flutter derivatives of Yangpu Bridge. These supports are gratefully acknowledged.

The nonlinear aerodynamic stability of long-span bridges: post flutter

Wang Qi [a], Liao Hai-li [a]

[a] *Research Centre for Wind Engineering, Southwest Jiaotong University, Chengdu, China*

ABSTRACT: The linear flutter analytical method can't give the reasonable explanation to post flutter status of bridges. Based on the nonlinear MIAF expressions, the nonlinear vibration differential equation can describe the aerodynamic stability of bridge under different amplitudes and reduced frequency. The nonlinear aerodynamic coefficients in the expression can be represented by the amplitude and initial phase of harmonic components. The nonlinear aerodynamic stability analysis had been performed in state space using the 4th Runge-Kutta algorithm, and the results indicated that the girder of long span bridge would appear different motion types in post flutter, including the convergence motion, the divergence motion and the identical amplitude oscillation. The girder of long span bridge can keep the identical amplitude oscillation status at different amplitude conditions, and the only requirement is the equilibrium in the aerodynamic works.

KEYWORDS: post flutter; nonlinear aerodynamic coefficient; nonlinear aerodynamic stability

1 INTRODUCTION

The motion-induced aerodynamic force (MIAF) in Scanlan's expression is only the function of reduced frequency, and is independent with the amplitude of bridge girder, and there are no nonlinear items and variables in the expression. According to the linear stability theory, there is only a critical status in flutter equation, thus it can't give the further results about aerodynamic stability of bridges especially in the post flutter status. Indeed, the large amplitude oscillation of Tacoma Bridge is typical motion of post flutter, although its collapse was only explained for flutter. The stability status or motion status in post flutter of long span bridges needs to be investigated by the means of nonlinear differential equation considering the nonlinear MIAF.

For the issue of large amplitude oscillation of Tacoma Bridge, several researchers analyzed the aerodynamic mechanism based on nonlinear aerodynamic force and nonlinear vibration theory. Steinmann[2] proposed an aerodynamic force expression of Tacoma deck in 1954, then Böhm[1] studied the nonlinear oscillation of Tacoma Bridge, and interpreted that the large amplitude oscillation of Tacoma Bridge was a limit cycle oscillation. Piccardo[3] also studied the nonlinear vibration of Tacoma Bridge by using Steinmann's expression, and obtained the wind speed 17.44m/s under the limit cycle oscillation of this bridge. Xu[4,5] deduced an expression of nonlinear aerodynamic force and nonlinear vibration equation, and obtained the nearly same critical wind speed as Piccardo under limit cycle oscillation state. Due to the restriction of wind tunnel test technique in acquiring nonlinear aerodynamic force, other bridges are scarcely studied on its nonlinear aerodynamic force or the post flutter state. Diana [6-8] studied nonlinear aerodynamic force of Messina Bridge girder, and indicated that the neglect of nonlinear component of aerodynamic force could lead to unsafely side for aerodynamic instability. Liao[9] found the distinct 8-shape aerodynamic hysteresis loops of streamline box

girder under the larger pitching amplitude, which means that the aerodynamic forces can provide both the positive and negative works within one vibration period. And the 8-shape aerodynamic hysteresis loops also gave a favorable support of limit cycle oscillation of long-span bridge. Chen[10] indicated that the soft flutter phenomenon of long-span bridge was a typical nonlinear vibration, and he used Von Del Pol equation to describe the phenomenon and the nonlinear MIAF of bridge girder.

The other researches on nonlinear aerodynamic oscillation of flexible and long-span structures, were mainly focused on the galloping, such as iced transmission line. Den Hartog[11,12] studied the galloping of iced transmission line in details first time, and proposed the analysis method of galloping using semi-steady theory. Pakinson[13] studied the galloping theory of square column in details. He studied the process of square column galloping by aero-elastic model wind tunnel tests, and found the leap and hysteresis phenomenon in galloping under different reduced frequency. Novak[14], based on SDOF torsional vibration model, studied the galloping of square column in details. His theoretical researches can be correspondent with the wind tunnel test results conducted by Pakinson. The galloping theory based on the semi-steady has developed greatly, the main reason is the simplification of nonlinear aerodynamic force. Lift and pitching moment acting on a transmission line, or square column, has been described only as the function of incidence angle, namely the aerodynamic force can be expressed only with incidence angle.

Although the nonlinear aerodynamic force of bridge girder can be described at very low reduced frequency, under which the aerodynamic hysteresis loop is almost a single curve (this phenomenon was verified in wind tunnel test by Diana[6] and Liao[9]), the bridge may occur flutter at a common reduced frequency, under which the aerodynamic hysteresis is loop.

Combining with the nonlinear MIAF expressions[15], the nonlinear vibration differential equation can describe the aerodynamic stability of bridge girder under different amplitudes and reduced frequency, especially the large amplitude oscillation in the post flutter status of bridges. The nonlinear aerodynamic stability analysis had been performed in state space by using the 4th Runge-Kutta algorithm, and the results indicated that the girder of long span bridge would appear different motion types in post flutter, including the convergence motion, the divergence motion and the identical amplitude oscillation (limit cycle oscillation). The girder of long span bridge can keep the identical amplitude oscillation status at different amplitude conditions, and the only requirement is the equilibrium in the aerodynamic works.

2 AERODYNAMIC FORCE AND COEFFICIENTS

2.1 *Typical aerodynamic force*

Based on the results of the wind tunnel tests, the empirical mathematic model[15] was proposed to describe the nonlinear MIAF under different conditions by using Taylor expanding. Before the analysis, the typical aerodynamic forces under different conditions were selected from the reference paper [16], and one of them represented the special energy inputting to the girder. The outline of the deck cross section is shown in Fig.1, and the wind tunnel test was interpreted in the reference paper [9] and [16]. The selected aerodynamic forces were presented in the form of hysteresis loop, and all of them with the same static incidence angle +5 degree. The forces were shown in Fig.2 ~ Fig.5 respectively and the illustration were as follows.

The aerodynamic force in Fig.2 was obtained under the condition of 10° amplitude and $\pi/5$ reduced frequency, and defined as the case-1. The direction of rotation is counter clock,

which indicates the aerodynamic work is negative. The aerodynamic force in Fig.3 was obtained under the condition of 10° amplitude and π/8 reduced frequency, and defined as the case-2. Varying with the decrease of reduced frequency, the hysteresis loop became the 8-shape, which means that the aerodynamic forces can provide both the positive and negative works within one vibration period. The area of clockwise is less than the c counter-clockwise, namely the negative one is greater than the positive one a little. The aerodynamic force in Fig.4 was obtained under the condition of 10° amplitude and π/10 reduced frequency, and defined the case-3, and the negative work is less than the positive work a little while the *K* decreasing. The aerodynamic force in Fig.5 was obtained under the condition of 20° amplitude and π/10 reduced frequency, and defined the case-4, and positive one is more greater than the negative one while the amplitude increasing.

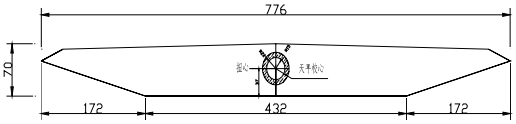

Fig. 1. The cross-section of test model

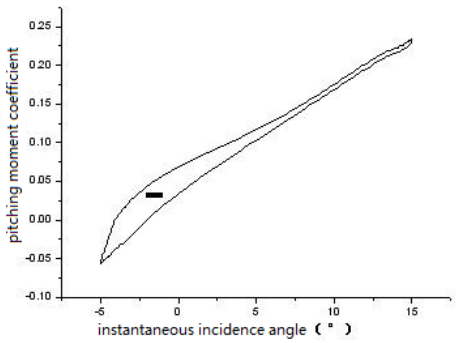

Fig.2 the hysteresis loop of pitching moment coefficient (case-1: *K*=π/5, Amplitude=10degree)

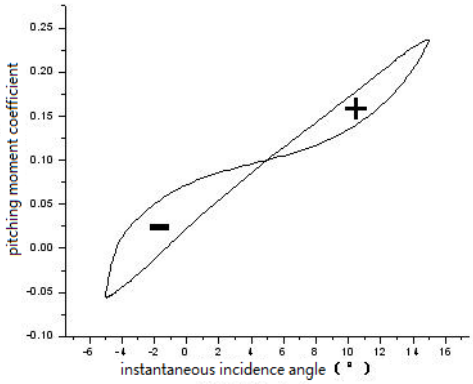

Fig.3 the hysteresis loop of pitching moment coefficient (case-2: *K*=π/8, Amplitude=10degree)

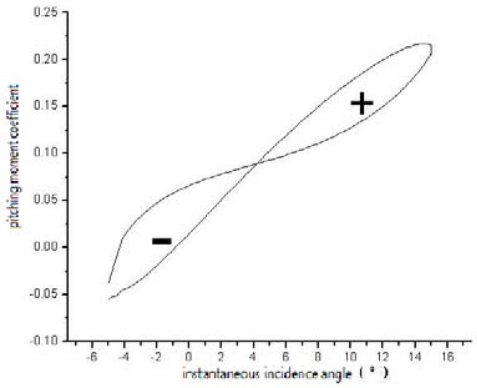

Fig.4 the hysteresis loop of pitching moment coefficient (case-3: K=π/10, Amplitude=10degree)

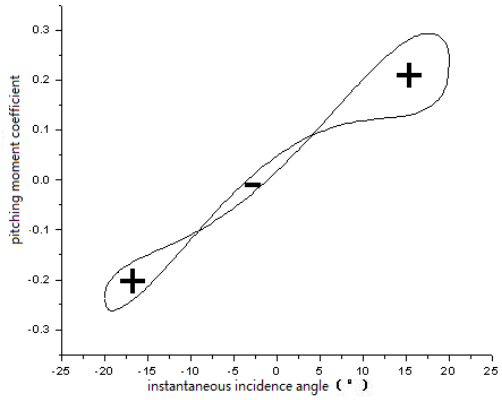

Fig.5 the hysteresis loop of pitching moment coefficient (case-4: K=π/10, Amplitude=20degree)

2.2 *Aerodynamic coefficient*

The aerodynamic coefficients were obtained by the method proposed in reference paper[15], and expressed as follows.

$$C^k_{\dot\alpha^m\alpha^n}=\frac{X^k_{TM}k!}{\omega^m}\sin(\theta^k_{TM}+\frac{n\pi}{2}) \tag{1}$$

In which, k=1,2……n, is the order of nonlinear harmonic components; m is the nonlinear aerodynamic coefficient order which represents the derivative order of velocity and displacement. X^k_{VL} is the pitching amplitude of the k^{th} order torsional pitching moment harmonic component and θ^k_{VL} is the initial phase angle.

If taking the first five orders in aerodynamic coefficient, the C_M can be written as,

$$\begin{aligned}C_M=&C^1_{\dot\alpha}\dot\alpha+C^1_{\alpha}\alpha\\&+\frac{1}{2}C^2_{\dot\alpha^2}\dot\alpha^2+C^2_{\alpha\dot\alpha}\dot\alpha\alpha+\frac{1}{2}C^2_{\alpha^2}\alpha^2\\&+\frac{1}{6}C^3_{\dot\alpha^3}\dot\alpha^3+\frac{1}{2}C^3_{\alpha\dot\alpha^2}\dot\alpha^2\alpha+\frac{1}{2}C^3_{\alpha^2\dot\alpha}\dot\alpha\alpha^2+\frac{1}{6}C^3_{\alpha^3}\alpha^3\\&+\frac{1}{24}C^4_{\dot\alpha^4}\dot\alpha^4+\frac{1}{6}C^4_{\alpha\dot\alpha^3}\dot\alpha^3\alpha+\frac{1}{4}C^4_{\alpha^2\dot\alpha^2}\dot\alpha^2\alpha^2+\frac{1}{6}C^4_{\alpha^3\dot\alpha}\dot\alpha\alpha^3+\frac{1}{24}C^4_{\alpha^4}\alpha^4\\&+\frac{1}{120}C^5_{\dot\alpha^5}\dot\alpha^5+\frac{1}{24}C^5_{\alpha\dot\alpha^4}\dot\alpha^4\alpha+\frac{1}{12}C^5_{\alpha^2\dot\alpha^3}\dot\alpha^3\alpha^2+\frac{1}{12}C^5_{\alpha^3\dot\alpha^2}\dot\alpha^2\alpha^3+\frac{1}{24}C^5_{\alpha^4\dot\alpha}\dot\alpha\alpha^4+\frac{1}{120}C^5_{\alpha^5}\alpha^5\end{aligned} \tag{2}$$

In order to show the coefficients clearly, Table 1 gives the correspondence of the coefficients and characters. The coefficients of aerodynamic force shown in Figs. 2-5 were illustrated in Tables 2-5.

3 NONLINEAR DIFFERENTIAL EQUATION AND SOLUTION

3.1 *Nonlinear differential equation.*

Based on the direct Taylor expanding of nonlinear MIAF, and combined with the free vibration equation of the dynamic system, the nonlinear differential equation was constructed to describe the nonlinear aerodynamic stability of bridge girder. Because of the nonlinear items and variables in this equation, the limit cycle, the convergence motion and the divergence motion may exist under a special condition, which can prediction the motion of long bridges at the post-flutter status.

Taking an example of aerodynamic moment under torsional motion condition, the nonlinear differential Eq. can be written as follows:

$$\ddot{\alpha}+(2\xi_\alpha\omega_\alpha-\eta)\dot{\alpha}+(\omega_\alpha^2-\mu)\alpha=0 \tag{3}$$

In above, $\eta=f(\dot{\alpha},\alpha),\mu=g(\dot{\alpha},\alpha)$, and both of them are the nonlinear function of motion variables of bridge girder. Considering the motion variables (velocity and displacement) in the wind tunnel tests are certain values, and the parameter η and μ is also a certain value, and the solution of Eq. 3 in the different case only represents the tendency of girder motion with a special condition (including the dynamic parameters and initial motion parameters).

Because the 2nd order variables in Eq. 3 could bring on the difficult in solving, the state variables, which can reduce the order of the variables, are introduced, thus the equation can be transformed to the 1st order in the state space,

$$\dot{Y}=\begin{bmatrix}\dot{y}_1\\ \dot{y}_2\end{bmatrix}=\begin{bmatrix}\dot{\alpha}\\ \ddot{\alpha}\end{bmatrix}=\begin{bmatrix}y_2\\ -(2\xi_\alpha\omega_\alpha-\eta)y_2-(\omega^2-\mu)y_1\end{bmatrix}=\begin{bmatrix}\dot{\alpha}\\ -(2\xi_\alpha\omega_\alpha-\eta)\dot{\alpha}-(\omega^2-\mu)\alpha\end{bmatrix} \tag{4}$$

$$Y_0=\begin{bmatrix}y_1(0)\\ y_2(0)\end{bmatrix}=\begin{bmatrix}\alpha_0\\ \dot{\alpha}_0\end{bmatrix} \tag{5}$$

Giving the initial condition, the Eq. 3 can be solved using the 4th Runge-Kutta algorithm, and the results show the locus of the motion, which represent the motion status in post flutter.

3.2 *Solving conditions*

The general nonlinear differential equation to investigate the nonlinear aerodynamic stability of bridge girder under the special condition is shown below,

$$\ddot{\alpha}+2\xi\omega\dot{\alpha}+\omega^2\alpha=pC_M^T(\alpha,\dot{\alpha}) \tag{6}$$

where $p=\frac{1}{2}\rho U^2\mathrm{B}^2L\Big/I_m$ is the merging term, and the ρ=air density, *U*= wind speed, *B*= girder width, *L*= girder length, I_m= mass moment of inertia, ξ=damping ratio，ω=cycle frequency. $C_M^T(\alpha,\dot{\alpha})$ is the pitching moment coefficient of the different cases illustrated in Tables 2-5.

The standard form of solution in state space is as follow,

$$\dot{Y}=\begin{bmatrix}\dot{y}_1\\ \dot{y}_2\end{bmatrix}=\begin{bmatrix}\dot{\alpha}\\ \ddot{\alpha}\end{bmatrix}=\begin{bmatrix}y_2\\ -2\xi\omega y_2-\omega^2y_1-pC_M^T\end{bmatrix}=\begin{bmatrix}\dot{\alpha}\\ -2\xi\omega\dot{\alpha}-\omega^2\alpha-pC_M^T\end{bmatrix} \tag{7}$$

The initial condition in solution is ,

$\alpha_0 = 0$， $\dot{\alpha}_0 = 0.1745\omega$

The width of the girder in analysis is 0.776m, and considering the 2D analysis assumption the length is 1.0m. The other initial parameters for 4 cases are listed in Table 6.

Table 6 Parameters in different cases

	ω(rad/s)	2ξω	U(m/s)	I_m(Kgm^2)	p(/s^2)
Case1	12.13	0.01	15	1.0	82.987

4 NONLINEAR AERODYNAMIC STABILITY OF POST FLUTTER

The different motion corresponding to the differential equation can be desicribed in solution curve and phase plane diagram. Generally, the analysis results can express as follows: the positive work in the hysteresis loop is less than the negtive one, the motion of bridge girder will converge, see in Fig.6 and Fig.7. On the other hands, the motion will converge while the aerodynamic positive work is greater than the negative one, see in Fig.8. The identical amplitude oscillation could appear while the energy which structure consumed is equal to the aerodynamic energy, as shown in Fig.9. Because the area of positive work is almost equal to negative work in case-3, the speed of convergence is slow down dramatically, and the amplitude trends to the identical. The larger mass moment can consume the more aerodynamic energy in one period, and the identical amplitude oscillation can also occur even if the positive aerodynamic work is larger than the negative one. For case-4, if the I_m become the twice of the original one, and the amplitude will be identical, and the girder could occur limit cycle oscillation, see Fig.10

On the contrary, if the structural stiffness is so small, or the mass moment is too small to consume the aerodynamic energy in one period, the displacement of bridge girder increases vary rapidly, and the aerodynamic negative damping and structural damping can't consume the positive energy in time, even if the negative work is larger than the positive one, the girder motion will divergence directly as show in Fig. 11. In fact, because of the exist of 8-shape loop under different conditions, the motion of bridges girder may tend to the limit cycle oscillation, and may convert to different amplitude depending on wind speed. Of course, the girder could also occur the direct divergence while the positive aerodynamic energy increasing.

5 CONCLUSIONS

By introducing nonlinear MIAF expressions, nonlinear vibration differential equation can describe the aerodynamic stability of bridge girder under different amplitudes and reduced frequency, especially the large amplitude oscillation in the post flutter status of bridges. The nonlinear aerodynamic stability analysis had been solved in state space by using the 4th Runge-Kutta algorithm, and results show that the girder of long span bridge would appear different motion types in post flutter, including the convergence motion, the divergence motion and the identical amplitude oscillation (limit cycle oscillation). The motion of bridges girder may tend to the limit cycle oscillation, and convert to different amplitude due to 8-shape loop under different conditions. The girder can also occur the direct divergence while the positive aerodynamic energy increasing.

6 ACKNOWLEDGEMENTS

The paper is based on the project: The study on nonlinear motion-induced aerodynamic force and nonlinear aerodynamic stability of long-span bridge, which is supported by the Major Research plan of the National Natural Science Foundation of China (Grant No. 90815016).

Eco-generation of energy from flutter based on energy-recycling mechanism

Kanjuro Makihara [a]

[a]*Tohoku University, 6-6-01 Aramaki-Aza-Aramaki, Aoba-Ward, Sendai, Japan*

ABSTRACT: This paper presents a harvesting system that extracts electrical energy by effectively using wing flutter, which is called eco-generation or energy-harvesting. This study utilizes the quasi-steady aerodynamic theory and FEM for simulating the dynamics of a plate wing. The use of piezoelectric patches and switching circuits can lead to effective harvesting from supersonic flutter. We evaluated our switching harvesting approach in supersonic flutter. Our harvesting system via wing flutter can generate 10 times more energy than a conventional harvesting system.

KEYWORDS: Eco-Generation, Flutter, Energy-Harvesting, Energy-Recycling, Piezoelectric

1 INTRODUCTION

The interaction between the structural motion of a wing and the aerodynamic load exerted on the wing can cause flutter phenomenon. It is a self-excited aeroelastic phenomenon that occurs in wings, thin walls, and so on. Wing flutter can be found most frequently within a high-speed, i.e., transonic, supersonic, and hypersonic flow (Dowell, 1966).

Eco-generation or energy-harvesting is a process by which energy is extracted from various sources and stored for future use, such as solar energy, tidal energy, piezoelectricity, thermoelectricity, and kinematic energy. Energy-harvesting techniques are expected to be of vital importance in the future when fossil fuel reserves will exhaust completely. Among the various sources mentioned above, this study focuses on harvesting energy from vibrating structures using piezoelectricity. Sodano et al. (2003) reviewed investigations of piezoelectric energy-harvesting techniques. Lesieutre et al. (2003) discussed the damping associated with harvesting electrical energy from a mechanically excited piezoelectric structure. Cornwell et al. (2005) developed an approach to improve energy output by using a tuned auxiliary structure. Because of the interest in the use of wind in harvesting energy, various studies and investigations were conducted by researchers, as discussed below. Erturk et al. (2010) employed the lumped-parameter model that entails energy-harvesting from aeroelastic vibration of a two-degree-of-freedom system. Robbin et al. (2006) discussed vortex-induced oscillations of piezoelectric cantilevers located behind bluff bodies. Isogai et al. (2003) conducted a study on a power generation system that extracts wind energy from flutter of a binary elastic system.

So far, wing flutter has been considered as a phenomenon that should be avoided, especially in aerospace engineering. However, adding electromotor or piezoelectric transducers to wings under aeroelastic vibrations is a feasible method for harvesting energy, as Isogai (2010), verified in simulation and experiments. We introduce an energy-harvesting system that extracts electrical energy from wing flutter using piezoelectric materials and a switching circuit. The effective use of wing flutter changes our perception of it; from being a destructive phenomenon as it was formerly known to be to being useful in various applications.

2 WING FLUTTER MODEL

2.1 *Outline of tail wing of rocket*

We focus on harvesting energy from wing flutters of sounding rockets (National Research Council Board, 2009). Japan Aerospace Exploration Agency has developed a sounding rocket S-310, which we consider as an example in our research. This rocket is 310 mm in diameter, and can reach an altitude of 150 km. The rocket attains approximately Mach 4.6 in 23 seconds, which indicates that it flies at a supersonic speed during most of its flight. Thus, it can be subject to supersonic flutter during the flight of the sounding rocket. The rocket has four tail wings made of a solid titanium plate (Fig. 1) flying at a supersonic speed. We include a cantilevered-plate wing to investigate the harvesting of energy from wing flutter. Piezoelectric patches are attached to the wing surface to generate electrical energy from the wing motion. In reality, patches attached to the wing surface may adversely affect fluid dynamics because they cause discontinuity of the wing surface. Furthermore, the patches may be adversely affected by the heat generated by aerodynamic interference. However, in this study, we do not consider these issues.

2.2 *Derivation of aerodynamic pressure for flutter analysis*

The flow velocity field, (u_1, u_2, u_3), is written as

$$u_1 = 0, \quad u_2 = U + \tilde{u}_2, \quad u_3 = \tilde{u}_3. \tag{1}$$

Here, U is the steady flow in the direction x_2. It is assumed that the variation of velocity is sufficiently small, compared with the steady flow. The continuous equation is

$$\frac{\partial \rho}{\partial t} + \frac{\partial}{\partial x_j}\left(\rho u_j\right) = 0. \tag{2}$$

The conservation of momentum is

$$\frac{\partial u_i}{\partial t} + u_j \frac{\partial u_i}{\partial x_j} = -\frac{1}{\rho}\frac{\partial p}{\partial x_i}. \tag{3}$$

The variation of velocity occurs in an adiabatic reversible manner, and the law of conservation of energy in an isentropic process can be written as

$$\frac{1}{2}u_i u_i + \frac{a^2}{\gamma - 1} = \frac{1}{2}U^2 + \frac{a_\infty^2}{\gamma - 1}. \tag{4}$$

The inner-product with u_i of Eq. (3) yields

$$u_i\left(\frac{\partial u_i}{\partial t} + u_j \frac{\partial u_i}{\partial x_j}\right) = -u_i\left(\frac{1}{\rho}\frac{\partial p}{\partial x_i}\right) = -\frac{u_i}{\rho}\left(\frac{\partial p}{\partial \rho}\right)_s\left(\frac{\partial \rho}{\partial x_i}\right) = -\frac{u_i}{\rho}a^2\left(\frac{\partial \rho}{\partial x_i}\right). \tag{5}$$

The substitution of Eq. (2) to Eq. (5) becomes

$$u_i\left(\frac{\partial u_i}{\partial t} + u_j \frac{\partial u_i}{\partial x_j}\right) = a^2\left(\frac{1}{\rho}\frac{\partial \rho}{\partial t} + \frac{\partial u_k}{\partial x_k}\right). \tag{6}$$

By substituting Eq. (1) in Eq. (6), and exchanging right and left terms, we get

$$a^2\left(\frac{1}{\rho}\frac{\partial\rho}{\partial t}+\frac{\partial u_2}{\partial x_2}+\frac{\partial u_3}{\partial x_3}\right)=(U+u_2)\left\{(U+u_2)\frac{\partial u_2}{\partial x_2}+u_3\frac{\partial u_2}{\partial x_3}\right\}+u_3\left\{(U+u_2)\frac{\partial u_3}{\partial x_2}+u_3\frac{\partial u_3}{\partial x_3}\right\}$$
$$+(U+u_2)\frac{\partial u_2}{\partial t}+u_3\frac{\partial u_3}{\partial t}. \tag{7}$$

The variation symbol, $(\tilde{\bullet})$, is removed. The substitution of Eq. (1) to Eq. (4) yields

$$a^2=a_\infty^2\left[1-\frac{\gamma-1}{2}M_\infty^2\left\{2\frac{u_2}{U}+\left(\frac{u_2}{U}\right)^2+\left(\frac{u_3}{U}\right)^2\right\}\right]. \tag{8}$$

By combining Eqs. (7) and (8), we obtain

$$a_\infty^2\left[1-\frac{\gamma-1}{2}M_\infty^2\left\{2\frac{u_2}{U}+\left(\frac{u_2}{U}\right)^2+\left(\frac{u_3}{U}\right)^2\right\}\right]\left(\frac{1}{\rho}\frac{\partial\rho}{\partial t}+\frac{\partial u_2}{\partial x_2}+\frac{\partial u_3}{\partial x_3}\right)=(U+u_2)\frac{\partial u_2}{\partial t}+u_3\frac{\partial u_3}{\partial t}$$
$$+(U+u_2)\left\{(U+u_2)\frac{\partial u_2}{\partial x_2}+u_3\frac{\partial u_2}{\partial x_3}\right\}+u_3\left\{(U+u_2)\frac{\partial u_3}{\partial x_2}+u_3\frac{\partial u_3}{\partial x_3}\right\}. \tag{9}$$

In Eq. (9), we omit higher variation terms than the first-order because $(u_i/U)\ll 1$;

$$\left(M_\infty^2-1\right)\frac{\partial u_2}{\partial x_2}+M_\infty^2\frac{\partial u_2}{\partial t}-\frac{\partial u_3}{\partial x_3}=\frac{1}{\rho}\frac{\partial\rho}{\partial t}. \tag{10}$$

The velocity potential, $\phi=\phi(x_2,x_3,t)$, is introduced as

$$\frac{\partial\phi}{\partial x_2}\equiv u_2,\quad \frac{\partial\phi}{\partial x_3}\equiv u_3. \tag{11}$$

By using D'Alembert's method without the time variation, a general solution can be expressed as

$$\phi\equiv F(x_2-\lambda x_3)+G(x_2+\lambda x_3),\quad \lambda\equiv\sqrt{M_\infty^2-1} \tag{12}$$

These functions F and G hold constant values along lines $x_2\pm\lambda x_3=const.$, respectively, Boundary condition at wing surface $w=0$ is

$$-\lambda\frac{\partial}{\partial x_2}\{F(x_2-\lambda x_3)\}|_{w=0}=U\frac{\partial w}{\partial x_2}. \tag{13}$$

Ashley and Zartarian (1956) developed the piston theory under the notion that at high Mach numbers the shock waves and expansion fans on an airfoil form at small angles to the undisturbed flow. The stream wise gradients are small compared to gradients perpendicular to the flow. Normal fluid velocity produced by the wing's motion results from Eq. (13) as

$$u_3=\frac{\partial w}{\partial t}+\left(U\frac{\partial w}{\partial x_2}\right) \tag{14}$$

Considering Eqs. (3) and (10) to (14), the pressure is expressed as

$$\frac{p}{p_\infty}=\left(1+\frac{\gamma-1}{2}\frac{w}{a_\infty}\right)^{(2\gamma)/(\gamma-1)}\approx 1+\gamma\frac{w}{a_\infty}+\frac{\gamma(\gamma+1)}{4}\left(\frac{w}{a_\infty}\right)^2+\frac{\gamma(\gamma+1)}{12}\left(\frac{w}{a_\infty}\right)^3. \tag{15}$$

When high order terms are truncated, the low-order aerodynamic pressure is described by

$$p - p_\infty = \frac{2q}{\lambda}\left[\frac{\partial w}{\partial x_2} + \left(\frac{\lambda^2 - 1}{\lambda^2}\right)\frac{1}{U}\frac{\partial w}{\partial t}\right]. \tag{16}$$

Other parameters are defined in Appendices A and B. Assuming that the pressure is exerted on both sides of the wing, we can express the resultant pressure $p_a(x, y, t)$ exerted on the wing as

$$p_a(x_1, x_2, t) \equiv -\frac{4q}{\lambda}\left[\frac{\partial w}{\partial x_2} + \left(\frac{\lambda^2 - 1}{\lambda^2}\right)\frac{1}{U}\frac{\partial w}{\partial t}\right]. \tag{17}$$

3 FLUTTER HARVESTING WITH PIEZOELECTRIC PATCHES

3.1 *Equations of motion for wing dynamics*

Piezoelectric patches shown in Fig. 1 are assumed to be polarized in the thickness direction (x_3 direction) and isotropic in the in-plane direction ($x_1 - x_2$ plane). Hence, their constitutive equations (Jaffe et al., 1971) are given by

$$\sigma_p = \mathbf{c}_p^D \varepsilon_p - \mathbf{h} D_3,\ E_3 = -\mathbf{h}^{\mathrm{T}} \varepsilon_p + \beta_{33}^S D_3. \tag{18}$$

The stress–strain relation of a wing is written as

$$\sigma_w = \mathbf{c}_w \varepsilon_w. \tag{19}$$

The linear strain-displacement relation based on the Kirchhoff–Love assumption is

$$\varepsilon = -x_3\left[\frac{\partial^2}{\partial x_1^2}, \frac{\partial^2}{\partial x_2^2}, 2\frac{\partial^2}{\partial x_1 \partial x_2}\right]^{\mathrm{T}} w(x_1, x_2, t). \tag{20}$$

On the surface of the wing, n_{p} pieces of piezoelectric patches are attached, and the j th patch ($1 \le j \le n_p$) is attached at positions $x_{1Sj} \le x_1 \le x_{1Ej}$, $x_{2Sj} \le x_2 \le x_{2Ej}$, and $x_{3Sj} \le x_3 \le x_{3Ej}$. To ensure the generality of this theoretical analysis, a multiple-input–multiple-output system is considered. Using Hamilton's principle, we construct

$$\int_{t_1}^{t_2}\left[\delta T_w - \delta U_w + \sum_{j=1}^{n_{\mathrm{p}}}(\delta T_{pj} - \delta U_{pj}) + \delta W\right]\mathrm{d}t = 0, \tag{21}$$

where virtual work δW can be written as

$$\delta W \equiv \int_S \delta w[f(x_1, x_2, t) + p_a(x_1, x_2, t)]\,\mathrm{d}S + \sum_{j=1}^{n_{\mathrm{p}}} V_j \int_{S_{pj}} \delta D_{3j} g_j(x_1, x_2, x_3)\,\mathrm{d}S. \tag{22}$$

Here, $f(x_1, x_2, t)$ is the external force normal to the wing and V_j is the voltage applied to the j th piezoelectric patch as a generalized external force. The finite element method (FEM) element proposed by Adini, Clough, and Melosh that is known as the ACM element (Zienkiewicz and Taylor, 1985), which is a four-node non-conforming plate element, is employed to discretize the partial derivative equations of motion. From Eqs. (17)–(22), the equation of motion for the cantilevered wing with multiple piezoelectric patches attached to it can be expressed as

$$\mathbf{M}\ddot{\vec{y}} + (\mathbf{K} + \psi\mathbf{A})\vec{y} = \mathbf{B}\vec{Q} + \vec{f}, \tag{23}$$

$$\vec{V} = -\mathbf{B}^{\mathrm{T}}\vec{y} + \mathbf{C}^{-1}\vec{Q}. \tag{24}$$

We perform the modal transformation

$$\vec{y} = \mathbf{\Phi}\vec{\eta}, \tag{25}$$

and introduce the modal damping in Eq. (23) as

$$\ddot{\vec{\eta}} + \mathbf{\Xi}\dot{\vec{\eta}} + (\mathbf{\Omega} + \psi\mathbf{\Phi}^{\mathrm{T}}\mathbf{A}\mathbf{\Phi})\vec{\eta} = \mathbf{\Phi}^{\mathrm{T}}\mathbf{B}\vec{Q} + \mathbf{\Phi}^{\mathrm{T}}\vec{f}. \tag{26}$$

This eigenvalue problem is solved for the homogenous part of Eq. (23) with $\psi = 0$.

3.2 *Switching eco-generation and circuit enhancement*

A conventional energy-harvesting device that employs piezoelectric materials to generate energy includes a vibrating piezoelectric structure and an energy storage system (Priya and Inman, 2003). The energy generator is composed of piezoelectric materials, which are attached to the structure, and a harvesting circuit. Circuit A shown in Fig. 2 is a conventional harvesting circuit consisting of a diode bridge of four diodes. The diode bridge is connected to the piezoelectric materials and it provides a mechanism for current rectification. This harvesting system is used in many vibration systems; however, it does not satisfactorily harvest electrical energy.

To enhance the energy-harvesting performance, we use the energy-recycling semi-active approach (Onoda et al, 2003) as an effective energy-harvesting mechanism. This approach involves the use of Circuit B, which is connected to the piezoelectric material, as shown in Fig. 3. The circuit has only two diodes and a selector switch. The selector switch is connected to point 1 or 2 to control the current flow. According to our previous study (Onoda et al, 2003), the advanced energy-recycling approach can simultaneously manage multiple circuits and piezoelectric patches. This type of energy-harvesting was described in (Makihara et al, 2006). Because our semi-active method just changes the switch connection to point 1 or 2 in Fig. 3, it never increases the vibration energy by its switching action. Hence, our semi-active approach is safer than other active approaches that usually involve a risk of instability such as spillover.

As will be seen later, in flutter problems, modal frequencies can shift according to dynamic pressure. Therefore, sophisticated controls based on modal decomposition are impractical. One way of implementing switching controls without modal information is to adopt an approach based on the direct velocity feedback method (Balas, 1979). The control reads that switching point should be changed according to the strain at the position of piezoelectric patch.

4 NUMERICAL ANALYSIS OF FLUTTER HARVESTING

4.1 *Wing flutter design*

We carried out numerical simulation of the energy-harvesting on the plate wing (Fig. 1). The wing was made of a titanium alloy (Ti-6Al-4V). This configuration is essentially a simpler model of the S-310's tail wing for explaining the harvesting performance on which we focus in this study. The wing was rigidly supported on one of its boundaries, i.e., $\psi = 0$. A piezoelectric patch was attached at $0 \le x_1 \le 0.15$ and $0.28 \le x_2 \le 0.46$ on the wing. The total resistance in the circuit was $30\,\Omega$, and the piezoelectric capacitance C_p was 1.17×10^{-6} F. Without considering the aerodynamic influence, the first and second mode frequencies of the open circuit (i.e., constant charge) were 43.0 Hz and 84.5 Hz, respectively. The simulation parameters are listed in Table 1. These parameters were determined on the basis of the materials used in the investigation to carry out realistic simulations. This study focuses on the energy harvested from wing flutter via

piezoelectric patches. We here explain the harvesting mechanism shown in Circuit B (Fig. 3) using a single-degree-of-freedom (SDOF) system, as this system is comprehensible. Figure 4 shows a schematic of the single-mode vibration in energy-harvesting.

4.2 *Eigenvalue analysis for flutter phenomenon*

Equation (23) can be reduced into an eigenvalue problem:

$$\left|\mathbf{K}+\psi\mathbf{A}-\mu\mathbf{M}\right|=0, \tag{27}$$

where μ is a complex eigenvalue. Because the eigen-analysis is performed on a no-control system, the control input and the external disturbance are neglected. Figure 4 plots eigenvalues as a function of the dynamic pressure parameter ψ. The curves of the two values of the real part approach each other as ψ increases. When $\psi=2.86\times10^{6}$, the two values of the real part can be combined as $\mathrm{Re}[\mu]=1.86\times10^{3}$. At this critical value of ψ the wing experiences a flutter phenomenon. This figure shows the loci of only the first and second modes. Since this critical value indicates the smallest dynamic pressure among all critical values, we focus on the relation between only two vibration modes.

4.3 *Flutter harvesting simulation*

We simulated flutter dynamics in the case that a white noise force was exerted on the wing surface. The power spectral density (PSD) per unit frequency of white noise had a constant nonzero value in the range of 30 to 100 Hz and a value of 0 in the rest of the frequency range. Therefore, the frequency range of the nonzero PSD covered the first and second modes.

The history of wing dynamics at a critical dynamic pressure with Circuit B is shown in Fig. 5. The wing tip displacement increases due to the wing flutter phenomenon. Following the displacement, the piezoelectric voltage also increases. Then, the stored voltage increases and harvested energy is accumulated. The stored voltage in the harvesting device is shown to have a step-like curve, which is characteristic of harvesting systems that use diode bridges. Figure 6 shows the magnified view of voltage in the two harvesting systems with Circuit A and Circuit B for $C_s=1.17\times10^{-6}$. The harvesting system with Circuit B outperforms in harvesting energy from wing flutter. Figure 7 presents a comparison of the energy harvested by the two systems with $C_s=1.17\times10^{-6}$. Our harvesting system with Circuit B can generate 10 times more electrical energy than the system with Circuit A. The generation ratio, i.e., 10 times, is quite a striking and attractive number as a powerful energy harvester. Our harvesting system shows potential and is effective because it takes advantage of the wing flutter that has thus far been considered as destructive.

5 CONCLUSIONS

Eco-generation from the flutter phenomenon of a plate wing is studied using the quasi-steady aerodynamic theory and the finite element method. The wing is modeled as sounding rockets' wings. We harvest electrical energy from supersonic flutter by using piezoelectric patches and electric devices. To assess their harvesting performances, we simulate flutter dynamics of the plate wing to which piezoelectric patches are attached. We demonstrate that our harvesting sys-

tem can generate 10 times more electrical energy from wing flutter than conventional harvesting systems can. We expect that our proposed technique will be applicable to various energy-harvesting systems, and we anticipate that it will be the basis for further studies in this field. More experimental validation is essential for assessing the harvesting performances, and an experiment is currently being carried out for this purpose.

ABSTRACT: This paper presents overall procedure for wind energy harvesting at elevated bridge in order to enable the self powered bridge. The test bed bridge was carefully selected from short term wind data measured at 86 sites considering wind energy potential and safety issues for traffic. The position of wind turbine around bridge girder was chosen from the CFD analysis and wind tunnel tests, where wind speed boosted 17~27% by oncoming wind. Two small wind turbines and associate monitoring system for wind data and electric power have been installed at the concrete girder of an elevated bridge over 57m above ground. Monitoring results for recent two months reveals a high correlation between the wind speed probability distribution and actual generated electric power. Long term monitoring of wind data and electric power is ongoing for further investigation.

KEYWORDS: Wind Energy, Bridge, Wind Turbine, Wind Tunnel Test.

1 INTRODUCTION

In modern bridges, electricity is needed for service and maintenance such as traffic control, lighting, and structural health monitoring. However, it is not easy to supply electricity to bridges in remote area. The cost for electric grid connection is $50/m in Korea, and is not acceptable for many bridges in rural or mountain area. One feasible way is to provide the harvested electricity from ambient energy sources to rechargeable battery equipped at bridges. Wind has an advantage of a continuous source of energy. The traditional wind turbines convert the ambient wind flows into useful electrical energy.

Elevated bridges are good places for wind energy harvesting because of escalated wind speed from the ground. Wind speed is also increased at elevated bridges which cross a valley or canyon, producing a convergence of streamlines. When wind turbines are installed at bridge girder, the major concerns for bridge are probable wind forces increase, mechanical vibration and wind-induced vibrations. In case of short and mid span bridges, wind induced vibrations and mechanical vibrations may be not significant because of its stiffness. The additional wind forces at the bridges introduced by wind turbines seem to be negligible compared with self load and other live loads.

In the first step for realizing the self powered bridges, an elevated concrete bridge with sufficient stiffness has been selected and equipped two different types of small wind turbines. This paper presents overall numerical and experimental results of site selection, position of wind turbine, monitoring system and short term measurement at field.

2 WIND RESOURCE ASSESSMENTS

2.1 *Long term estimation of wind resource*

While field observation of wind data at a specific site is the best solution for accurately assessing the wind energy potential, it is generally not feasible to acquire sufficient long-term wind data for the site. To overcome this problem, the Measure–Correlate–Predict (MCP) method has generally been used to estimate the long-term wind data at the target site from the wind data at the reference site. The fundamental principle behind MCP is that the wind at a new "test site" can be predicted on the basis of comparisons with data from a long-term "reference" site, which is located somewhere in the general vicinity [Manwell, *et al*., 2001].

When we obtained sufficient number of wind data at target site from the MCP method, we need to model the wind speed using probability distributions. The Weibull distribution is widely used in practical application. However, it is not acceptable at some case that the sources of wind are two or more. If probability density function of wind speed reveals two peaks, it is suitable to use the conventional Weibull distribution, and the mixed probability distribution seems to be solution. These two probability distributions are explained at next section.

Once the probability distribution is determined, next step for wind energy assessment is combining and integrating the probability distribution and power performance curve of the selected wind turbines. The output electrical power can be expressed as

$$E = T \int_0^\infty P(v) f_v(v) dv \tag{1}$$

where, v is wind speed, $P(v)$ is power performance curve of wind turbine, f_v is probability density function, and T is time period. T is 8760(=365×24) hours for calculating annual energy production (AEP).

2.2 *Probability distributions of wind speed*

The two parameter Weibull is a flexible distribution that is useful frequency distributions of wind speeds. The probability density function (PDF) of the Weibull distribution is expressed as

$$f_v(V) = \frac{k}{c}\left(\frac{V}{c}\right)^{k-1} exp\left\{-\left(\frac{v}{c}\right)^k\right\}, \qquad \text{for } V>0 \tag{2}$$

where, c>0 is the scale parameter, and k>0 is the shape parameter of the distribution. The following shape and scale parameters can be calculated from the maximum likelihood method.

$$k = \left[\frac{\sum_{i=1}^n v_i^k \ln(v_i)}{\sum_{i=1}^n v_i^k} - \frac{\sum_{i=1}^n \ln(v_i)}{n}\right]^{-1} \tag{3a}$$

$$c = \left(\frac{1}{n}\sum_{i=1}^n v_i^k\right)^{\frac{1}{k}} \tag{3b}$$

where, v_i is the wind speed in i^{th} time step, and n is the number of data points.

A mixture density is a probability density function that is linear combination of other probability density functions. Suppose that $v_i (i = 1,2)$ are independently distributed as two-parameter Weibull $f(v,c,k,)$, a random variable v that is distributed as v_i with mixing parameters ω_i is said to have a two-component mixture Weibull distribution. The PDF of v, which depends on five parameters (c_1,k_1,c_2,k_2,ω), is given by [Carta, *et al*., 2007]

$$f_v(c_1, k_1, c_2, k_2, \omega) = \omega f_{v1}(c_1, k_1) + (1-\omega) f_{v2}(c_2, k_2) \tag{4}$$

where, $v > 0$, $c_1,k_1,c_2,k_2 > 0$, and $0 \le \omega \le 1$. Parameter estimation method consists of finding the values of the parameters (c_1,k_1,c_2,k_2,ω), which maximize the function of log-likelihood is given by

$$Maximise \ \ln L_v(c_1,k_1,c_2,k_2,\omega)$$
$$= \sum_{i=1}^{n} \ln\left\{\omega\left[\frac{k_1}{c_1}\left(\frac{v_i}{c_1}\right)^{k_1-1}\exp\left\{-\left(\frac{v_i}{c_1}\right)^{k_1}\right\}\right] + (1-\omega)\left[\frac{k_2}{c_2}\left(\frac{v_i}{c_2}\right)^{k_2-1}\exp\left\{-\left(\frac{v_i}{c_2}\right)^{k_2}\right\}\right]\right\} \quad (5)$$

3 SELF POWERED BRIDGE

3.1 *Site survey*

Short term wind speeds measured at 86 bridges were used to find a test bed bridge site for wind energy harvesting. The wind data on bridge were measured for one year in order to investigate the effect of side wind on vehicle runnability [KEC, 2009]. These were the only reliable wind data for bridges in mountainous region where local topographical effect dominated. The strong seasonal variations of the measured short term wind speeds were interpolated comparing the wind data at nearby local weather station.

Bridges near residential area and overpass were eliminated from test bed site to avoid any civil complaint and traffic danger. Figure 1 shows the average wind speeds measured at several highway bridges. All bridges except the first one were located at mountainous area. Though the Seohae Bridge revealed the highest average wind speed, it was discarded from the candidate bridge because of high traffic volume.

The KJC Bridge shown in Figure 2 was finally selected as test bed for wind energy harvesting because of its relatively high wind speed, stiff girder and low traffic volume. The KJC Bridge, located in Yangyang, Kangwon, Korea which was north eastern part of South Korea. Annual average wind speed of the bridge was 4.38m/s. Single span length and width of the prestressed concrete box girder were respectively 57m and 11.3m. Height of the superstructure was 57m from ground. Wind barrier of 3m high has been installed at southwest side of the bridge for traffic safety.

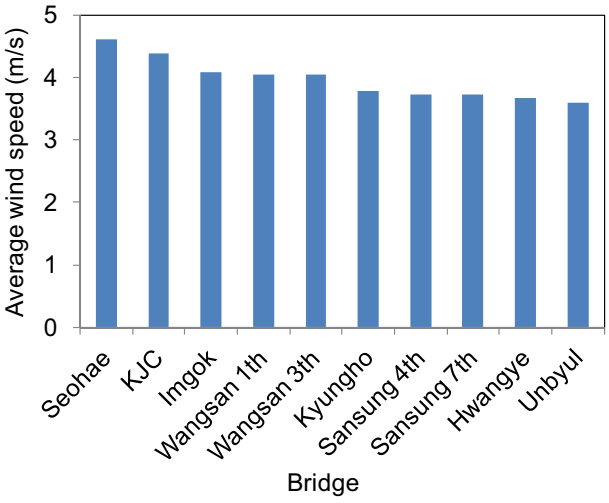

Figure 1. Average wind speed measured at highway bridges in Korea.

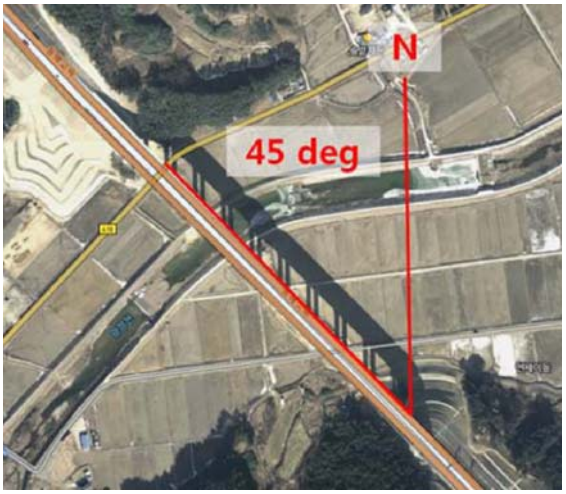

Figure 2. Aerial view of the KJC Bridge.

3.2 *Wind data at test bed bridge*

10 minutes averaged wind speed and direction of the KJC Bridge were measured from June 2007 to May 2008 to obtain the basic data for assessment of traffic safety. KJC Bridge was tilted 45 degrees from the north. As shown in Figure 3, the main wind direction represented frequency of more than 50% from the southeast that was perpendicular to the bridge. These wind direction was good to install wind turbines near the side surface of bridge girder.

The MCP interpolation was not carried out because of poor correlation among wind speed at the bridge and those at nearby weather stations. The wind speed and directions at the bridge seemed to be strongly influenced by local topography. Table 1 shows annual mean wind speed, power density, and Weibull scale and shape parameters above the girder of KJC Bridge, which were respectively 4.38m/s, 173W/m^2, 4.95 and 1.9. The graphical representation of the same data in the table is given in Figure 3. Figure 4 shows probability distribution function for the observed wind speed above the girder from June 2007 to May 2008.

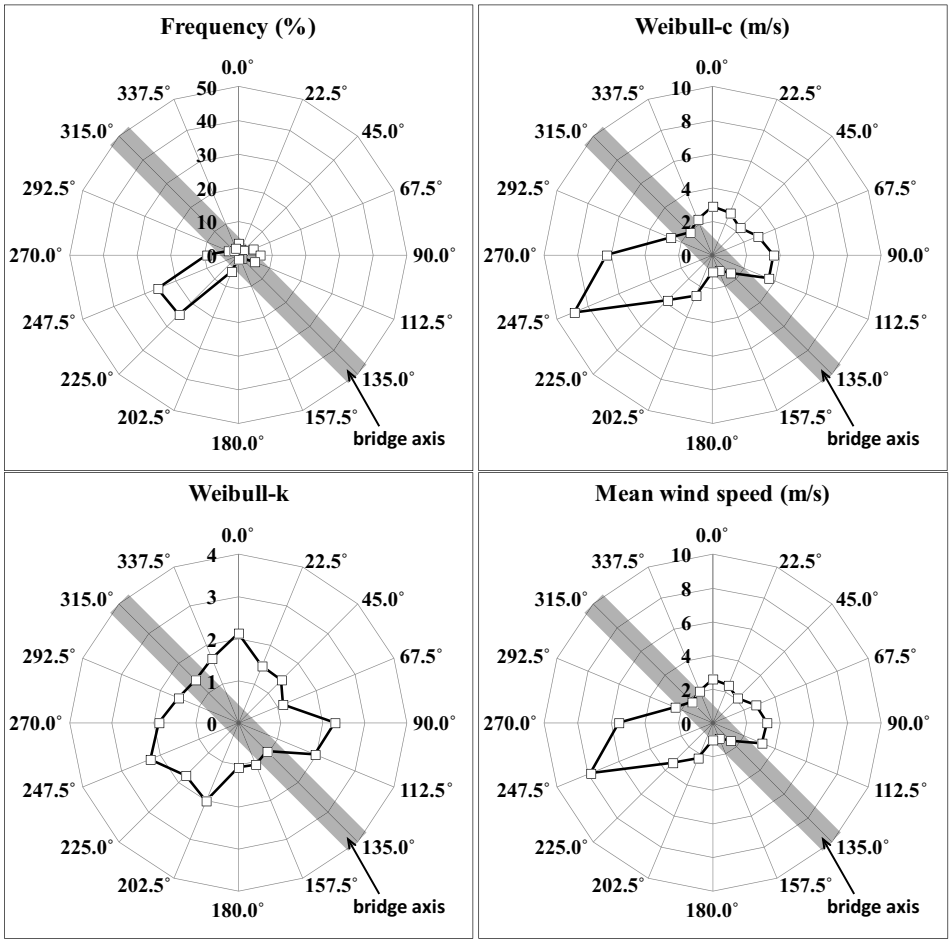

Figure 3. Wind characteristics of KJC Bridge. Marks represent the values evaluated from the measured wind data, and the shaded area represents bridge axis.

Table 1. Wind characteristics above the girder from June 2007 to May 2008.

No.	Angle (°)	Frequency (%)	Weibull-c (m/s)	Weibull-k	Mean wind speed (m/s)	Power Density (W/m²)

3.3 *Estimation of annual energy prediction at test bed bridge*

By applying the measured wind data and associate Weibull distribution into the Equation (1), annual energy production of a turbine equipped at bridge girder was roughly estimated. In the study, a wind turbine with rated power of 2.4kW was assumed to be installed at bridge. The power performance curve of the target wind turbine, Skystream3.7, is shown in Fig. 5. Fig. 6 shows estimation of energy production for the observed wind speed above the girder from June 2007 to May 2008. In this case, the annual energy production estimated from histogram was 3.26 MWh, and that from Weibull distribution was 3.21 MWh. The Weibull distribution could be effectively used for estimating energy production at present wind data.

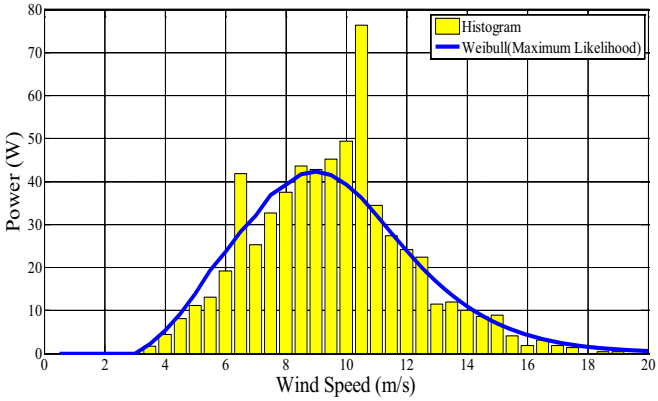

Figure 6. Estimation of energy production from the observed wind speed from June 2007 to May 2008

4 PLACING WIND TURBINES AT BRIDGE GIRDER

It was very important to decide where the wind turbines were installed at bridge girder. The electric output power might be varied depending on position of the wind turbine because wind speeds around the girder are different at point by point. However wind flow field near the girder was complicated and was dependent on girder shape. Accordingly, numerical simulation based on computational fluid dynamics (CFD) analysis was first performed, and then wind tunnel test were carried out in order to investigate wind speed, wind direction and turbulent intensity around the bridge girder.

4.1 *Numerical simulation*

For the selection of the optimal installation location for wind turbines, CFD analysis was performed to examine the flow field around the bridge girder prior to wind tunnel test. A commercial CFD software, FLUENT, on supercomputer in Korea Institute of Science and Technology Information was used in the analysis. Conditions and results of analysis are as follows.

In the two dimensional CFD analysis, a typical the bridge girder section at center span was adopted and pier was not modeled. Uniform wind speed of 30m/s was applied to the input domain regardless of height variation. Wind barrier installed at west side of the girder was included in the modeling. Transmittance of the wind barrier (wind speed passing wind barrier per basic wind speed) was set at the rate of 50%. Analysis was performed for two different wind directions; the southwest direction and the northeast direction. In former case, wind flow passed through the wind barrier at windward edge.

Figure 7 shows analysis results for two different wind directions. From the figures, wind speed just near the bridge girder decreased significantly, yet wind speed increased at beneath or above the girder height. Both safety of traffics and power efficiency of wind turbine were considered in determination of wind turbine position. Positions above the girder slab were excluded from the installation place for wind turbine to prevent any effects on high speed traffics passing the bridge. In the beneath of the girder, the wind speed at 13m beneath the bridge slab was respectively 17% and 2% higher than oncoming wind speed. In the figure, “x” mark denotes possible position of wind turbine to get more electric energy and less effect on traffics. Figure 8 shows variation of wind speed along height from leeward and windward edges of slab. It is apparent from the figure that wind speed boosts up at a few meters depart from the girder.

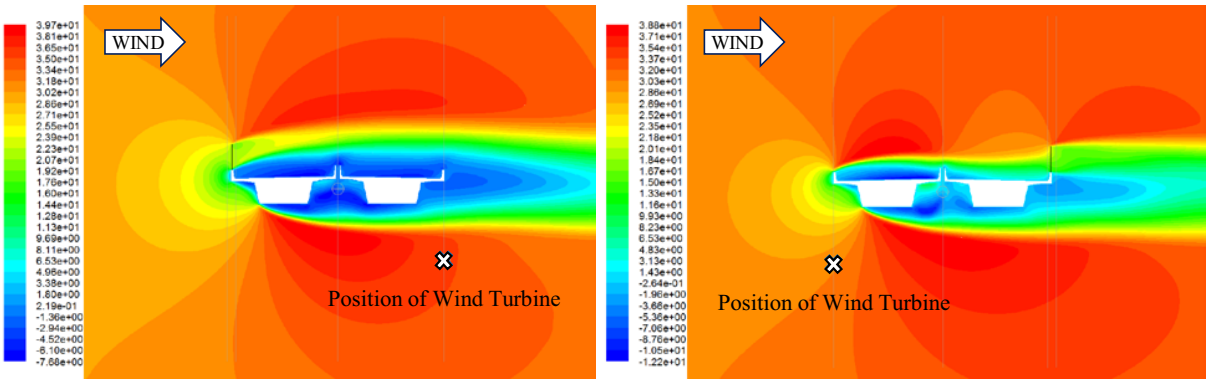

Figure 2. Contour of x-direction wind speed. left: wind barrier at windward edge, right: wind barrier at leeward edge.

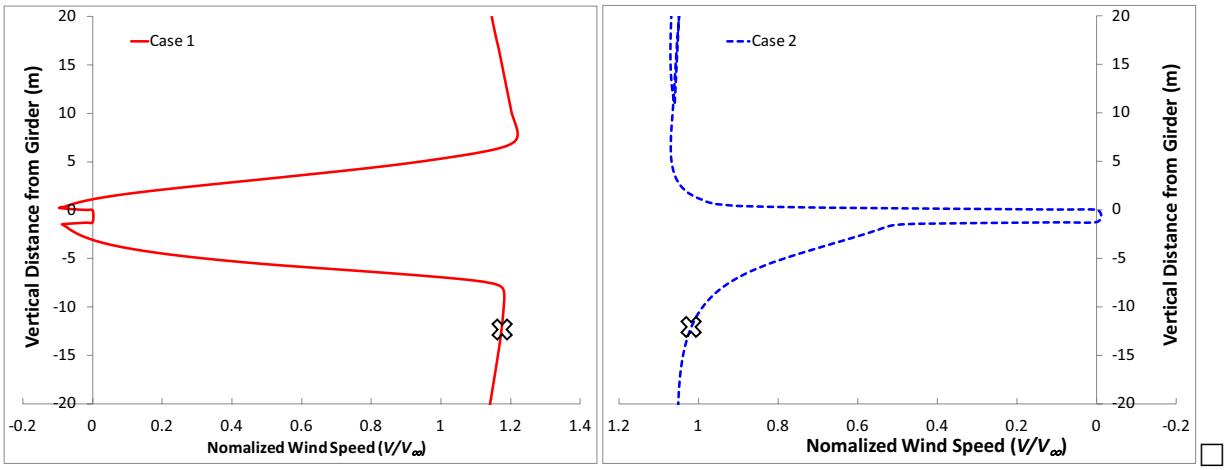

Figure 3. Variation of wind speed along height (a) from windward edge of slab, (b) from leeward edge of slab.

4.2 *Wind Tunnel test*

Wind tunnel test of single span bridge was performed at KOCED Wind Tunnel Center in Chonbuk National University. Model scale was 1:15. Wind speeds were measured at total 113 points near the bridge girder to investigate the flow field. Figure 9 shows the bridge model in the wind tunnel.

This closed return type vertical returning wind tunnel has two test sections. The tests were carried out at the high speed test section of 5m(W) × 2.5m(H) × 20m(L). The wind tunnel has five fans and motors with 275 KW each. The free stream velocity of this low speed test section ranges from 0.5 m/s to 31m/s. The mean velocity of the free stream flow was made by using two pitot tubes and pressure transducers (Setra 239). A temperature and humidity sensors (Vinotech GHP-20R) was used to evaluate air density. DANTEC CTA-90C10 constant temperature anemometer incorporated with DANTEC 55P11 hotwire sensors was used to measure the turbulent wind velocity near the bridge girder. At each measurement, velocity data for 100 seconds were acquired at a 6 kHz sampling rate.

Figure 10 shows wind speed contour around bridge girder measured from wind tunnel test. Undisturbed input wind speed was 10m/s. The wind speed at 10m beneath from bridge slab was 27% higher than oncoming wind speed. Turbulent intensity at the position was 4.1%. Finally it

was decide to install the wind turbine at 10m beneath the bridge slab to get more electric energy and not to disturb the passing traffics.

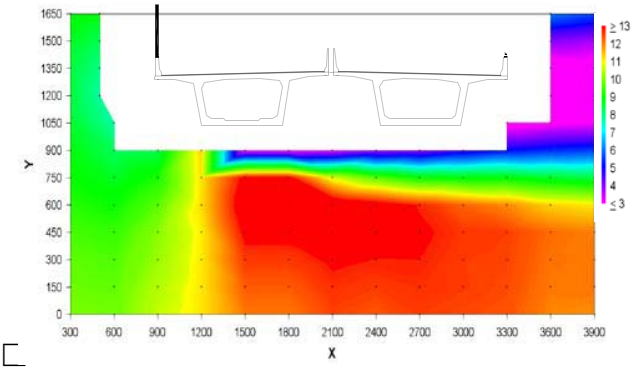

Figure 5. Wind speed measured at wind tunnel test.

5 FIELD MEASUREMENTS AND RESUTLS

5.1 *Wind turbines*

As shown in Figure 11, two wind turbines have been installed at 10m beneath the bridge slab of the KJC Bridge. The first wind turbine has three blades in horizontal axis. Diameter and rated power are respectively 3.7m and 2.4kW. The second one is Savonius type vertical axis turbine with 2kW rated power. Diameter and height of the second one are 0.8m and 1.4m respectively. Self weights of the two wind turbines excluding tower were 93kg and 140kg respectively.

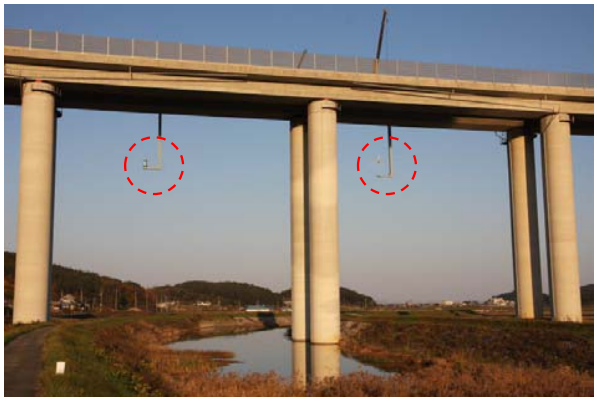

Figure 6. Tow wind turbines installed at the KJC Bridge.

Figure 7. Monitoring system at bridge site.

5.2 *Monitoring system*

Monitoring system shown in Figure 12 was designed and installed at the bridge to measure wind data as well as generated electric power. Total three cup anemometers provided by NRG System were equipped at the bridge; two at near each wind turbines, and one at 10m above bridge slab to measure undisturbed wind speed. Two digital power meters provided by LSIS were used to measure the electric voltage, current and power from wind turbines. All data from

electric power meters, anemometers, wind direction sensors, temperature sensor, relative humidity sensor and barometric pressure sensor have been recorded at the data logger, and periodically transmitted to remote computer at KOCED Wind Tunnel Center in Chonbuk National University through cellular network.

5.3 *Short term monitoring results*

The wind data and electric power at the KJC Bridge for every 10 minutes from 2/1/2012 to 3/31/2012 were measured by using the monitoring system. Figure 13 shows the frequency of occurrence and mean wind speed as function of wind direction. Wind shows strong directionality in southwest as was expected from the wind data at 2007~2008.

Table 3 summarizes the energy production during two months monitoring. It is clear from table that the mixture Weibull distribution reveals more accurate estimation of energy production compared with the conventional Weibull distribution. Power estimation error for the Weibull distribution was 6.4% but the mixture Weibull distribution showed 1.4% error in the estimation. The superiority of mixture Weibull distribution compared with conventional Weibull distribution can be clearly seen at Figure 14.

When we compare the recently observed two months data and those at the same period in 2008, there is some difference between two results. The generated electric power was less than expected one because of mainly poor average wind speed compared with that at 2008. Average wind speed at 10m above slab was 5.48 m/s at 2008 but decreased to 4.75 m/s at 2012. Moreover the wind speed at 10m beneath the slab was about 3% less than that at 10m above the slab.

Table 3. Wind energy production for two months from February to March.

Period	Location	Average speed (m/s)	Power density (W/m^2)	Energy production (kWh)	
				Weibull	Mixture Weibull
2/1/2008~3/31/2008	above slab	5.48	227	701	734
2/1/2012~3/31/2012	above slab	4.75	165	642	668
	beneath slab	4.61	95	414	434
				440 (measured)

6 CONCLUDING REMARKS

This paper presents design, analysis, test, installation and monitoring of wind turbine equipped at elevated bridge in order to enable the self powered bridge. Two small wind turbines have been installed beneath the bridge girder that was selected from 86 sites considering wind energy potential and safety of passing traffics. The installation position of wind turbine near the bridge girder was chosen from the CFD analysis and wind tunnel tests, where wind speed boosted 17~27% by oncoming wind. Monitoring results for recent two months reveals a high correlation between the wind speed probability distribution and actual generated electric power.

ABSTRACT: A study of key parameters affecting flutter characteristics and power output levels from a thin piezoelectric patch immersed in a parallel, smooth flow was examined. The piezoelectric patch vibration amplitudes were augmented through the use of a polymeric "leaf", freely hinged to the trailing edge of the patch. The leading edge of the patch was rigidly clamped to a relatively narrow, rectangular support that extended across the wind-tunnel test domain, giving effectively a two-dimensional testing scenario. The influence of clamping base geometry on the flutter characteristics was evaluated. It was found that the stream-wise dimension of the rectangular clamp had little effect, whilst an increasing cross-stream dimension tends to delay the onset of flutter. Stream-wise proximity experiments were conducted with two leaf-stalk systems, and it was found that there exists a point tandem and downstream of a fluttering leaf-stalk system, whereby a second leaf-stalk can output more than 40% more power than when alone.

KEYWORDS: piezoelectric, energy harvesting, flow-induced flutter, vortex shedding

1 INTRODUCTION

A fluttering leaf on a tree, a vibrating automobile antenna, or blinds flapping in the wind; all of these seemingly trivial events actually reveal a complex engineering and scientific problem: fluid-flow induced flutter. Traditionally, flutter has been considered a detriment to structural integrity, and engineers would design the structure to obviate flutter occurrence. In fact, much research has been conducted to comprehend the underlying mechanisms of an object fluttering in a fluid flow (e.g. Lord Rayleigh 1879; Theodorsen 1935; Kornecki *et al.* 1976; Fredericks *et al.* 1986; Huang 1995; Paidoüssis 1998; Zhang *et al.* 2000; Argentina & Mahadevan 2005; Paidoüssis *et al.* 2011).

Recently, however, there has been a realization that flutter could be exploited for the purposes of energy harvesting, using thin, flexible piezoelectric materials immersed in a fluid flow. Flutter is related to resonance of the system, and thus the amplitudes of an object in flutter become large. In order to extract large amounts of energy from a piezoelectric material large mechanical strain must be applied, and if this can be induced by flutter then energy can be extracted from a fluid flow. One of the first known attempts in the laboratory environment to realize this concept was by Allen & Smits (2001); where flutter of a thin, polyvinylidene-fluoride[1]-laden membrane was induced by introducing an upstream vortex-shedding, bluff body. The vortices would impinge on the flexible membrane, and due to the imposed pressure gradients, would cause time-varying membrane deformation according to the vortex shedding frequency of the bluff body. This method of flutter excitation is classed by Naudasher & Rockwell (1980) as Extraneously Induced Excitation, or EIE; flutter is induced from external pressure gradients caused by turbulence or vortices. Taylor *et al.* (2001) carried out a similar study, whereby a bluff body was used

[1] Polyvinylidene-fluoride (PVDF) is a flexible, isotropic piezoelectric material.

to excite undulations of the so-called piezoelectric "eel" within a water flow; however, they focused their attention on optimizing the electrical subsystem. Pobering & Schwesinger (2004) suggest two designs that exploit vortex shedding in a water flow; along with a simplified analysis, they state that such a piezoelectric system, when scaled up, could have a higher power density than that of a conventional wind turbine.

Dickson (2008) envisioned a piezoelectric flutter system that would not only be efficient, but aesthetically-pleasing and safe; a tree-like construct with multiple piezoelectric "stalks" with polymeric "leaves" attached the stalks – figure 1 shows this concept.

Figure 1. The piezoelectric "tree" concept proposed by Dickson (2008).

Li & Lipson (2009) initiated research on this concept, by starting with a single piezoelectric, cantilevered leaf and stalk system in parallel, laminar flow. There was no vortex-shedding bluff body in this study, as flutter in this type of arrangement is meant to be self-induced. Naudasher & Rockwell (1980) classified this type of flutter excitation as Movement Induced Excitation, or MIE. Here, flutter is caused by a small perturbation of the membrane in the flow and further growth of this instability. Most theoretical and numerical studies in the past have focused on this type of flutter (see: references 1-9), because the instability growth and mechanisms by which the flutter initiates are still not quite fully understood. An important parameter to consider with this type of flutter is the critical flutter speed (U_c), which is the flow speed at which flutter of the membrane starts. In their studies, Li & Lipson (2009) examined different piezoelectric-stalk lengths, as well as different leaf geometries. They found that a triangular-shaped leaf coupled with a piezoelectric short stalk in the vertical configuration (Fig. 2b), gave the highest power output when properly load-matched, at a wind speed of 8.0m/s.

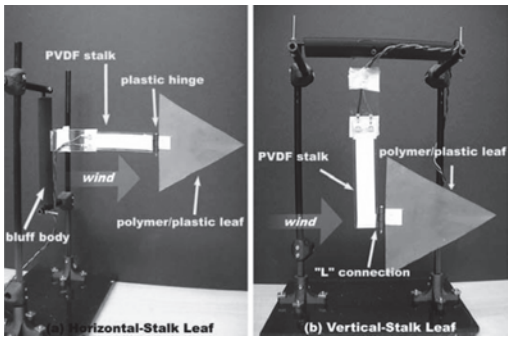

Figure 2. The two different piezoelectric leaf and stalk arrangements used by Li & Lipson (2009, Fig. 5).

They concluded that the hinge might play a significant role in amplifying the vibrations of the piezoelectric stalk, though no analysis was carried out.

Bryant *et al.* (2011) looked at the aerodynamic interaction between two piezoelectric/leaf beams, and the subsequent influence on the power output. The stalks were constructed of thin steel with a piezoelectric patch bonded along their length. In their experiments, one piezoelectric/leaf beam was placed at a fixed point in a laminar-flow wind tunnel, and another identical replica was placed downstream at varying stream-wise and cross-stream locations. It was found that when the second beam was placed aligned and downstream of the first beam, it could produce up to 30% more power in tandem than when alone. At all times, the frequencies of the beams were monitored, and the resistive load adjusted accordingly in order that the maximum power from each beam was always attained. The reason this was done is because there exists, for a given flutter frequency and piezoelectric capacitance value, an optimum load resistance value that will permit maximum power to be extracted (see Li and Lipson 2009; Roundy *et al.* 2003; Sodano *et al.* 2004). Nevertheless, real-world deployment of these piezoelectric/leaf devices would demand that minimal power is consumed by the device itself (i.e. would operate with a high efficiency), and it is unknown if the benefits of an active resistance tuning circuit would outweigh the performance degradation in terms of power output; Roundy & Zhang (2005) investigated active-tuning of a piezoelectric device via active mechanical resonance tuning and it was found that active tuning never resulted in a net power output increase, but active electrical tuning was not examined.

Such devices are likely to be "driven" by the atmospheric wind which is inherently turbulent and may approach from a wide range of angles, thus simulations or laboratory experiments in (usually) smooth flow may not give correct predictions of power outputs. Wind conditions vary widely with geographical location, notwithstanding the prevalence of local wind effects within urban settings. For instance, in Melbourne, Australia, the average wind speed in the Greater Metropolitan area as modeled by the Sustainable Energy Authority Victoria (2003) is 3.0m/s at a geometric height of 65 meters. However there are wind over- and under-speed effects, that occur due to topography and/or building proximity effects, hence the average wind speed may be far removed from the local speed.

Here, we aim to investigate the effect of the leading-edge geometry on U_c, as this has not been quantified in previous analyses. We also, for a given leaf area and aspect ratio, examine the power output effects of two of these piezoelectric beams in proximity with each other. Unlike Bryant *et al.* (2011), this will be done with a predetermined, load-matched circuit resistance that will remain unchanged during the course of the experiments.

2 METHOD

2.1 *Wind Tunnel Calibration and Setup*

The wind tunnel utilized in the experiments is a subsonic, closed-circuit design with an octagonal test section, measuring 1320mm high by 1070mm wide. A honeycomb mesh and an anti-turbulence screen, plus a 4:1 contraction ratio inure the test-section incoming airflow. A 134-horsepower DC motor powers a six-bladed fan, giving a maximum tunnel flow speed of approximately 45m/s. According to previous calibration work, the free-stream longitudinal turbulence intensity was much less than 3% (Creazzo 1999). A pitot-static tube installed that linked to an MKS Baratron® was used for velocity measurements, according to a standardized air density value of 1.23kg/m^3. A simple error analysis was carried out, in order to determine the impact of standardizing the density across a large range of tests, and a maximum error of 0.5% in velocity

measurements was obtained. Tunnel blockage due to the experimental setup was also found to be negligible.

Due to the electrical nature of the experiments, the wind-tunnel electromagnetic noise (EMI) was evaluated so that a signal-to-noise ratio could be estimated and any destructive interference identified and attenuated. First, the coaxial, shielded cable for the experiments was connected to a 20MHz oscilloscope, and the other end left free near the wind tunnel (but not contacting the wind tunnel, so as to avoid an 'antenna' effect). The wind tunnel was ramped up to a wind speed of 14.6m/s and voltage curve observed, with no noticeable peaks occurring throughout the frequency sweep range. Next, a piezoelectric element was mounted in the wind tunnel, and the shielded cable connected to the electrodes. The voltage curve was then observed with no wind speed, and a small peak of the order 2.5-10mV was appearing at a frequency of 40Hz, presumably stemming from the fluorescent lights in the room. Finally, the voltage curve was evaluated for a piezoelectric element in flutter, initiated by the airflow in the wind tunnel traveling at around 5.1m/s. The voltage peaked at 3-3.2V, at a frequency of around 7.1Hz, the flutter frequency of the piezoelectric element. Therefore, the signal-to-noise ratio was deemed large enough that no further action was required.

2.2 *Base Clamping Geometry Experimental Setup*

In order to assess the influence that the clamping geometry could potentially have on the critical flutter speed, a quick parametric study that included varying the length and width of the rectangular clamp was carried out. Figure 3 shows a diagrammatic of the clamp cross-section characteristic dimensions.

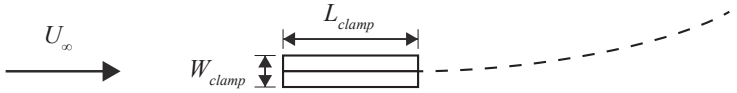

Figure 3. The base clamping setup, showing the clamping length, L_{clamp}, and the clamping width, W_{clamp}. The dashed line illustrates the test specimen, and the free-stream uniform flow is denoted by U_∞.

The test specimen was chosen based on tests performed elsewhere, and consisted of a polypropylene membrane that was 248mm long by 60mm wide by 0.35mm thick, placed well outside of the tunnel boundary layer. The membrane was clamped at its leading edge so that the effective length was 236mm. The membrane material density is 995kg/m^3 and the elastic modulus is 1261MPa. A stand was installed in the wind-tunnel test section to fix the top of the clamping base, and the bottom was fastened to the wind-tunnel floor. Guying wire was used so that there would be no transverse vibrations of the clamp in the flow, as shown in figure 4.

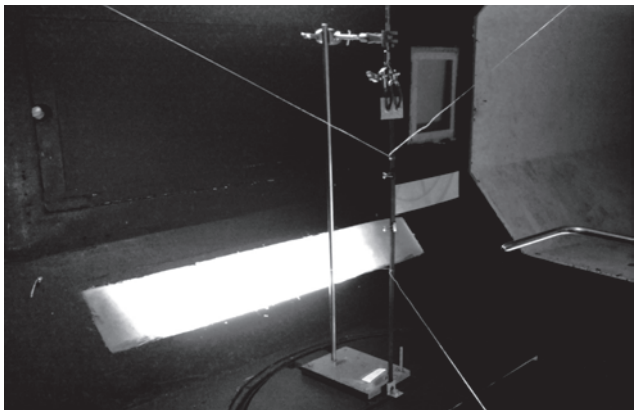

Figure 4. A photograph of the clamping geometry sensitivity tests wind-tunnel setup.

The clamping base was fabricated out of two lengths of 1.25mm-thick steel; one 600mm-long strip that extended from the stand to the wind-tunnel floor, and a 100mm strip that would be fastened to the other strip with the specimen clamped in between (Fig. 4). The baseline width of the clamping base was 3.5mm, and the baseline length was 12mm.

The base clamping length was varied first, while keeping the clamping width at the baseline dimension. The length was varied from the baseline value to 70mm. Then, the clamping width was altered while keeping the baseline length dimension; the width was varied from 3.5mm to 12.5mm. For each dimension, the wind speed was ramped up slow enough so as to ensure steady-state flow, and the membrane start-up flutter wind speed was recorded. A Reynolds number range of 129,000-214,000 was observed in the testing, based on the membrane effective length.

2.3 *Proximity Testing Experimental Setup*

Due to their flexibility, durability and relatively low cost, PVDF piezoelectric patches were utilized (Measurement Specialties, Inc., LDT1-028K/L type) in these experiments. The length, width and thickness of the piezoelectric patch are 72mm, 16mm and 205 !m respectively. These patches were the same ones used by Li & Lipson (2009) in their work. Bryant *et al.* (2011) utilized Lead-Titanium-Zirconate (PZT) patches bonded to their steel beams, which are capable of outputting higher power but are generally less durable than PVDF.

The leaves used for the experiments were fabricated from 0.35mm-thick polypropylene (whose properties are mentioned in section 2.2). The shape of the leaf is an isosceles triangle with dimensions of 80mm by 80mm (base by height), as this is the shape and area that caused the PVDF's to output the highest power in previous work (Li and Lipson 2009). The leaf and piezoelectric stalk were coupled with a plastic revolute hinge, which would allow free rotation of leaf about the vertical axis. The mass of the hinge was 0.009kg. The leading edge of the piezoelectric stalk was securely clamped and the leaf end was free. The clamping length utilized for these experiments was 12mm. This length was chosen in order to securely hold the leads and wires attached to the PVDF stalk. The clamping strips were bolted to the wind-tunnel floor and ceiling, and guyed to the sidewalls to prevent any transverse oscillations. The clamping base was also taped, so as to prevent the piezoelectric electrodes from contacting the metal. The overall length (L) of the system with the piezoelectric stalk, leaf, hinge and the clamping length were measured to be 180mm.

In order to determine the optimum placement of these leaf-stalk systems in a given volume, two such systems were placed co-linearly in the wind tunnel and the stream-wise distance be-

tween them (*d*) varied, see figure 5. The separation distance was normalized by a single leaf-stalk length such that it is expressed as (*d/L*). At first, the two devices were positioned with a normalized separation distance of 1.0. Subsequently, the separation distance was increased to 2.0 and 3.0. This was done to examine the aerodynamic effects of the upstream leaf-stalk system on the downstream one. The wind speed range considered here was 3-8m/s. Figure 6 shows a photograph of the wind-tunnel setup.

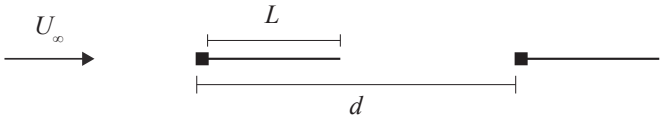

Figure 5. A cross-section schematic of the co-linear proximity experiments, showing the relevant parameters.

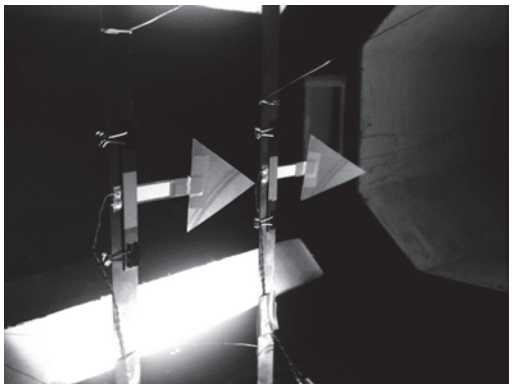

Figure 6. A photograph of the proximity experimental setup in the wind tunnel.

The piezoelectric stalks were connected to a simple parallel electrical circuit. The load resistance used for this experiment was 5.6MΩ. This value was experimentally obtained by recording the power output from a single leaf-stalk system across various load resistances in parallel (R_L); from 1.0MΩ to 60MΩ, at a constant wind speed of 5.0m/s. The voltages from the piezoelectric stalks were measured using a differential probe (Elditest, GE8115) which has a high internal resistance (60MΩ) compared to the load resistance. The data from the differential probe was sent to a DAQ board (National Instruments, BNC2110) and the RMS voltage (V_{RMS}) of the AC waveform was calculated in one-second intervals using LabView®.

The electrical power generated in one second of leaf-stalk flutter is given by equation 1 (Bryant *et al.* 2011):

$$P_i = \frac{V_{RMS_i}^2}{R_L} \tag{1}$$

Then, the total average power generated over the 30-second data acquisition window was calculated as:

$$P_{ave} = \frac{1}{30}\sum_{i=1}^{30} P_i \tag{2}$$

3 RESULTS AND DISCUSSIONS

3.1 *Clamping Base Geometry Sensitivity*

Figures 8 and 9 show the experimental results for the sensitivity of the critical flutter speed to the clamping length and width dimensions, respectively. The critical flutter speed is normalized by the critical flutter speed observed with the baseline clamp dimensions. The ordinate axis is plotted as such, for clarity.

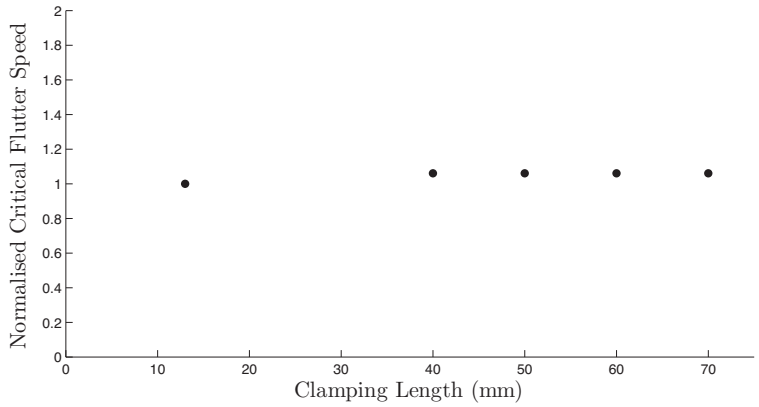

Figure 8. Clamping length sensitivity results.

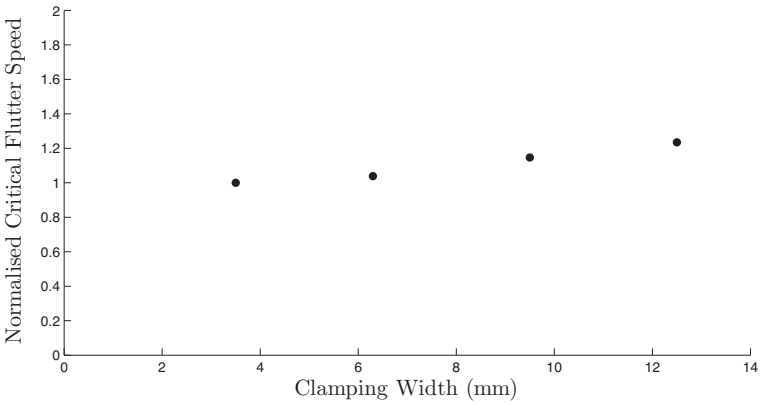

Figure 9. Clamping width sensitivity results.

Altering the length of the clamping base does not seem to affect the critical flutter speed of the membrane. This could mean that the stream-wise boundary layer manifesting on the clamp topology is not causal to membrane flutter, at least for the Reynolds number range experienced. However, if the length of the clamping base were to greatly increase, assuming a constant width, the membrane root would then by definition encounter a thicker boundary layer, since the boundary layer thickness varies as the square root of distance from the leading edge (e.g. see Anderson 2007, chpt. 18). Additionally, depending on the state of the boundary layer at the root location of the membrane, whether laminar or turbulent, the critical flutter speed may change.

The clamping width does seem to affect the membrane critical flutter speed. Considering previous theoretical treatments of flutter (e.g. Kornecki *et al.* 1976; Argentina and Mahadevan 2005), one major assumption made is that the clamped leading edge of the membrane is infinitely stiff, yet infinitesimally thin. Of course, this is very difficult to achieve in practice, and it can

be seen that as the width of the clamp deviates upwards from the infinitesimal value, there comes an increase in critical flutter speed. This could be attributed to vortex shedding off of the clamp at a frequency other than the membrane natural frequencies, thereby causing destructive interference and henceforth a damping effect. However, once a clamping width that generates shed vortices at a frequency equal to the membrane natural frequency is deployed, it is anticipated that the critical flutter speed would decrease dramatically.

3.2 *Proximity Experimental Results*

Figure 10 presents the proximity testing results for the downstream leaf-stalk. The output power is normalized by the power extracted with no upstream leaf-stalk (P_{baseline}) present, and this quantity is plotted against the wind speed.

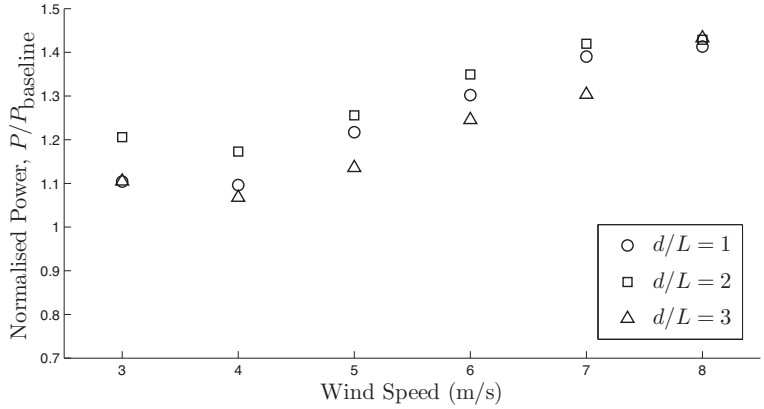

Figure 10. The downstream leaf-stalk power output as a function of wind speed for multiple separation distances.

A maximum normalized power of more than 1.4 is being obtained at 8.0m/s, even though the load resistance was optimized for a wind speed of 5.0m/s; this suggests that there is potential for even higher power outputs from the downstream leaf-stalk, should an actively-tuned load resistance be used. Bryant *et al.* (2011) obtained a trailing leaf-stalk normalized power of 1.3, for a wind speed of around 6-7m/s, so the results obtained here agree quite well. This correlation is despite a smaller cantilever length, different piezoelectric material and configuration, a different leaf shape, and a leaf area less than half of what Bryant *et al.* (2011) use. This strongly suggests that the increase in output power is purely an aerodynamic phenomenon, and not a structural dynamic one. Also, the flutter type occurring in this wind speed range is steady state, limit-cycle, sinusoidal; elsewhere it was determined by power spectral analysis that this flutter type contains the most bending energy at the discrete membrane natural frequencies (Alben and Shelley 2008). Once the flutter transitions to chaotic, stochastic motion with random snap-through events (Connell and Yue 2007), the maximum attainable power decreases and response becomes more broadband. It can be seen in figure 10 that for d/L = 1 and 2, the normalized power approaches a maximum. However, for d/L = 3 the normalized power growth rate is instead increasing. It could be that for separation distances of 1 and 2, transition to the chaotic flutter regime is starting and thus the power output has reached a peak. It is also interesting to note the local minimum transpiring at a wind speed of 4.0m/s – this is most likely due to anti-resonance occurring between the upstream leaf-stalk vortex shedding frequency and the flutter frequency of the downstream leaf-stalk.

Figure 11 shows the normalized power plotted against the normalized separation distance, for wind speeds of 3.0 and 8.0m/s. Clearly, there is a maximum occurring at a separation distance of 2 for a wind speed of 3.0m/s, but there is no global maximum occurring with a wind speed of 8.0m/s.

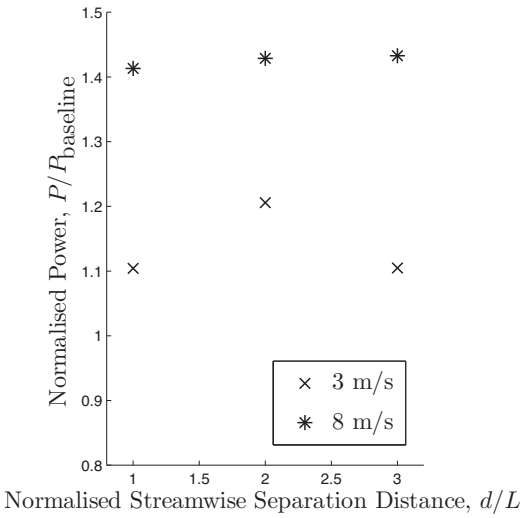

Figure 11. The normalized power plotted against the normalized separation distance for the minimum and maximum wind speeds tested.

Evidently, optimum increased power output is occurring for the downstream leaf-stalk at a normalized separation distance of 2, as this is also what Bryant *et al.* (2011) found. However, the coalescence of the normalized power output across the separation distances for a wind speed of 8.0m/s is intriguing. Perhaps the higher kinetic energy in the flow sustains the advection of the shed vortices from the upstream leaf-stalk flutter and delays transition to chaotic flutter, which was found to occur at wind speeds slightly greater than 8.0m/s for a single leaf-stalk. Further work would entail flow visualization using a dual smoke wire approach.

4 CONCLUSIONS

The sensitivity of the critical flutter speed to the clamping geometry was first examined. The results suggested that the clamping length has little or no effect on the critical flutter speed, and that an increasing clamping width tends to delay the onset of flutter. These results only hold for parallel, laminar flow; it would be erroneous to extrapolate to turbulent flow, and also the effect of the wind approaching from any direction hasn't been quantified. That said, any future work concerning piezoelectric fluttering systems could benefit from the findings, especially if there is a need to control the critical flutter speed, or perhaps minimize it.

Proximity testing, investigating exclusively the effect of a tandem configuration in the streamwise direction, was carried out. Results agree well with findings reported elsewhere for similar wind speeds tested. It is found that for wind speeds of 3-7m/s, a normalized separation distance of 2 causes the greatest increase in power output from the downstream leaf-stalk system, over a 40% increase. A wind speed of 8.0m/s caused a coalescence of the normalized power across the range of separation distances, and it is speculated that the increased kinetic energy in the flow

more readily sustains the advection of the vortices shed from the upstream leaf-stalk system, such that the transition of the downstream leaf-stalk system to chaotic flutter is impeded.

The flight of roofing tiles during strong winds

Richards P. J. [a], Norris S. E. [a]

[a]*Department of Mechanical Engineering, The University of Auckland, New Zealand*

ABSTRACT: Roof tiles are a common type of windborne debris and have been associated with significant damage during several severe storms. They have sufficient mass to do damage and sufficient area to accelerate quickly. Trajectory analysis is conducted for tiles breaking free from several generic buildings with a variety of roof slopes. These show that the upward flow around the windward eaves can lift a tile over the building, from which point it can be carried well downwind. The range and speed achieved under these conditions is much greater than would occur if the tile was released from the same height well away from the building. With steeper roofs a stronger gust is required to lift the tile over the roof but if this occurs, then the range is extended beyond than which would occur with the same gust but a shallower roof. It is shown that the flight of roofing tiles depends very strongly on the point of origin and the wind direction.

KEYWORDS: Windborne debris, roofing tiles.

1 INTRODUCTION

During extreme wind events considerable damage may be caused either directly or indirectly by windborne debris. In assessing the failures of structures during windstorms, Minor *et al.* [1] observed that windows were traditionally designed for wind pressures, but that breakage from impacts by windborne debris was the most common failure mechanism. While breaking a window may not be too important in itself, such breakages can result in internal building pressures that significantly increase the net load on building components, such as the roof, which in some cases my result in structural failure. In addition, since strong winds are often associated with heavy rainfall, a broken window can allow the ingress of water, leading to considerable damage to contents or structure. In 1974 Tropical Cyclone Tracey devastated Darwin in northern Australia. Walker [2] noted that “pressurisation of buildings following failure of windward windows, generally due to windborne debris,” was one of the major factors contributing to the widespread damage. Two decades later such debris related failures remained a problem, with Minor [3], referring to the damage inflicted by Hurricane Andrew in 1992, commenting “With few exceptions, glazing systems performed poorly, largely due to the impact of windborne debris, and damage to building contents was extensive”.

2 COMMON TYPES OF DEBRIS

The relevant source and type of debris varies greatly. Minor *et al.* [4] concluded that with tornadoes the most prevalent type of windborne debris in residential areas was timber from wood frame houses, whereas Minor [1] discusses several situations where roof gravel caused extensive glass breakages on high rise buildings, but also notes that investigations in south Florida following Hurricane Andrew tended to point to roofing tiles as the most prevalent type of windborne debris. He points out that initially the Dade County Building Code Committee chose a roofing

tile as the design missile for testing purposes but then recognised that it would be difficult to define a representative tile and almost impossible to propel a tile repeatedly with the same orientation and at the same speed as part of a standard test, and so ultimately the committee chose a 9 lb '2 × 4' timber instead. This test projectile is essentially the same as the 4 kg timber member with nominal cross-section of 100 × 50 mm, which first appeared in the Darwin Area Building Manual in 1976 and is still included in the Australia/New Zealand wind loading standard AS/NZS1170.2 [5]. For tropical cyclone affected areas this standard requires that internal pressure resulting from a dominant opening must be applied unless windows, doors and cladding up to a height of 25 m can be shown to be capable of resisting impact loading from windborne debris equivalent to:

1. Timber member of 4 kg mass with a nominal cross-section of 100 mm × 50 mm impacting end on at 0.4 V_R for horizontal trajectories and 0.1 V_R for vertical trajectories and
2. Spherical steel ball 8 mm diameter (approximately 2 grams mass) impacting at 0.4 V_R for horizontal trajectories and 0.3 V_R for vertical trajectories

where V_R is the regional wind speed, based on 3-second gust wind data. These test projectiles represent both roof gravel and larger debris such as tiles or chunks of framing timber.

Skerlj et al. [6], while analysing the damage caused by Hurricane Charley in 2004, noted "Single family residences constructed with clay tile roof covers performed poorly when mortar was used to attach the tiles to the roof structure as opposed to mechanical fasteners (i.e. nails or screws). Failed roof tiles can, and often do, become airborne and create additional damage by impact to either other sections of the roof from which they originate or to adjacent buildings." They also note that shutters significantly reduced damage in areas where tile roofs were common and that this went beyond just shielding the windows.

Following Tropical Cyclone Yasi, which affected northern Queensland in February 2011, Boughton et al. [7] made the following observations regarding the range of materials that had become windborne debris:

- Detached roof tiles had impacted other parts of the roof from which they had been removed and nearby buildings. Tiles were observed to have broken windows and penetrated steel roofing and wall cladding.
- Some pieces of timber close to the size of the standard test piece were observed. Some of these had penetrated the outer cladding of buildings but a few had made it into the inside other than through windows. One piece was observed to have come through a roof.
- Very large pieces of buildings had become windborne debris. These items included large assemblies of roofing and battens, significant portions of the roof structure, whole sheds and a complete shipping container.

3 ROOF TILES AS DEBRIS

It is apparent from the above comments that roof tiles are a significant form of windborne debris. This significance can be attributed to a number of factors including:

- Where roof tiles are used there are many hundreds, if not thousands, of individual pieces that have the potential to become a missile with a mass of several kilograms and an area large enough to attract sufficient aerodynamic drag.
- One tile pulling free is likely to lift its neighbour(s) and hence encourage others to break free in turn.
- The starting point for a roof tile trajectory is an elevated location which means that they can fly a reasonable distance.

- When roofing tiles are pulled free from their fixings they are likely to be in a region of flow where the velocity is locally accelerated. Hence the tile may achieve speeds which are higher than if they were simply released into the wind at that height.
- Most tiles are removed from the windward sloping section of the roof. The flow in this region will have an upward component and so tiles can be accelerated upwards in the early stages of a flight and hence can achieve greater distances.

4 SIMPLIFIED TRAJECTORY ANALYSIS

The ability of any piece of debris to accelerate and become a dangerous projectile can be partially characterised by the ballistic coefficient $B=C_D\rho A/(2m)$, where C_D is the average drag coefficient, ρ is the air density, A is the maximum face area (m^2) and m the mass (kg). Some typical values are given in Table 1, where the drag coefficient values are based on [8]. It includes the two standard test projectiles from the Australia/New Zealand Wind Loading Standard AS/NZS 1170.2 [5], a couple of typical roofing tiles, a lighter clay tile and a heavier concrete tile, and a section of roofing which has been arbitrarily assumed to be 3 m × 2.4 m and made up of 35 kg of roofing iron and 85 kg of attached timber battens and roofing framework.

Table 2 presents some calculated results for these five pieces of debris after a 20 m flight during a 50 m/s wind gust. This distance was chosen as a typical spacing of houses in a suburban area. For these simple calculations the wind is assumed to be uniform and the object is approximated as compact debris, that is no consideration is made of the orientation of the object.

The following points may be noted:

- All flights last less than 3 s (common design gust duration).
- All horizontal speeds are in excess of 40% of the gust speed (as used in [5]) and the four larger projectiles have reached 51-62% of the gust speed.
- The steel balls, which represent gravel or similar debris, have fallen 12 m and so would need to originate from a multi-storey building but the other projectiles have only fallen between 3.6 m and 6.2 m and so could originate from a single storey house.
- For such short flights the vertical speed is much less than the horizontal speed.

The tiles and timber projectiles have impact energies between 1 and 2 kJ, which is sufficient to do some damage, but perhaps more concerning is the corrugated iron and timber roof which has 60 kJ of energy on impact.

Table 1. Typical Windborne Debris Characteristics

	m (kg)	A (m^2)	C_D	B (m^{-1})
Steel Ball	0.002	5.03×10^{-5}	0.5	0.008
Clay Tile	2.3	0.1	0.9	0.024
Concrete Tile	4.5	0.14	0.9	0.017
Timber	4	0.2	0.8	0.025
Roof	120	7.2	0.9	0.033

Table 2. Data at x = 20 m during a 50 m/s gust

	Time (s)	Horizontal speed (m/s)	Height dropped (m)	Vertical speed (m/s)	Kinetic energy (J)
Steel Ball	1.7	20.2	-12.0	-13.3	0.6
Clay Tile	1.1	28.5	-4.7	-7.8	1006
Concrete Tile	1.3	25.8	-6.2	-9.2	1692
Timber	1.1	28.8	-4.5	-7.6	1776
Roof	1.0	31.0	-3.6	-6.7	60301

5 DETAILED TRAJECTORY ANALYSIS

Although the simple trajectory analysis in the previous section can provide some indication of the relative hazard posed by various types of debris the situation is far from reality. As noted earlier, when tiles break free from a roof they are immediately immersed in a complex 3-dimensional flow field. In order to assess the likely impact of this flow field the trajectory modelling program developed by Richards et al. [9] has been modified to incorporate a non-uniform flow field which has been computed using computational fluid dynamics (CFD). It is assumed that the flow field isn't modified by the debris and is simply a function of the building geometry. It is also assumed that the flight of a roofing tile occurs during a gust which has sufficient duration for it to totally envelope the building and hence the flow field may be approximated by a steady flow of the same strength. In the current study three gable ended buildings have been considered. Each is gable ended, has a length of 18 m, width of 12 m and an eaves height of 3 m, but they have roof slopes of 14°, 18.4° and 26.6°, which are slopes of 1 in 4, 1 in 3 and 1 in 2 respectively. With these roof slopes the buildings have ridge heights of 4.5, 5 and 6 m. Figure 1 illustrates the flow field around the 6 m ridge height building with the wind perpendicular to the ridge, it clearly shows the upward flow on the windward slope and the wake behind the building.

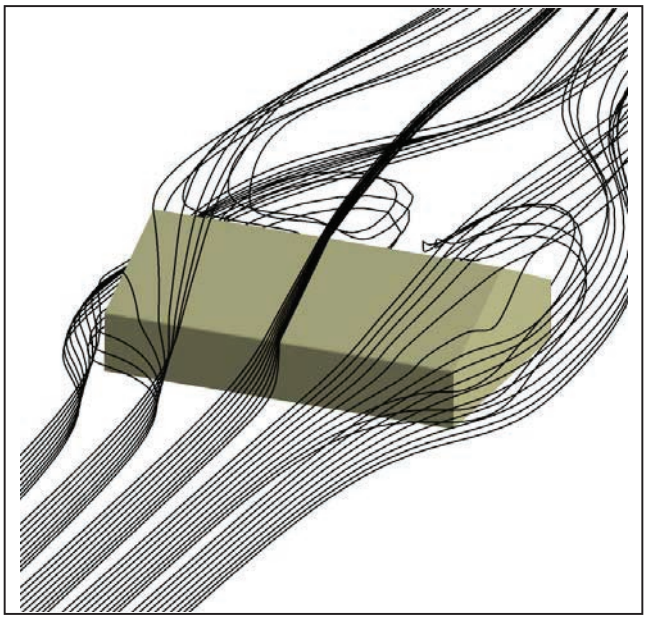

Figure 1. Streamlines around the 6 m ridge height building. Wind direction is perpendicular to the ridge.

5.1 *CFD modeling of the flow field*

The turbulent atmospheric flow around the buildings was modeled using the ANSYS CFX 13.0 CFD package as a steady flow approximated by the Reynolds Averaged Navier-Stokes equations. Different meshes were used for each building and flow direction, a 50 m high domain was used that extended 50 m upstream, 100 m downstream, and 50 m laterally from the center of the building, resulting in a 150 m × 100 m × 50 m domain for the cases when the building was aligned with the flow, and 150 m × 150 m × 50 m domain for the quartering flow. An unstructured mesh was used containing approximately 7.5×10^5 nodes, with inflation layers being used on the building and ground surfaces. The centre of the building is at co-ordinate (50,50,0).

At the upstream boundary, profiles of the velocity and turbulence scalars were prescribed using the velocity at the eaves height of the building (3 m) as the reference and with a roughness length appropriate for suburban terrain of $z_0 = 0.2$ m. Within the computational domain the ground was set as a no-slip wall with a roughness length of 0.01 m (appropriate for open terrain), since the suburban roughness elements (houses) were being explicitly modeled. The boundary for the building was set as a smooth no-slip wall, the top (and side surfaces when present) to symmetry planes, and the outlet was modeled as a constant pressure boundary with the velocity and turbulence fields having a zero-gradient normal to the boundary.

The turbulence was modeled using the SST two equation turbulence model [10], and the velocity field was discretized using the CFX solver's 'higher order differencing' scheme [11], a flux limited scheme that approaches second order with mesh refinement. For reasons of stability the turbulence scalars were discretized using first order upwinding. A convergence criterion of 10^{-6} was applied to the RMS residuals, resulting in the RMS residuals for a run being reduced by approximately 5 orders of magnitude.

The solution was interpolated onto a regular mesh, to allow easy interpolation of flow field data by the trajectory modeling code, with the velocities being non-dimensionalized with respect to the reference velocity at 3 m elevation (the height of the eaves). Within the trajectory code the wind velocity vector at each location was determined by tri-linear interpolation between the data points supplied by the CFD modeling, which is then scaled by the reference gust wind speed.

5.2 *Computed trajectories with the wind perpendicular to the ridge*

Figure 2 illustrates the central plane flow patterns of the 4.5 and 6 m ridge height buildings with the wind perpendicular to the ridge. With the steeper roof the flow on the windward slope has a much stronger upward component and this extends out over the much larger wake. However numerical experiments showed that with this steeper slope, if a clay tile (as specified in Table 1) broke free from the windward eaves then it would fall back onto the roof unless the gust wind speed was in excess of 60 m/s, while for a concrete tile the wind needed to exceed 70 m/s. In contrast a gust of only 35 m/s would lift a clay tile over the ridge of the 4.5 m high building and only 40 m/s for the concrete tile.

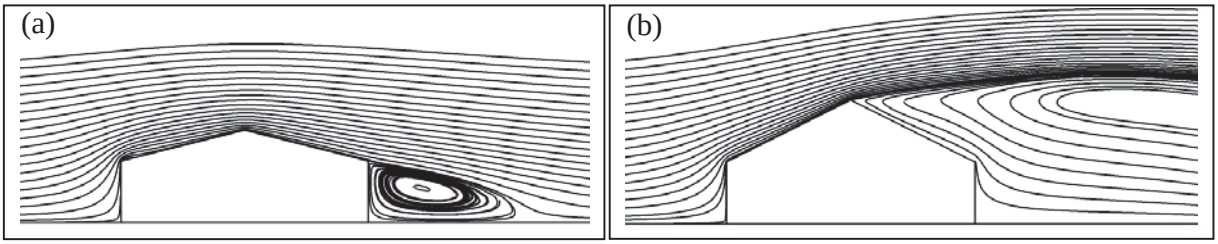

Figure 2. Streamlines on the central plane of (a) the 4.5 m and (b) 6 m ridge height buildings.

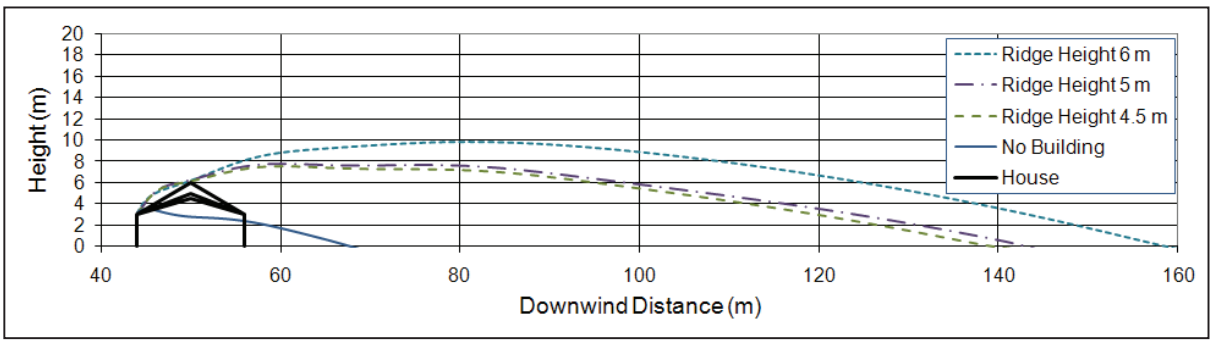

Figure 3. Computed trajectories of clay tiles originating from the windward eaves during a 65 m/s gust. Wind direction is perpendicular to the ridge.

Figure 3 shows the trajectories of clay tiles released from the windward eaves of the three buildings during a 65 m/s gust in comparison with that which occurs from the same height and in the same wind well away from a building. With this strong gust the flow over all of the buildings lifts the tiles well above the no building case and carries these tiles a long distance downstream. Without the influence of a building the tile falls to the ground about 24 m downwind, whereas even the lowest slope helps to carry the tile over 90 m and the steepest slope extends this to about 110 m. Since one cannot easily define the orientation of the tile at the moment it breaks free from its fixings a variety of release orientations have been tried and those shown here seemed to give the longest flights. Other orientations are likely to result in shorter flights or even the tile landing back onto the surface from which it has just broken free.

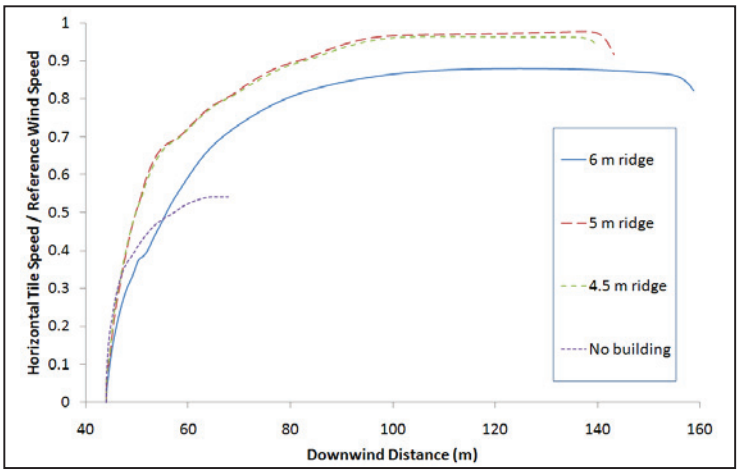

Figure 4. Ratio of clay tile horizontal speed to the reference gust speed (65 m/s at 3 m height) as a function of downwind distance.

Figure 4 shows the variation of horizontal velocity with downwind distance for these four cases. Without the influence of a building the velocity increases to just over 50% of the reference gust speed before it hits the ground. Since in this paper the reference velocity used is that at the eaves height (3 m), then this corresponds to about 35% of the gust speed at 10 m height in suburban terrain. This is slightly less than the 40% prescribed as a testing regime in AS/NZS 1170.2 [5]. However the results show that with the influence of a building not only the range but the velocity can be considerably higher. In all three building cases the maximum horizontal velocity attained

is over 80% of the reference gust speed and in two cases over 95%. This occur both because the flow field is modified, with some parts having higher speeds than the approach flow, and because the tile is lifted by the flow up and over the building to heights it wouldn't otherwise reach. With the 6.5 m ridge height case the highest velocity encountered by the tile is almost 80 m/s but it appears that the higher roof slope means that the velocities are lower in the early part of the trajectory. If the tiles reach about 95% of the 3 m gust speed then this corresponds to almost 70% of the 10 m gust speed, which is considerably higher than the testing regime in AS/NZS 1170.2. It may be noted that in the latter stages of the trajectory, as the tile drops into the wake and the slower flow near the ground, the velocity begins to decrease but this effect is fairly small.

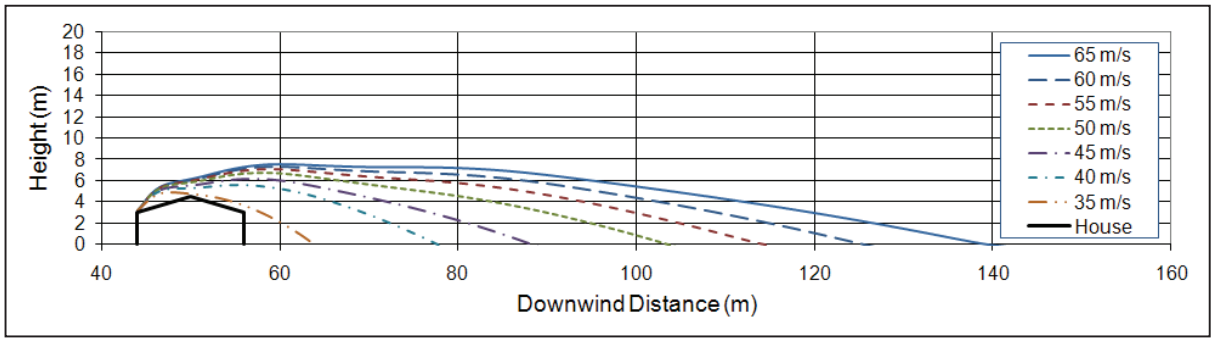

Figure 5. Computed trajectories of clay tiles originating from the windward eaves of the 4.5 m building with various gust wind speeds. Wind direction is perpendicular to the ridge.

Figure 5 shows the computed trajectories of clay tiles originating from the centre of the windward eaves of the 4.5 m high building assuming a range of gust wind speeds. As might be anticipated the stronger gusts lift the tiles more and carry then a much greater distance. With the weakest gust the tile barely clears the ridge and quickly drops into the wake of the building and falls to the ground. In Figure 6 the ratio of the tile's horizontal speed to the gust wind speed shows that not only does a weaker gust induce lower speeds but even the proportion is lower. With a 35 m/s gust the tile barely exceeds 40% of the gust speed whereas at 65 m/s the tile reaches 95% of the gust speed.

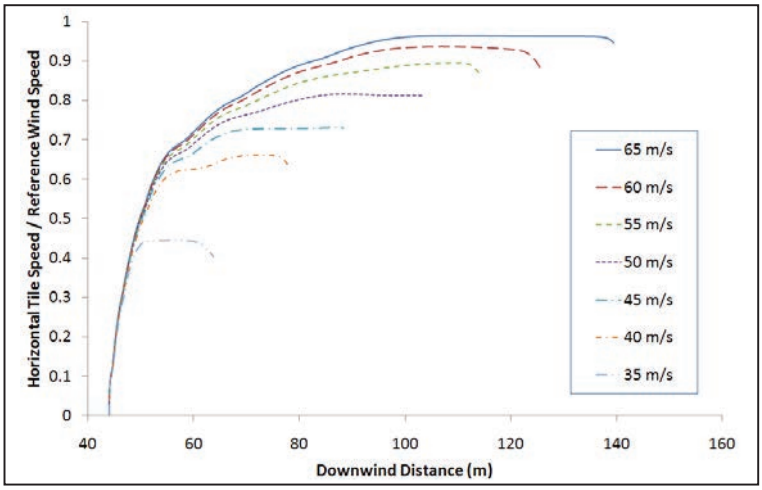

Figure 6. Ratio of clay tile horizontal speed to the reference gust speed as a function of downwind distance for the same cases as in Figure 5.

One of the consequences of this observation is the marked increase in the hazard posed by tiles as the gust speed increases. Not only are tiles more likely to be broken free from their fixings as the speed increases, but should this occur they will be projected over longer distances and at markedly higher speeds. In addition the flatter trajectory at higher gust speeds increases the chance that the tile might hit another building at a height where it might break a window. For example if one assumes that windows are located between 0.8 and 2.0 m above the ground, then with a 40 m/s gust the tile's path is only between these heights from 16 to 20 m downwind of the leeward wall, in contrast with a 65 m/s gust the tiles path falls between these heights from 60 to 68 m downwind of the leeward wall, doubling the downwind range band and hence approximately doubling the chance of an impact on a window.

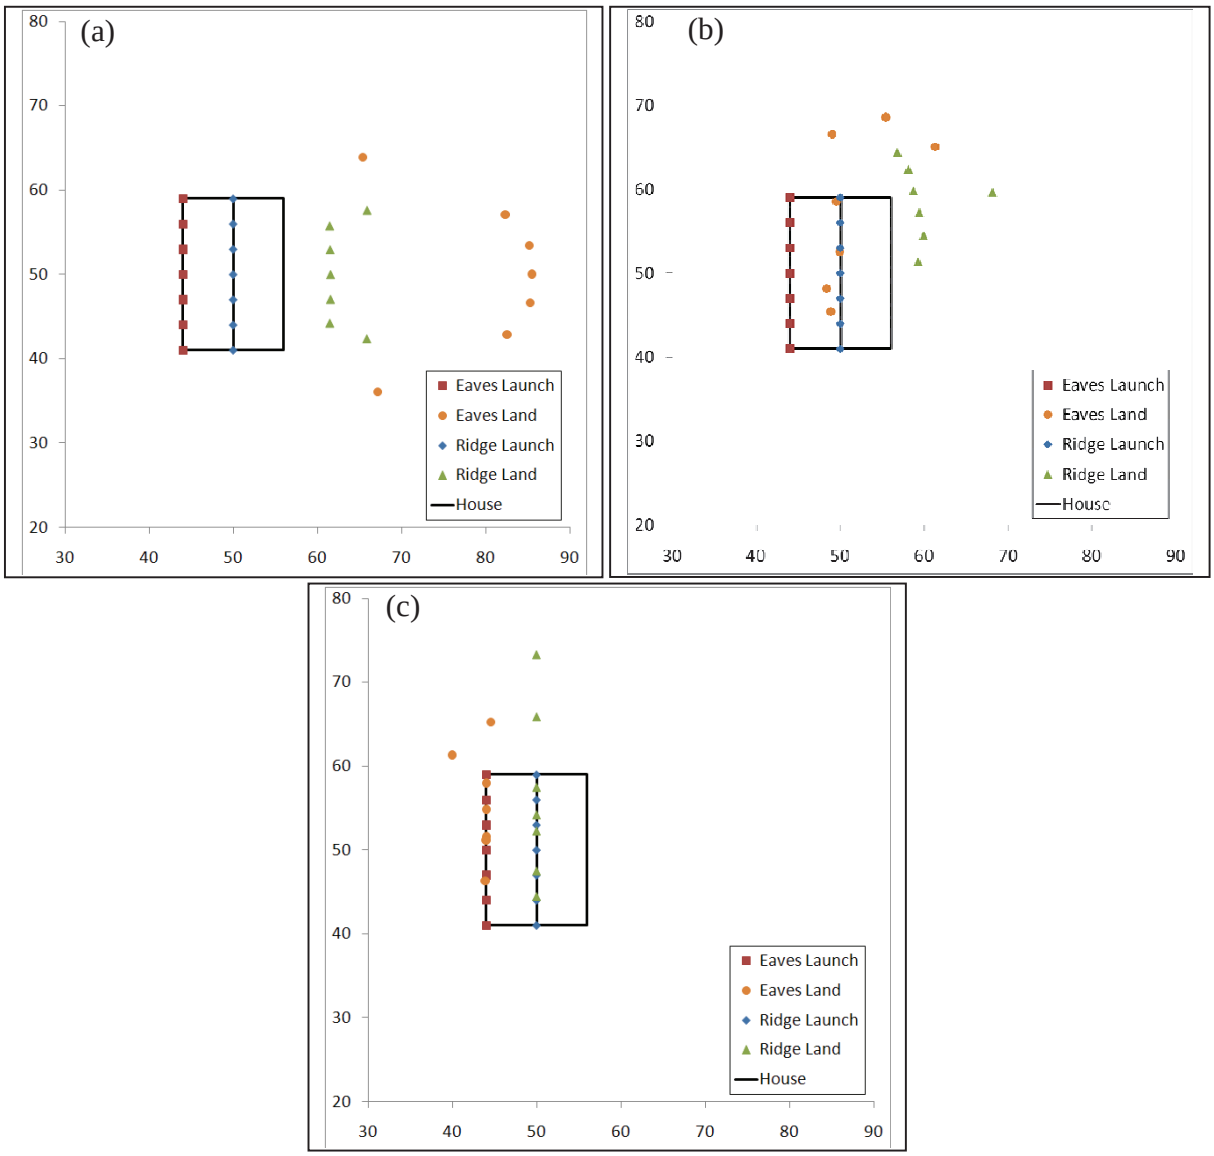

Figure 7. Computed landing locations for concrete tiles originating from various points on the 4.5 m ridge height building during a 50 m/s gust. Wind directions: (a) perpendicular, (b) 45° and (c) parallel to the ridge.

5.3 *The influence of wind direction and point of origin on trajectories.*

In the previous section only winds perpendicular to the ridge and tiles originating from the centre of the windward eaves have been considered. In order to assess the influence of wind direction and point of origin on the trajectories, flow fields have been computed with the wind at 45° and parallel to the ridge. The data presented in Figure 7 is for the heavier concrete tile, specified in Table 1, breaking free from the 4.5 m ridge height building during a 50 m/s gust. Fourteen release points have been considered, seven evenly spaced along the windward eaves and seven evenly spaced along the ridge. This figure shows both the points of origin and the landing points on plan views of the building and surroundings. With the wind perpendicular to the ridge, Figure 7(a), all fourteen tiles are carried clear of the building, with those originating from the eaves, but not at the corners, travelling a significant distance downwind. This occurs because the eaves are a region of relatively fast upward flow. At the corners the tiles are carried wide of the building but do not experience the same uplift and hence fall to ground sooner. Similarly those tiles originating from the ridge do not experience a strong uplift and hence fall into the wake and land close to the building. With the quartering wind case, Figure 7(b), four of the tiles from the eaves fall back onto the roof and the other three from the eaves are only carried about 10 m from the building. All of the ridge tiles are carried clear of the building but it is only the tile from the windward gable end that is carried any distance from the building and even this is quite moderate. In a similar manner with the wind parallel to the ridge, Figure 7(c), it is only the tiles from the two ends which are carried away from the building. In this case the tile that is carried furthest downwind originates from the ridge at the windward gable.

Overall these results show that should a tile break free from its fixing, the distance it is likely to travel will be strongly influenced by the wind direction and the local flow it encounters in the early stage of its trajectory. It is particularly, where there is a strong upward flow around the point of origin, that the tile is both lifted up and accelerated.

6 CONCLUSIONS

Roof tiles are a common type of windborne debris and have been associated with significant damage during several severe storms. They have sufficient mass to do damage and sufficient area to accelerate quickly. Trajectory analysis has been conducted for tiles breaking free from several generic buildings with a variety of roof slopes. These show that the upward flow around the windward eaves can lift a tile over the building, from which point it can be carried well downwind. The range and speed achieved under these conditions is much greater than would occur if the tile was released from the same height well away from the building. With steeper roofs a stronger gust is required to lift the tile over the roof but if this occurs then the range is extended beyond than which would occur with the same gust but a shallower roof. It has been shown that the flight of roofing tiles depends very strongly on the point of origin and the wind direction.

Modeling vegetation in Wind Engineering wind tunnel studies

Christof Gromke

Building Physics and Services, Eindhoven University of Technology, Den Dolech 2, Eindhoven, The Netherlands
Institute for Hydromechanics, Karlsruhe Institute of Technology KIT, Kaiserstrasse 12, Karlsruhe, Germany

ABSTRACT: A vegetation modeling approach for Wind Engineering wind tunnel studies is presented. The approach is based on fluid dynamical similitude. It enables the small-scale modeling of different vegetation types, e.g. trees, shrubs, hedges, forests and field crops. Its suitability and applicability is demonstrated by wind tunnel pollutant dispersion investigations. To this end, tree-avenues in an urban street canyon were modeled and their effect on pollutant concentration was investigated. The experiments substantiate the modeling approach to be practicable for wind tunnel studies and suggest to provide small-scale results which can be reliably transferred to full-scale.

KEYWORDS: vegetation, wind tunnel, similarity, trees, street canyon, tree-avenue

1 INTRODUCTION

The transfer of small-scale wind tunnel findings to full-scale requires the adherence to similitude which is expressed by similarity criteria. Whereas for investigations of buildings and civil engineering structures classical bluff body aerodynamic similarity criteria are well-defined and proved in practice, rather few knowledge and experience is available for the appropriate modeling of vegetation. In contrast to classical bluff body structures, vegetation is permeable to wind and from a general fluid mechanical point of view, a highly complex porous medium consisting of stems, branches, stalks and leafs or needles, all giving rise to the development of boundary layers. Flow past porous bodies differs essentially from flow past non-porous bodies. Wakes extend further downstream, recirculation zones are, in case they exist, detached from the leeward body side and skin friction contributes considerably to the overall drag due to large volume specific surface areas. Skin friction can no longer be neglected as with bluff bodies, where the pressure difference on the windward and leeward sides dominates the drag. Moreover, vegetation is relatively flexible and susceptible for oscillating motions giving rise to fluid-structure interactions. Trees adjust their shape when subjected to wind and show varying aerodynamic properties when exposed to moderate and strong winds [1], [2], [3]. Consequently, principles and similarity criteria of classical bluff body aerodynamics cannot carried forward directly to the modeling of vegetation.

In the following, after a short review of existing wind tunnel vegetation modeling approaches, a new approach is introduced. The modeling approach is validated using the results from wind tunnel experiments of pollutant dispersion in urban street canyons with tree-avenues.

2 REVIEW OF WIND TUNNEL VEGETATION MODELING APPROACHES

So far, only a few wind tunnel studies have been performed which explicitly include the small-scale aerodynamic modeling of vegetation. In these studies, vegetation has often been represented by model railway scenery accessories, e.g. [4], [5]. Moreover, brushes, metal screens, boughs, cotton balls, wooden pegs, matches and plastic stripes have been utilized [6]. Most of these materials have been used to model wind shelterbelts rather than single trees or forest stands. [6] investigated wind and turbulence characteristics in and above a model forest. The forest was assembled by tree models made up of plastic bough imitations and validated by arguing that drag coefficients and general wake characteristics agree well with those of real trees. In another study, [7] used pipe cleaners to simulate wind shelterbelts consisting of conifers. Attention was paid to comply with the Jensen number (ratio of shelterbelt height H to aerodynamic roughness length z_0) which was considered to be the dominating similarity criterion. Flow and stem ground-level bending moment measurements were performed by [8] at an aeroelastic forest model. The tree models were developed by Gardiner in Edinburgh (UK) according to aerodynamic and structure dynamical similarity criteria. The trees were made of injection-molded Nylon-66 stems with low density Polyethylene branch elements. Special attention was given to the branch element design in order to realize appropriate drag coefficients. Furthermore, tree model mass and stiffness were adjusted to match the natural sway frequency. [9] investigated flow fields in forest clearings in a wind tunnel study. Their forest was made of flexible tree models with eigenfrequency of 2.2 Hz. The foliage was modeled by plastic stripes which were attached to two interwounded steel wires forming the tree trunk. This approach allowed to simulate distinct leaf area densities or indices. More recently, [10] and [11] employed metallic mesh rings to model a forest. Their aim was to simulate the mean flow and turbulence characteristics in the above canopy region in order to study the exchange of biogenic emission with the atmosphere. By comparison with full-scale measurements, they concluded that their forest model satisfactorily simulates the mean flow and turbulence structure in the above canopy region. A further example for the modeling of forest stands can be found in [12]. In this study an open-porous foam material (foam 10 ppi - pores per inch) was used and the storm stability of the near forest edge region was investigated. Their results showed that the design of the near forest edge region is crucial for its storm stability. [13] found that the drag coefficient of model railway scenery conifer trees lies in the range for natural conifer trees and employed a wind tunnel forest set up of those tree models to validate numerical simulations of flow over forest clearings. [14] built wind tunnel tree models using filamentous materials which were enlaced and formed to porous crowns of spherical shape. Different porosities were realized by the amount of filamentous material used to form the crown. They demonstrated that the approach enables the aerodynamic modeling of trees in terms of drag and wake characteristics.

3 MODELING APPROACH

3.1 *Vegetation modeling approach*

Tree-avenues were modeled for wind tunnel investigations of pollutant dispersion in urban street canyons. For this purpose, a line-like lattice cage construction of street canyon length with equally sized cells was built and filled with a filamentous synthetic wadding material (Figure 1). Trunks were not modeled as they are fairly small compared to the crowns and their influence on the flow past trees is negligible.

The approach allows to model tree-avenues of different stand density (trees per unit length) and crown porosity (pore volume fraction), see also [15], [16]. Different stand densities can be realized by filling every nth cell (n = 1, 2, 3, …) and different crown porosities by filling the cells with defined masses of the wadding material. For the present study, tree-avenues of maximum stand density (n = 1) and crown porosities with pore volume fractions of P_{Vol} = 97.5% and P_{Vol} = 96.0%, typical for deciduous trees, e.g. [17], [18], were realized.

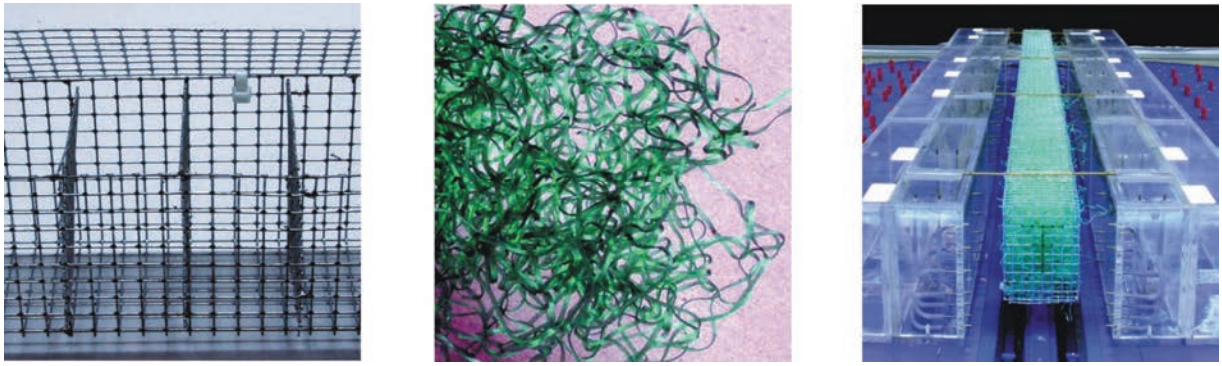

Figure 1. Close-up of lattice cage, filamentous wadding material, and street canyon model with tree-avenue.

In addition to the pore volume fraction, the texture of porous media, i.e. the form, arrangement and size distribution of the pores and their wall roughness as well as their orientation to the flow influence the wind permeability. A definite measure for the permeability of porous media is given by the pressure loss coefficient λ [m^{-1}]. The pressure loss coefficient is determined in forced convection flows, see Figure 2 (left), according to

$$\lambda = \frac{\Delta p_{st}}{p_{dyn}\, d} = \frac{p_{windward} - p_{leeward}}{0.5\, \rho\, u^2 d} \tag{1}$$

where Δp_{st} is the static pressure drop [Pa] over the porous media of streamwise thickness d [m], p_{dyn} is the dynamic pressure [Pa] and u is the bulk velocity [ms^{-1}].

Figure 2 (right) shows the measured pressure loss coefficients λ for different flow speeds. No pronounced dependency of λ on u is visible for both porosities. The slight decreases in λ with increasing u for P_{Vol} = 96.0% is attributed to viscous effects. A deformation or compaction of the wadding material samples was not observed in the tested flow speed range. From these measurements, the pressure loss coefficients were determined to λ = 80 m^{-1} and λ = 200 m^{-1} for the tree model crowns of high (P_{Vol} = 97.5%) and low (P_{Vol} = 96.0%) porosity, respectively.

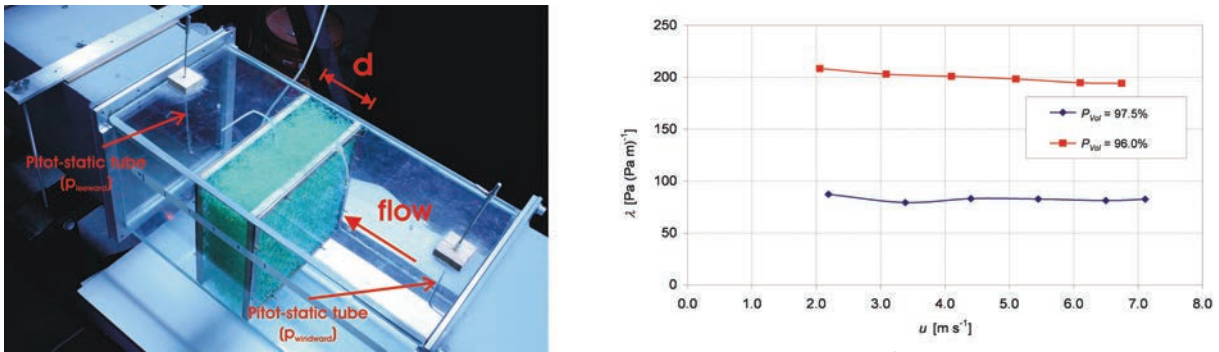

Figure 2. Forced convection flow setup for measuring pressure loss coefficient λ [m^{-1}], and pressure loss coefficient λ vs. flow speed u.

As already stated in the introduction, fluid dynamical similarity is required in order to transfer the wind tunnel model results to full-scale. In the present modeling approach, a similarity criterion is established based on energy considerations. Postulating equality in the normalized static pressure drops $\Delta p_{st}/p_{dyn}$ for forced convection flows in full-scale (fs) and in small-scale (ss), i.e.

$$\left[\frac{\Delta p_{st}}{p_{dyn}}\right]_{fs} = \left[\frac{\Delta p_{st}}{p_{dyn}}\right]_{ss} \tag{2}$$

ensures that the flow potential energy which is extracted by the resistance of the porous media relative to the flow kinetic energy is equal in both scales. This gives with Equation 1

$$\frac{\lambda_{fs}}{\lambda_{ss}} = \frac{d_{ss}}{d_{fs}} = M \tag{3}$$

with M [-] the wind tunnel model scale.

Applying Equation 3 to the tree models, results with the wind tunnel model scale M = 1:150 in up-scaled pressure loss coefficients of $\lambda_{fs} = 0.53$ m^{-1} and $\lambda_{fs} = 1.33$ m^{-1}. For the purpose of comparison and validation, pressure loss coefficients λ of vegetation shelterbelts formed by broad-leaved trees measured in forced convection flows by [19] are provided in Table 1. It has to be noted that these shelterbelt values are the most appropriate data available as pressure loss coefficients of tree crowns lack.

Table 1. Pressure loss coefficients λ [m^{-1}] for leaved vegetation shelterbelts [19].

density ρ_S [a]	1.33	1.00	0.67
poplar	1.2 - 3.6	0.8 - 2.4	0.5 - 1.5
Norway maple	1.5 - 3.5	1.1 - 2.5	0.7 - 1.6
field maple	4.7 - 8.9	3.5 - 6.9	2.2 - 4.0
small-leaved lime	1.5 - 4.0	0.9 - 2.3	0.4 - 1.5
bird cherry	1.5 - 13.4	1.2 - 6.5	0.6 - 3.1

[a] density ρ_S refers to the branch arrangement in the shelterbelt. $\rho_S = 1.00$ is the 'normal density'.

From Table 1 it can be seen that the up-scaled tree model pressure loss coefficients λ_{fs} are in agreement with the values of [19] for thinned out shelterbelts ($\rho_S = 0.67$). The reason for employing the thinned out values is that the branch and foliage arrangement in ground-near shelterbelts of rather shrub-like stature appears to be denser and more uniform than in elevated tree crowns. In elevated tree crowns, most of the foliage is concentrated at the crowns' envelopes whereas the crowns' interiors are almost empty. Based on this argument it is hypothesis that the thinned out shelterbelt pressure loss coefficients are more adequate for the validation.

3.2 *Urban street canyon model*

The line-like lattice cage was positioned in a generic urban street canyon model with aspect ratios W/H = 1 and L/H = 10 (H = 0.12 m). The whole setup was placed in a wind tunnel and subjected to perpendicular approaching flow simulating an urban-type atmospheric boundary layer of model scale M = 1:150 (Figure 3). For more detailed information on the boundary layer wind tunnel characteristics, the reader is referred to [20] or to the internet database CODASC - Concentration Data of Street Canyons [21].

The Reynolds number Re based on the velocity u_H of the undisturbed flow at building height H is equal to 37000, ensuring a Reynolds number independent flow field. Traffic emis-

sions were simulated by tracer gas emitting line sources according to functional principle described in [22]. Sulfur hexafluoride SF_6 was used as tracer gas. Measurement taps were applied along the leeward and windward canyon walls (hereafter referred to as wall A and wall B, respectively) to sample the near-façade canyon air. Mean concentrations were measured with Electron Capture Detection (ECD), model Meltron LH108. The measured concentrations c [-] were normalized according to

$$c^+ = \frac{c\, u_H\, H}{Q_T / l} \tag{4}$$

where QT/l [$m^3 s^{-1} m^{-1}$] is the tracer gas source strength per unit length.

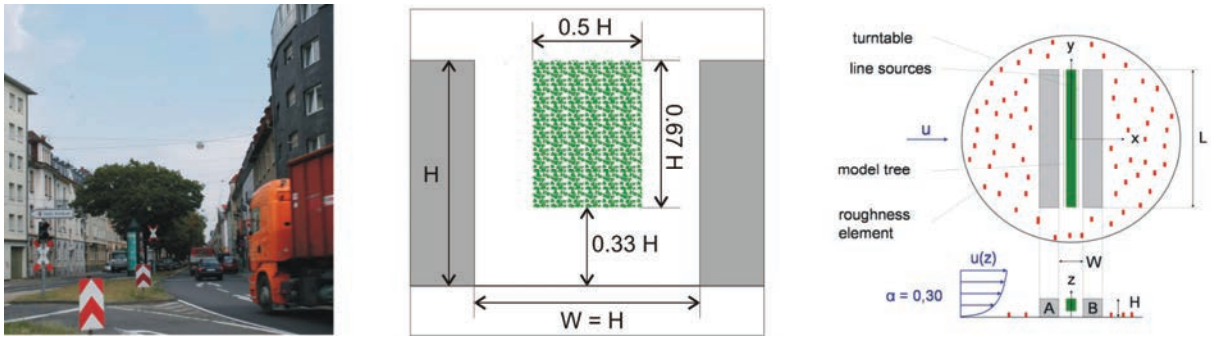

Figure 3. Urban street canyon with tree-avenue and geometry of generic model setup.

4 APPLICATION TO POLLUTANT DISPERSION STUDIES

Figure 4 shows contour plots of normalized pollutant concentrations c^+ [-] at the canyon walls A and B for tree-avenues of maximum stand density (n = 1). Starting with the tree-free street canyon at the top (a), tree crowns with decreasing permeability, i.e. increasing pressure loss coefficients λ were investigated, with λ_{ss} = 80 m^{-1} in (b) and λ_{ss} = 200 m^{-1} in (c). Finally, in (d), the tree-avenue model was formed by a solid block corresponding to an infinite pressure loss coefficient. The latter was considered as a limiting case revealing the highest possible concentrations. Please note that the vertical dimension z [m] and the along street dimension y [m] are normalized by the building height H and that only one half of the building walls is shown (-5 < y/H < 0) utilizing symmetry.

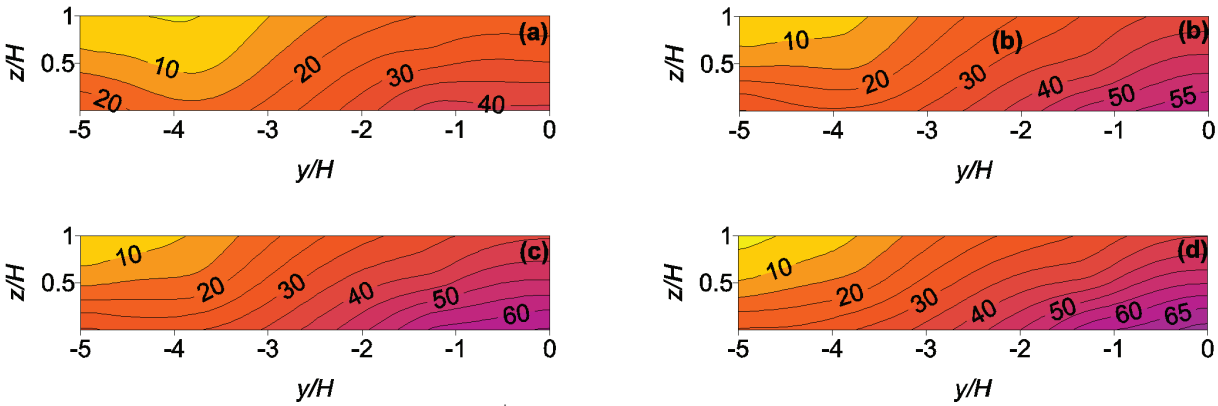

Figure 4. Normalized pollutant concentrations c^+ [-] at building wall A for (a) tree-free street canyon, (b) tree crown with λ_{ss} = 80 m^{-1}, (c) tree crown with λ_{ss} = 200 m^{-1}, and (d) solid block ($\lambda_{ss} = \infty$).

The contour plots of Figure 4 reveal the general implications of tree-avenues and crown permeability on traffic pollutant concentrations in urban street canyons. At the leeward canyon wall A, increasing traffic pollutant concentrations with decreasing crown permeability, i.e. increasing pressure loss coefficient λ, are visible. Both the wall average pollutant level and the peak concentration increase continuously.

In order to understand the influence of tree-avenues on the canyon wall concentrations, it is useful to consider the dominating flow and dispersion processes in the tree-free street canyon first. The flow field in the tree-free street canyon is dominated by two vortex structures, the canyon vortex and the corner eddies. Driven by the above roof wind, a clockwise rotating canyon vortex forms and entrains air into the street canyon in front of the windward wall B. On the reverse flow from wall B to wall A, the canyon vortex accumulates traffic exhaust emissions. Thus, the upward flow in front of the leeward wall A contains increased pollutant concentrations which are then partially entrained and mixed into the above roof wind before re-entrained into the street canyon again. At the street ends additional air exchange is provided by the corner eddies leading to reduced pollutant concentrations [23], [24]. In street canyons with tree-avenues, flow and pollutant dispersion are also dominated by the canyon vortex and corner eddies as was found by Laser Doppler velocimetry (LDV) measurements [23] and by CFD simulations [25], [26], [27]. However, the presence of trees leads to smaller flow velocities inside the street canyon and modified air exchange with the surroundings at the canyon roof and ends. Smaller flow velocities implicate a reduced volume flux of the canyon vortex. Consequently, the traffic exhaust emissions are less diluted and the concentrations in the upward flow in front of the leeward wall A are higher. The contour plots of Figure 4 indicate that these effects are stronger pronounced with decreasing crown permeability, resulting in continuously increasing traffic pollutant concentrations at the leeward wall A. Additionally, the tree crowns partly block the corner eddies and reduce the lateral air exchange which is reflected by increased concentrations at wall A close to the street canyon ends.

Figure 5 summarizes the influence of tree-avenues on pollutant concentrations at wall A. Shown are the relative changes $\Delta c/c_{ref}$ [%] in wall average and peak concentrations with crown permeability λ [m^{-1}] according to

$$\frac{\Delta c}{c_{ref}} = \frac{c_{trees} - c_{tree-free}}{c_{tree-free}} . \tag{5}$$

Steady increases in wall average and peak concentrations with increasing pressure loss coefficient can be seen. The incremental increases are strongest for small values of λ. For larger pressure loss coefficients, the wall average and peak concentrations asymptotically approach their upper limits given by the solid block tree model (dashed lines in diagram).

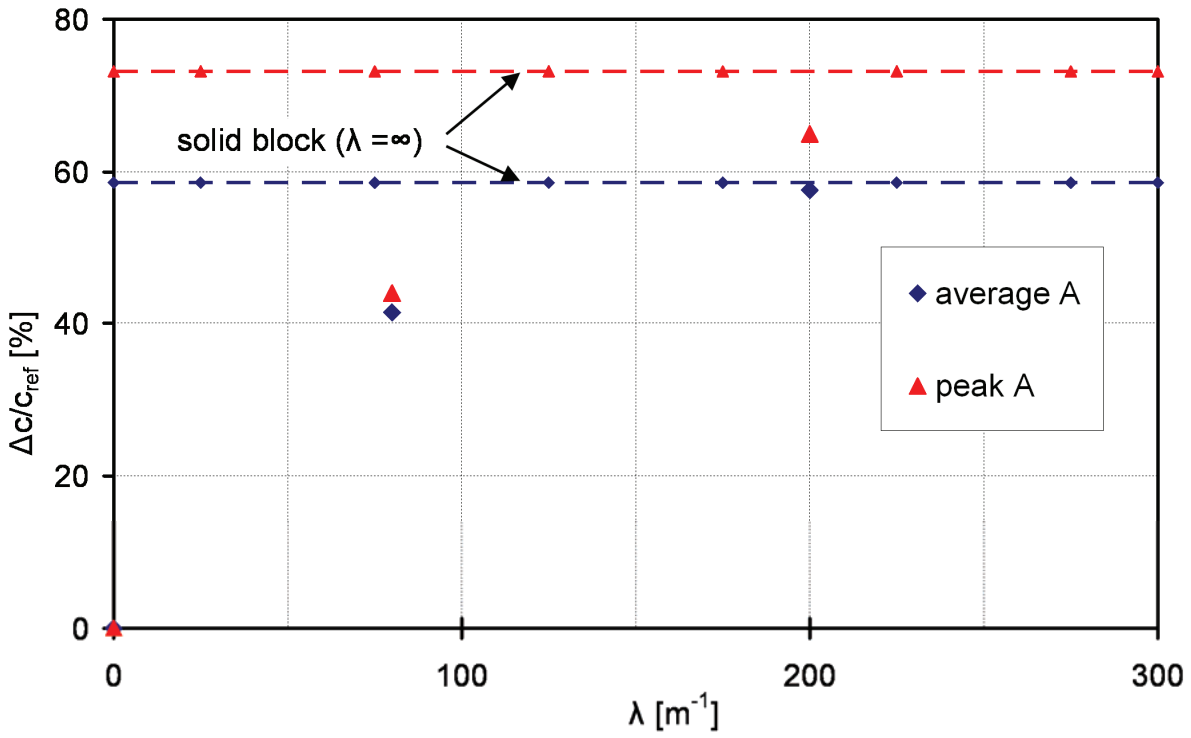

Figure 5. Rel. changes $\Delta c/c_{ref}$ [%] in wall average and wall peak concentrations with crown permeability λ [m^{-1}].

5 CONCLUSIONS

A new vegetation modeling approach was introduced and successfully applied in Wind Engineering small-scale pollutant dispersion studies. The transferability of the small-scale wind tunnel results to the full-scale was ensured by compliance with fluid dynamical similitude requirements. The permeability to wind was identified as relevant for the aerodynamic of vegetation. Consequently, the similarity criterion was set up based on the pressure loss coefficient which is a measure for permeability.

In this study, the modeling approach was employed to model tree-avenues in an urban street canyon and to study pollutant dispersion. The wind tunnel dispersion experiments a posteriori proved the vegetation modeling approach to be practicable and provided strong evidence for its reliability. Beyond the scope of the investigation presented herein, the approach can also be applied to other vegetation types, such as single trees, shrubs, hedges, forest stands or field crops, in diverse Wind Engineering wind tunnel studies, concerning e.g. pedestrian wind comfort or wind loads on structures.

ABSTRACT: Existing turbulence model had been improved by introducing additional source/sink terms in the governing equations to appropriately consider the effect of tree canopy on the wind environment flow. The new source term model S_ω for the turbulence frequency ω equation in the SST k-ω model was proposed and numerically verified through the simulation of the windbreak flow firstly. Then it was adopted in the wind environment optimal design of the twin high-rise buildings of CABR (China Academy of Building Research). With the new inflow boundary conditions developed in the previous studies, it was concluded that the theoretically reasonable source term model was applicable for modeling the tree canopy flow and could get relatively better results.

KEYWORDS: wind environment, numerical simulation, SST k-ω model, additional source/sink term, high-rise building, optimization design.

1. INTRODUCTION

In studies on wind environment around buildings, usually the influence of vegetation cover cannot be ignored. The windbreak formed by the vegetation cover increases the wind drag and subsequently reduces the downstream wind speed effectively. Vegetation cover and its influences on surface roughness have therefore induced considerable complexity to computational modeling of airflow.

For large-scale atmospheric flows, the broad characteristics of flow are concerned most, and the modified wall function considering roughness modification can be then used to model the near ground flow. From the viewpoint of numerical simulation, the wall function has substantially reduced the excessive grid requirement, particularly in the viscous sub-layer. It is however that this method is not suitable for modeling the near ground canopy flow since the use of roughness parameters in the modified law of the wall provides no information of the turbulence structure within the canopy region in terms of the vegetation-related parameters, such as leaf area density (LAD) [1].

In focusing on surface flow complexity, plant drag can be accounted for by incorporating surface roughness parameters and/or introducing additional source/sink terms[1-4]. As such, modified transport equations can be derived to establish mean momentum, turbulent kinetic energy and turbulent kinetic dissipation rate.

In this paper, a more appropriate source term S_ω in the k-ω model has been deduced through the theoretical analogy with the two turbulence models, i.e. the k-ε model and the k-ω model. The new source term S_ω for the SST k-ω model was numerically verified by comparing the numerical results with the mean velocity profiles at different downstream locations of the vegetated windbreak experiment conducted by Kurotani et al.(2002)[5]. At last, the proposed source term model was adopted in the wind environment optimal design of the twin high-rise buildings of China Academy of Building Research (CABR). The effects of tree canopy on the wind flow in the passage formed by the two closely arranged buildings

was numerically investigated and then compared with the situation without the tree canopy. In the numerical simulations, the new inflow boundary conditions proposed by Yang et al. (2008, 2009, 2012)[6-8] are used to model the equilibrium ABL. By using this new inflow boundary condition profiles, the stream-wise errors can be significantly reduced if a good fit between the inflow profiles and the model was used [9]. Based on the results of the numerical simulation, technical measures to ameliorate the unfavorable wind environment were then suggested.

2. TURBULENCE MODELS AND ADDITIONAL SOURCE/SINK TERMS

2.1 *k-ω model*

For the k-ω model [10], the governing equations for the turbulent kinetic energy k and turbulence frequency ω can be expressed as follows:

$$\frac{\partial k}{\partial t}+\frac{\partial u_i k}{\partial x_i}=\frac{\partial}{\partial x_j}(\frac{\nu_t}{\sigma_k}\frac{\partial k}{\partial x_j})+P_k-Y_k+S_k \tag{1}$$

$$\frac{\partial \omega}{\partial t}+\frac{\partial u_i \omega}{\partial x_i}=\frac{\partial}{\partial x_j}(\frac{\nu_t}{\sigma_\omega}\frac{\partial \omega}{\partial x_j})+P_\omega-Y_\omega+S_\omega \tag{2}$$

where P_k and P_ω represents the production terms of k and ω, and Y_k and Y_ω are the effective dissipation terms due to turbulence. The S_k and S_ω are the additional source/sink terms of the k and ω transport equations, respectively. The turbulent viscosity is computed by combining k and ω as follows:

$$\nu_t=\frac{k}{\omega} \tag{3}$$

2.2 *Additional source/sink terms model of the SST k-ω model*

The k-ω based SST model developed by Menter (1994)[10] employs the k-ω model near the surface and the k-ε model in the free-shear layers. A blending function is adopted to bridge these two models. The SST k-ω model takes into account of the transport of the turbulent shear stress and gives accurate predictions of the onset and the amount of flow separation under adverse pressure gradients[10]. In view of its relatively high efficiency for numerical simulation and accurate solution, the SST k-ω model was adopted in this study.

The plant effects were accounted for by introducing the additional source/sink terms in the mean momentum, the turbulence kinetic energy k and turbulence frequency ω equations in the SST k-ω model, which is more suitable for blunt body flow, compared with the standard k-ε model [6]. The expressions of the additional source/sink terms have been proposed by a number of researchers [2-4]. Mochida et al. (2006)[10] conducted a numerical study and compared the performances of different forms of additional source/sink terms on the tree canopy flow.

For the k-ε model, the source/sink terms accounting for the plant drag are expressed as follows [12]:

$$S_{ui}=-C_d A u_i U \tag{4}$$

$$S_k = C_d A \beta_p U^3 - C_d A \beta_d U k \tag{5}$$

$$S_\varepsilon = C_d A \alpha_p \beta_p \frac{\varepsilon}{k} U^3 - C_d A \alpha_d \beta_d \frac{\varepsilon}{k} U k \tag{6}$$

In Eqs. (4)-(6), C_d is the drag coefficient; A is the leaf area density (LAD) (m^2m^{-3}); u_i is the velocity component of i direction; where $U=|u_i u_i|^{1/2}$ is the absolute value of the spatially averaged wind speed. β_p was the fraction of mean flow kinetic energy being converted to wake-generated energy by canopy drag, and β_d was the magnitude of energy losses from interactions with obstacles. For the standard k-ε model, the typical values of β_p and β_d are 1 and 4, respectively [13]. α_p and α_d are the adjustable model constants, and the analytical values are both 1.5. For the SST k-ω model, the values of α_p and α_d are modified to 3.2 and 0, respectively [1][14].

Due to the relationship between the SST k-ω model and the standard k-ε model, the source/sink terms of the mean momentum and k equations in the standard k-ε model, i.e. Eqs. (4) and (5), can be adopted in the SST k-ω model directly. While, for the source/sink term of the ω equation, almost no theoretical expression can be referred to directly. For example, Pattanapol et al. (2008) adopted the equation of S_ε as the form of the expression of S_ω directly only through a simple linear transformation between ε and ω.

Theoretical derivation had been conducted to obtain a reasonable source term S_ω as Eq.(7)[15].

$$S_\omega = C_d A(\alpha_p - 1)\beta_p \frac{\omega}{k} U^3 - C_d A(\alpha_d - 1)\beta_d \frac{\omega}{k} U k \tag{7}$$

The newly-derived source term S_ω of Eq. (7), which was deduced from the turbulence model equations, will be employed along with the source/sink terms of S_u and S_k in the numerical simulation of windbreak flow in the next section.

3. NUMERICAL VERIFICATION

3.1 *Model Setup*

Kurotani et al. (2002)[5] performed a field experiment of vegetated windbreak flow and the experimental results are available in the website (http://www.aij.or.jp/). Based on the experimental results, Mochida et al. (2006)[12] carried out a series of parameter optimization studies on the additional source/sink terms of k-ε model.

The experiment and the numerical simulations conducted by Mochida et al. (2006)[12] were referred to, and a corresponding 2D numerical model was built. The dimensions of the rectangular computational domain were 100m(L)×100m(W), which could be referred to Franke et al. (2007)[16]. The domain was discretized by structural grids and the finest mesh grid close to the ground was set as 0.1 m. The total amount of cells was 50,000. The present work was conducted using the CFD code Fluent 6.3 (Fluent Inc.). The effect of tree canopy on the wind flow was modeled by adding the source/sink terms of S_u, S_k and S_ω (i.e. Eqs. (4), (5) and (7)) into the momentum, k and ω equations, respectively, using the user defined functions (UDF). The flow was assumed incompressible and steady, and the SIMPLE algorithm was used for pressure-velocity coupling. The second order upwind difference scheme, QUICK, was adopted for all the convective terms in the momentum equation and turbulence model equations. The diffusive terms were discretized by second order central difference scheme. The flow field was initiated by the inlet boundary condition. The

convergence criteria of the scaled residuals for all variables and the continuity equation were set as 10^{-4}. To obtain convergent results, although the convergence criteria were achieved, additional iterations were performed to ensure a stable convergence over a sufficient period.

The numerical simulations on different mesh resolutions were performed at the onset to check the requirement of mesh independence. Four variations of mesh densities, which was similar to that was adopted in Yang et al. (2009)[7], were investigated. It was concluded that the CFD simulation results under the present settings were independent of the mesh resolution. The mean velocity profiles obtained from the current numerical simulation at different locations downstream of the vegetated windbreak were compared with the experimental data [5] and acceptable results have been obtained [15].

3.2 *Modeling of equilibrium atmospheric boundary layer*

The modeling of equilibrium atmospheric boundary layer (ABL) was an important precondition for a proper numerical simulation of flows around buildings[17]. The most important requirement of equilibrium ABLs was the horizontal homogeneity, which means that the stream-wise gradients of all variables should be zero.

The issue of generating an equilibrium ABL was investigated from the viewpoint of the turbulence model. The approximate solution to the standard k-ε model was derived based on the assumption of the local equilibrium of turbulence, and then a new set of inflow turbulence boundary conditions for modeling equilibrium ABL was proposed [6][7]. The application of the new inflow boundary conditions was further extended to the SST k-ω model for modeling equilibrium ABL [8]. The performance and applicability of this new set of inflow boundary condition have been recently validated [9][18], and it has been adopted in the numerical simulations of ABL transport phenomena [19-21].

The first step of the numerical verification was the simulation of simple boundary layer flow in an empty domain to confirm whether the equilibrium ABL is adequately generated. The boundary conditions of the numerical model were stipulated in Table 1. The parameters in the inflow boundary conditions were referred to the experiment of Kurotani et al. (2002) and the numerical simulations by Mochida et al. (2006)[11], in which u=5.6m/s, H_b=9m, α=0.22, D_1=-8.94$m^{4-\alpha}/s^4$, D_2=53.4 m^4/s^4.

Numerical simulation shows that both the mean velocity and turbulent kinetic energy profiles were sustained satisfactorily throughout the whole domain under the present inflow turbulence boundary conditions [7][15].

Table 1. Boundary conditions of the numerical model

Location	Boundary conditions	
Inflow face	Defining the mean velocity (u), TKE (k) and turbulence frequency (ω)	$u = u_b(z/H_b)^{\alpha}$, $v = 0$, $w = 0$; $k = \sqrt{D_1 z^{\alpha_i} + D_2}$, $\omega = \varepsilon / \left(C_\mu \cdot k\right)$; where $\varepsilon = \alpha_i C_\mu^{\frac{1}{2}} (u/z)\sqrt{D_1 z^{\alpha_i} + D_2}$
Outflow face	Fully developed outflow	$\frac{\partial}{\partial x}(u, v, w, k, \omega) = 0$
Upper face of computational domain	Free slip	$w = 0$, $\frac{\partial}{\partial y}(u, v, k, \omega) = 0$
Side faces of computational domain	Free slip	$v = 0$, $\frac{\partial}{\partial y}(u, w, k, \omega) = 0$
Ground surface boundary	wall	No slip wall with wall roughness modification, roughness height Ks=0.05m and roughness constant Cs=0.5

4. APPLICATION

4.1 *Introduction*

The assessment and modification research of wind environment of the high-rise buildings Silvertop Towers had been reported by Blocken et al. (2004)[22]. CFD simulation was demonstrated being an effective method for such assessment [23].

The method of introducing the additional source/sink terms in governing equations to appropriately consider the tree canopy effect are further applied to the wind environment optimization of the high-rise buildings of China Academy of Building Research (CABR).

The new mansion of CABR (i.e. the left building in Figure 1) was built close to the existing building, and both were 80m in height (h). Due to the limited site area, the minimum width of the passage, b_{min}, is only about 15m. Therefore, the ratio of b_{min}/h was as small as 0.19. This narrow passage formed by two closely arranged high-rise buildings will be the main entrance of CABR in the future.

Due to lack of obstacles in front of the buildings, moreover, the passage being towards the local dominant wind direction in the whole year, therefore, the pedestrian wind environment was deteriorated in windy days for the wind speed in the passage being accelerated apparently. In order to quantitatively evaluate the pedestrian wind environment comfort and safety around the buildings, particularly at the narrow passage, a detailed wind tunnel test and numerical simulations had been carried out.

According to the wind tunnel test and the numerical simulations, the maximum wind speed ratio C_u, which was defined as the ratio of the local mean wind speed U_p to the undisturbed wind speed U_f at the pedestrian level., i.e., $C_u=U_p/U_f$, could reach 1.8. Combining with the local wind climate statistic data, it resulted that the peak wind speed was as high as the Beaufort scale 8. The probability of occurrence of such high wind speed in the passage was estimated to be nearly 8 times per year. That implied the wind environment in the passage does not satisfy the basic requirements of safety and comfort for pedestrians.

4.2 *Wind environment optimization design*

In order to ameliorate the unfavorable wind environment, additional optimization scheme in cooperation with architects have been performed. Some remedial measures were suggested, for example, a large billboard as high as 9m was planned to set up in front of the windward opening of the passage as a windbreak, and the semi-opened corridor on the ground floor of the new mansion was recommended to be closed and used as pedestrian pathway, as depicted in Figure 2.

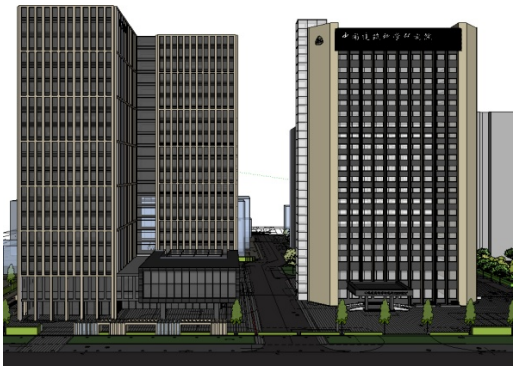

Figure 1. Scheme of the new building of CABR

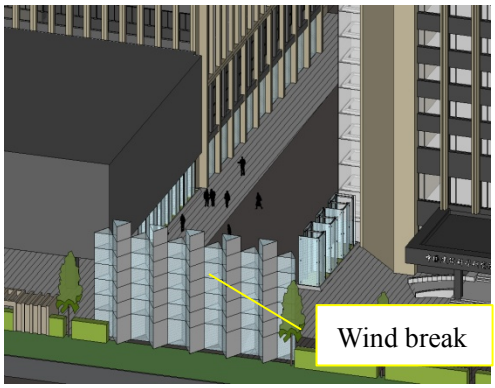

Figure 2. The optimization measures of alleviating unfavorable wind

Though the proposed measures can potentially ameliorate the high wind speed environment at some extent, further numerical simulation (numerical model see Figure 3)

showed that the wind speed at the pedestrian level still tended to unfavorable. This is because the major characteristic of the narrow passage formed by the two high-rise buildings largely remains unchanged.

For example, the big billboard can successfully block off strong wind from north in the downstream near field but the flow separated over the billboard was speeding up and reattaching farther downstream, as reported in Figure 4. Therefore the high wind speed environment in the southern end of the passage was not mitigated and may even be worse in some situations as demonstrated here. Consequently, optimizing the quality of the wind environment around the building, in particular the passage was challenging for wind engineers.

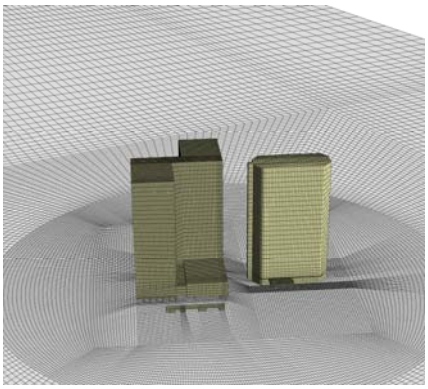

Figure 3. Grid discretization of the numerical model of CABR buildings

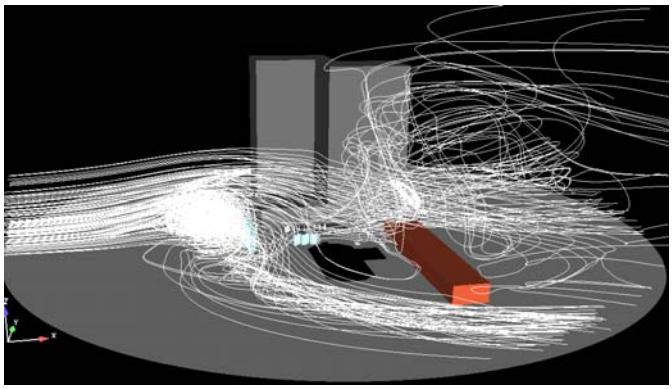

Figure 4. The wind flow streamlines around the building under the north wind

4.3 *Application of the tree canopy in the optimization design*

4.3.1 *Numerical model*

The idea of installing tree canopy in the passage acting as a "soft" windbreak was then proposed and the numerical simulation was carried out. The full scale 3D model of CABR buildings was built according to the architectural design. Some unnecessary architectural details and features were simplified to avoid over-weighted calculation load. The dimensions of the computational domain were set as 720m x 1360m x 560m (i.e. W x L x H), resulting in the blockage ratio of the domain being smaller than 3%.

The grid discretization scheme was designed to achieve a balance between the precision of numerical results and the computational time. The whole domain was divided into two parts as showed in Figure 3 and then hexahedron cells were adopted for both internal and external parts' discretization. The size of the smallest cells close to the building boundaries in the internal part was approximately 0.5m. This scheme gives the total grid cells of about 2 million.

The boundary conditions were set following the expressions in Tab.1, while the two constants of k, D_1 and D_2 were changed slightly in consideration of the local wind terrain feature. Here they were defined as: D_1=-8.93$m^{4-\alpha}/s^4$, D_2=53.1 m^4/s^4; where α=0.22.

In the numerical model, a line of tree canopy was set in the middle of the passage, as illustrated in Figure 5(b). The dimensions of the tree model were 50.0m(L)×1.0m(W) ×1.5m(H). The drag coefficient C_d and LAD of the tree model were 0.8 and 1.17m^2/m^3, respectively. The details of the tree windbreak can be referred to the paper of Kurotani et al. (2002)[5].

4.3.2 *Calculation results*

Figure 5 illustrates the comparisons of the wind velocity ratios C_u at the pedestrian level

before and after setting up the vegetated windbreak in the center of the passage subject to the north wind. It can be clearly seen from the figure that the high wind velocity ratio (i.e. C_u >1.5) was restrained and the area with high wind velocities, especially in the southern part of passage, was reduced significantly after the tree canopy was "planted"(Figure 5 (b)). Therefore, it could partly overcome the negative influence brought by the installation of the windbreak at the northern end as showed in Figure 4.

Numerical simulations exhibited the effects of the tree canopy partly eliminating the unfavorable strong pedestrian wind and improving the wind environment in the passage. Based on the numerical results, a proposal of ameliorating the wind environment of this development project was presented. A line of tree canopy in the middle of the passage with properly designed windbreak facilities installed at the northern end of the passage can effectively reduce the high wind speed and avoid the unfavorable wind environment.

5. CONCLUSIONS

Existing turbulence model has been improved in order to appropriately consider the effect of tree canopy on the wind environment flow, which is realized by introducing additional source/sink terms in the governing equations. The new source term model S_ω for the turbulence frequency ω equation in the SST k-ω model was derived through the theoretical analogy. Its applicability and performance were numerically verified by performing the simulation of the windbreak flow. Then the proposed source term model was adopted in the wind environment optimal design of the twin high-rise buildings of CABR.

Using the new inflow boundary conditions developed in the previous study to model the equilibrium atmospheric boundary layer, it was concluded that the theoretically reasonable source/sink term model of the SST k-ω model was applicable for the modeling of tree canopy flow. Though some optimization works of the parameters in the model have been performed to achieve better results, the authors believe that more refined study will be helpful for further improving the numerical accuracy.

6. ACKNOWLEDGEMENT

The study reported in this paper is partly carried out under the support of the RGC General Research Fund, HKSAR Project No. 9041338. Financial supports of this study from the National Natural Science Foundation of China under Grant No. 50708014, 51178441 and the National Key Technology R&D Program during the 11th Five-Year Plan Period under Grant No. 2006BAJ02A05 are gratefully appreciated.

ABSTRACT: Three tree species appropriate for intensive green roofs with different aerodynamic forms were tested through a boundary layer wind tunnel experiment, including one deciduous tree, one coniferous tree and one broadleaf evergreen tree. Drags and over-turning moments under different wind speeds were measured; wind-speed-specific frontal areas and tip displacements were recorded. Even considering frontal area reduction due to increasing wind speeds, drag coefficients decrease with increase in wind speed for deciduous and coniferous trees. The effect of crown porosity varies among tree species.

KEYWORDS: tree; drag coefficient; over-turning moment coefficient; wind-speed-specific frontal area; wind tunnel experiment.

1 INTRODUCTION

Green roofing systems are lightweight, engineered roofing systems that allow for the propagation of rooftop vegetation while protecting the integrity of the underlying roof (Earth Pledge Foundation, 2004). There are two main classifications of green roofs: extensive and intensive. Extensive green roofs have a thin substrate layer with low-level planting, typically sedum or lawn, and can be very lightweight in structure. Intensive green roofs have a deeper substrate layer to allow deeper rooting plants such as shrubs and trees to survive (Castleton, 2010). The likelihood of tree failure in green roofing systems is high since trees on the tops of buildings are exposed to higher wind velocities than those on the ground. Therefore, wind loads on trees and their mitigation is an important issue in the design and maintenance of green roofing systems.

During past decades, the effects of wind forces on trees have been studied from the viewpoint of forest stability. Mayhead (1973) was among the first to systematically present drag coefficients for various British forest tree species based on through wind tunnel measurements. Rudnicki et al. (2004) and Vollsinger et al. (2005) also studied the relationship between crown streamlining and drag in a wind tunnel for several young hardwood species and juvenile conifers. Of these studies, Rudnicki et al. (2004) was the first to identify wind speed specific crown frontal area simultaneously with crown drag, while crown frontal areas in still air were used before. Recently, researches relating to wind forces on real urban trees were conducted through wind tunnel experiments (Ishikawa, 2006) and field measurements (Takamori et al, 2003; Kane and Smiley, 2006; Kane et al, 2008; Koizumi et al, 2010) to determine how to prevent wind damage to them. Although field measurements tended to overcome the size restriction of wind tunnel testing, it was difficult to record the reconfigurations of trees.

The goal of this study was to evaluate drag and over-turning moment coefficients, reconfigurations and deflections of different trees. Drag coefficients based on frontal areas in still air and wind-speed-specific frontal areas were both determined; Over-turning moment coefficients based on frontal areas in still air and aerodynamic centers were provided. Other parameter considered was crown porosity as affected by crown pruning.

2 METHODS AND MATERIALS

2.1 *Trees*

Three trees including one deciduous tree, Rose of Sharon (*Hibiscus syriacus*) (HS); one coniferous tree, Emerald Cedar (*Thuja occidentalis 'Smaragd'*) (TO); and one evergreen tree, Japanese Holly (*Ilex crenata*) (IC), were chosen, as shown in Figure 1. The criteria for choice of tree species were: (1) suitable for green roofs and (2) representatives of different types of trees, especially from the aerodynamic viewpoint. Table 1 summarizes morphometric data for each species, including tree geometries, main characteristics of branching habits and foliage textures. Trees were cut just above the root flare and mounted to the five-component force balance. Rotation of the bottom of stems was not allowed after the mounting.

2.2 *Measurements*

Wind tunnel experiments were carried out in a Boundary Layer Wind Tunnel at Tokyo Polytechnic University, Japan. The test section was 2.2m wide by 1.8m high. Drag and over-turning moment data measured through a five-component commercial force balance where the tree was mounted and the reference wind pressure recorded at 1.2m above the wind tunnel floor were simultaneously collected at 500Hz and the sampling time for each run was 10 minutes. Two digital cameras were installed, one downstream of the tree and the other outside the wind tunnel, to capture the frontal areas and deformations after each run for each intended wind speed respectively.

(a) HS (b) TO (c) IC

Figure 1. Experimental trees

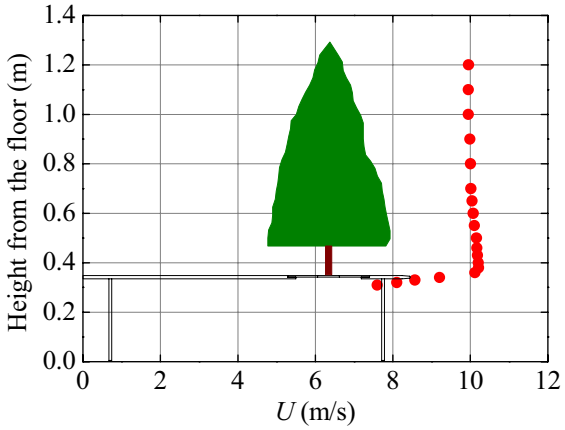

Figure 2. Uniformity of mean wind speed (U=10 m/s)

Table 1. Tree geometries and tree forms

Item		HS	TO	IC
Tree geometry	Height (H: m)	1.24	0.98	0.40
	Width (B: m)	0.53	0.45	0.42
	Caliper (b: cm)	2.3	3.7	3.3
	Frontal area (As: m^2)	0.15	0.33	0.11
	Volume (V_0: cm^3)	555	2280	930
	Porosity (VP: %)	/	97.1	96.6
Branching habit	Crown shape	upright	pyramidal	round
	Trunk and Branches	multi-trunked	with a single leader	clumping stems
Foliage texture	Leaf shape	rhomboid	scale-like	obovate
	Leaf margin	dentate	entire	serrulate

Uniform flow fields were adopted. Wind speeds ranged from 5m/s to 15m/s, the maximum wind speed in this wind tunnel, with 1m/s interval. The uniformity of the wind speed at the measurement position is shown in Figure 2 and a 30cm-high end plate was used to compensate for the non-uniform wind flows near the wind tunnel floor. The exposed part of force balance was covered by the wooden cover with a streamlined shape attached to the end plate.

2.3 *Variation in crown porosity*

The original crown porosities were reduced by pruning the branches several times using thinning pruning method (ANSI, 2001) which only removed small-diameter branches along the outside of the crown and almost kept the post-pruning crown dimensions. Four pruning for TO (Fig. 3) and three pruning for IC (Fig. 4) were conducted. The pruning dose (volumes of pruned branches and leaves) were measured using a water-displacement method after each tree pruning.

The original volume of each tree was V_0, and the volume after each pruning was V_i, (i was the times of pruning) and pruning dose (PD) (Table 2) was performed using:

$$PD = \frac{V_0 - V_i}{V_0}\left(i = 1, 2, ..., N\right) \tag{1}$$

The imaginary solid volumes V_E (gross volume) formed by the boundary of the tree structure were estimated by the special software "Tree analyzer 1.20" (Phattaralerphong and Sinoquet, 2005) through eight photos of the tree structure taken from 8 directions.The 3D crown porosity (VP) (Table 1, 2) was defined by the ratio between the volume of the trees and V_E:

$$\mathrm{VP} = \frac{V_E - V_i}{V_E}\left(i = 0, 1, ..., N\right) \tag{2}$$

(a) VP = 97.1% (b) VP = 97.8% (c) VP = 98.2% (d) VP = 98.7% (e) VP = 99.1%

Figure 3. Variation of shape of TO due to crown porosity (VP)

(a) VP = 96.6% (b) VP = 96.9% (c) VP = 97.1% (d) VP = 97.5%

Figure 4. Variation of shape of IC due to crown porosity (VP)

Table 2. Tree volumes after pruning

Tree	Item	Pruning 1	Pruning 2	Pruning 3	Pruning 4
TO	Volume (V0: cm3)	1730	1400	1020	720
	Porosity (VP)	97.8	98.2	98.7	99.1
IC	Volume (V0: cm3)	855	775	690	
	Porosity (VP: %)	96.9	97.1	97.5	

2.4 *Calculations*

E value, an alternative measure of crown reconfiguration suggested by Vogel (1984), represents the exponent to which the wind speed must be raised to be directly proportional to either the drag coefficient or the drag divided by the square of wind speed:

$$\frac{F_{\mathrm{D}}}{U^2} \propto U^E \tag{3}$$

where F_{D} is measured mean drag and U is measured mean wind speed.

Two sets of results for mean drag coefficients (Fig. 7) for each tree ($C_{\mathrm{D,U}}$ and $C_{\mathrm{D,S}}$) were calculated based on wind-speed-specific frontal areas and frontal areas in still air.

$$C_{\mathrm{D,U}} = \frac{F_{\mathrm{D}}}{0.5\rho U^2 A_{\mathrm{U}}} \tag{4}$$

$$C_{\mathrm{D,S}} = \frac{F_{\mathrm{D}}}{0.5\rho U^2 A_{\mathrm{S}}} \tag{5}$$

where ρ is air density calculated using readings from a barometer and thermometer before each experimental run; A_{U} and A_{S} are wind-speed-specific frontal areas of trees and frontal areas of trees in still air, respectively.

Overturning moment coefficients C_{M} at the bottom of tree stems were calculated based on frontal areas in still air as follows:

$$C_{\mathrm{M}} = \frac{M_{\mathrm{OT}}}{0.5\rho U^2 A_{\mathrm{S}} H} \tag{6}$$

where M_{OT} is measured mean overturning moment and H is the height of tree in still air.

The distance between stem base and the height of aerodynamic center of trees (H_{C}) can be identified based on:

$$H_{\mathrm{C}} = \frac{M_{\mathrm{OT}}}{F_{\mathrm{D}}} = \frac{0.5\rho U^2 A_{\mathrm{S}} H \cdot C_{\mathrm{M}}}{0.5\rho U^2 A_{\mathrm{S}} \cdot C_{\mathrm{D,S}}} = \frac{C_{\mathrm{M}} H}{C_{\mathrm{D,S}}} \tag{7}$$

and the non-dimensional height of the aerodynamic center of the trees (α_{C}) were normalized by the height of the tree in still air:

$$\alpha_{\mathrm{C}} = \frac{H_{\mathrm{C}}}{H} = \frac{C_{\mathrm{M}}}{C_{\mathrm{D,S}}} \tag{8}$$

3 RESULTS AND DISCUSSIONS

3.1 *Force and wind speed relationship*

Fig. 5 shows the relationship between drag force and wind speed for the three trees, including the experimental data and curve fit using power function. *E* values are -0.36, -0.29 and -0.01 for HS, TO and IC respectively.

Although the aerodynamic forms of HS and TO are totally different, including branching habit and leaf texture as indicated in Table 1, their *E* values do not show a large difference. However, the *E* value for IC, close to 0, is different from the previous two trees. This is mainly due to higher branch stiffness of IC and its reconfiguration is limited compared to HS and TO. It can be concluded that other than morphological differences among species, *E* values, which reflects the ability of reconfiguration, are mainly affected by the branch stiffness.

3.2 *Frontal area and wind speed relationship*

The wind-speed-specific frontal areas of the three trees and corresponding curve fits are shown in Fig. 6. The high capacity for reconfiguration of HS showed the largest exponent -0.20, while the exponent was -0.07 for TO. IC presented a positive power exponent of 0.04, which indicates that the frontal area slightly increased with increase in wind speed. This is mainly because the high frequency movements of branches and leaves at large wind speeds cannot be identified by the relatively low-frequency digital camera and overlapping in photographs was available.

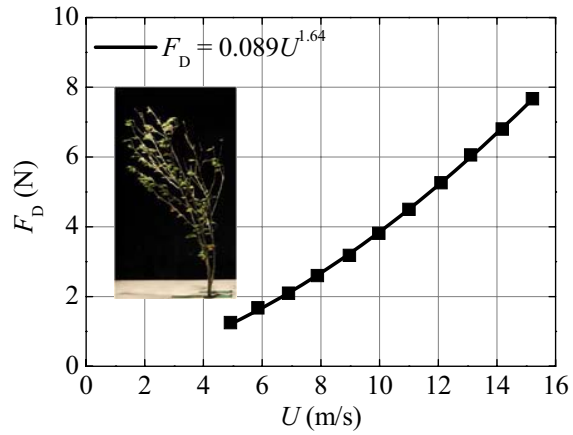
When the wind speed increased from 5m/s to 15m/s, frontal areas decreased by 20% for HS from $0.15m^2$ to $0.12m^2$, and 10% for TO from $0.33m^2$ to $0.30m^2$, and the values kept constant for IC. Unlike HS and TO, the reconfiguration of both branches and leaves of IC was not obvious because of the smaller size of the crown; the less flexible branches and leaves do not easily change their shapes.

3.3 *Deflection of tree*

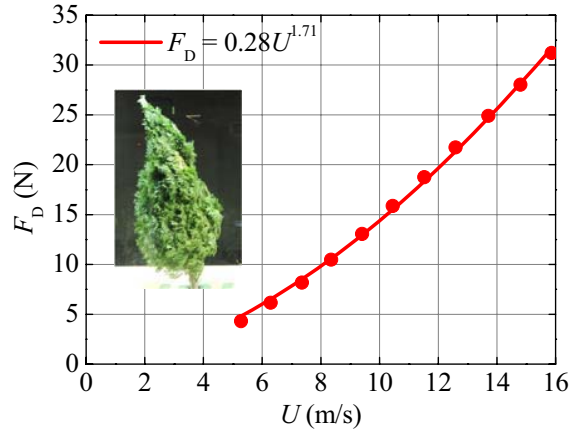
The tip displacements normalized by the tree height as well as the fitted curves are presented in Figure 7. The maximum relative displacement x_{top}/H for HS was the largest among the three species, 0.3 when the wind speed was 15m/s and the values for TO and IC were 0.17 and 0.03, respectively. Although the quantity of the wind-speed-specific tip displacement for HS was around twice that of TO, the exponents for the curve fitting were almost the same: 1.58 and 1.57. Moreover, since the power exponent for IC was 3.78, which was close to 4, pure bending theory for a rigid body in which the second-order derivative of the deformation was proportional to horizontal force seemed to be appropriate for it.

3.4 *Drag coefficient*

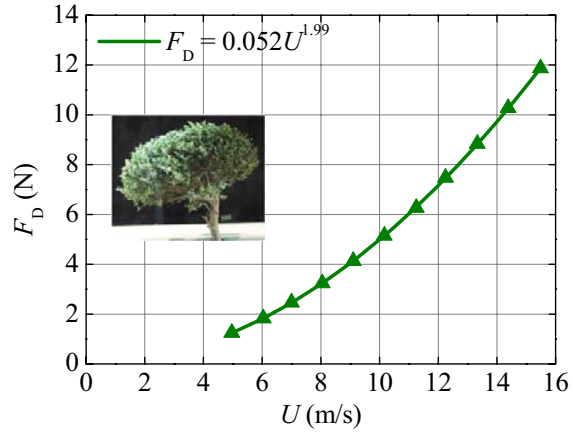
Two sets of results for mean drag coefficients (Fig. 8) for each tree were calculated. For HS and TO, it can be seen that even drag coefficients based on wind-speed-specific frontal area also decreased with increase in wind speed. This indicates that wind-speed-specific frontal area is not the only parameter to affecting drag coefficients, but that there are other factors caused by reconfiguration of trees.



(a) HS

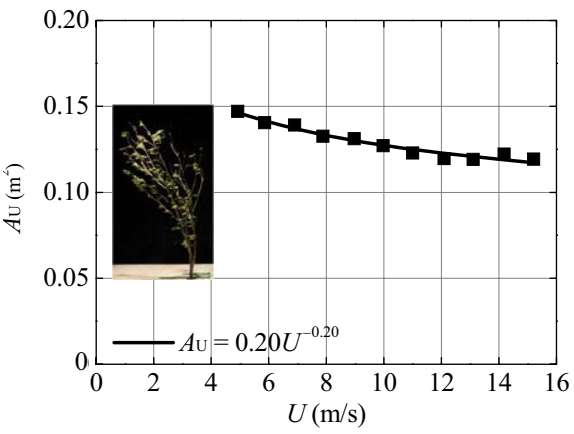


(b) TO

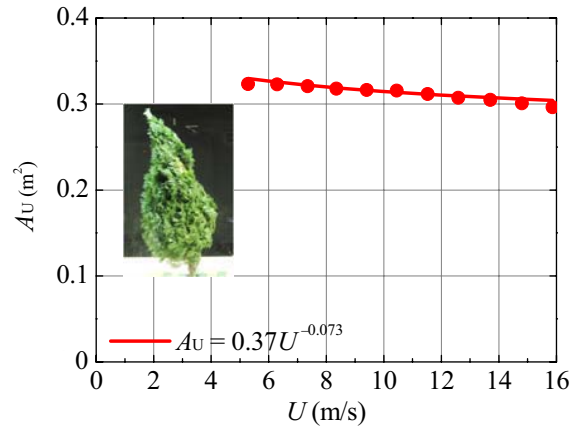


(c) IC

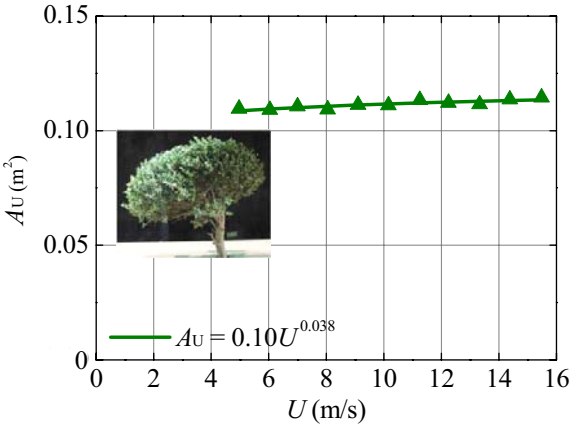
Figure 5. Variation of mean drags due to mean wind speeds



(a) HS



(b) TO

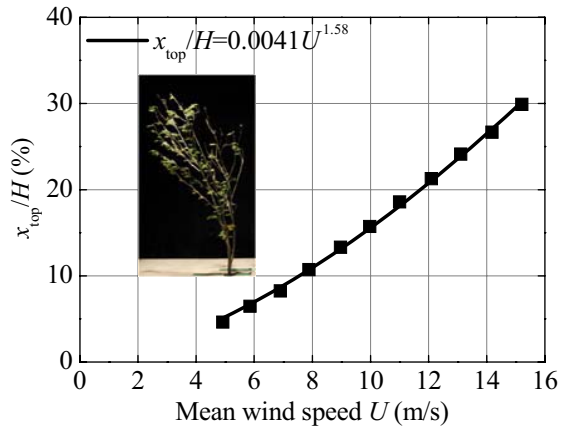


(c) IC

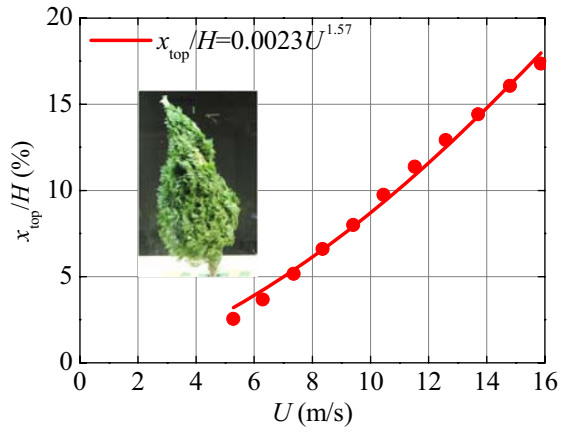
Figure 6. Variation of wind-speed-specific frontal areas due to mean wind speeds

As expected, drag coefficients for HS and TO based on frontal area in still air decreased more rapidly with increase in wind speed and were consistently smaller than those calculated based on wind-speed-specific frontal area. For wind speeds from 5m/s to 15m/s, for HS, the drag coefficients based on wind-speed-specific frontal area decreased by 20% from 0.61 to 0.49, while those based on frontal area in still air decreased by 36% from 0.59 to 0.38; for TO, the

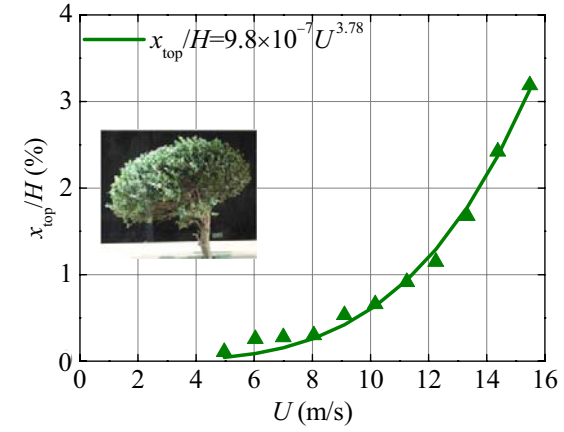
values based on wind-speed-specific frontal area decreased by 12% from 0.83 to 0.73, while those based on frontal area in still air decreased by 19% from 0.83 to 0.67. For IC, drag coefficients keep constant around 0.79.



(a) HS

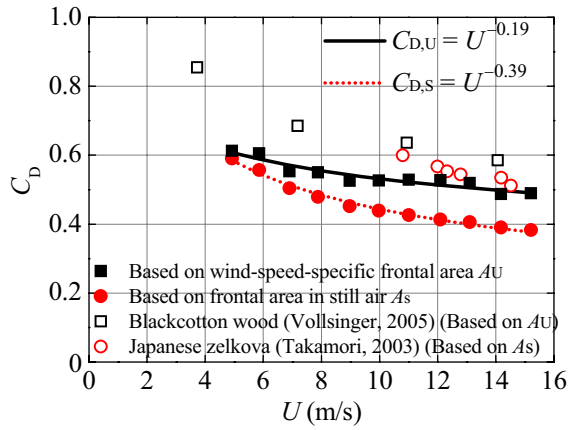


(b) TO

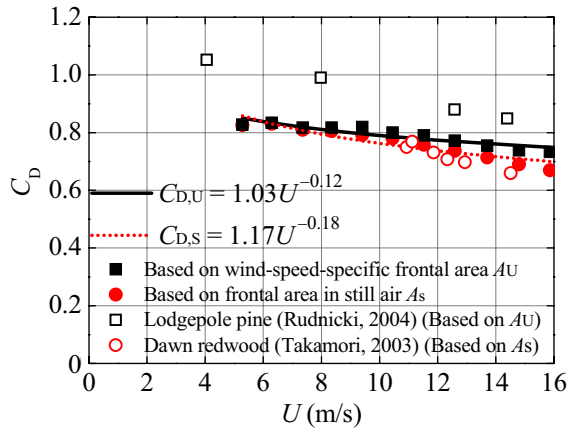


(c) IC

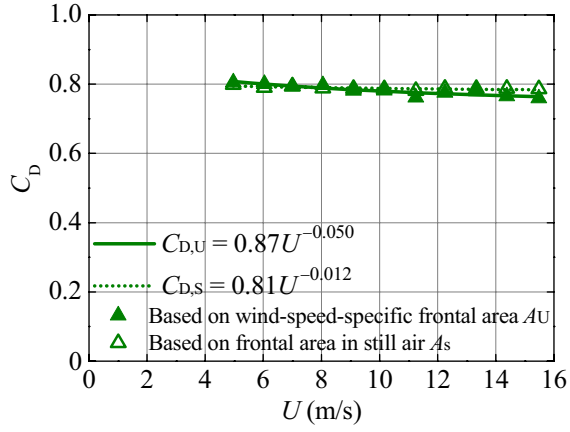
Figure 7. Variation of tip displacements due to mean wind speeds



(a) HS



(b) TO



(c) IC

Figure 8. Mean drag coefficients

The exponents for the fitted curves using $C_{D,U}$ values based on wind-speed-specific frontal area of the three trees were -0.19, -0.12 and -0.05. Since the only difference between the two sets of drag force coefficients was the area used for calculation, the discrepancy in the exponents of the curve fitting for the two sets of data can be reflected by the exponents of the curve fitting for wind-speed-specific frontal area. The exponents for wind-speed-specific frontal area were -0.20, -0.07 and 0.04; thus, the exponents for $C_{D,S}$ values based on still air area were -0.39, -0.19 and -0.01.

Drag coefficients of HS and TO have been compared with those obtained from similar researches on real trees. Two deciduous trees, Blackcotton wood (Vollsinger, 2005) and Japanese zelkova (Takamori, 2003), and two coniferous trees, Lodgepole pine (Rudnicki, 2004) and Dawn redwood (Takamori, 2003), in a similar wind speed range were chosen for comparison. The results showed that the present data for both HS and TO were comparable to the previous data. For HS, the values ranged from 0.49 to 0.61 were between the reported range from 0.51 to 0.85; and the range from 0.73 to 0.83 for TO was also located in the range for previous data from 0.66 to 1.05, which validate the reasonableness of the present data.

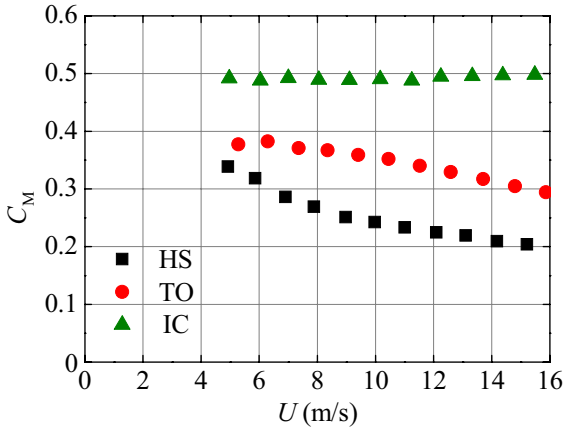


Figure 9. Mean overturning moment coefficients

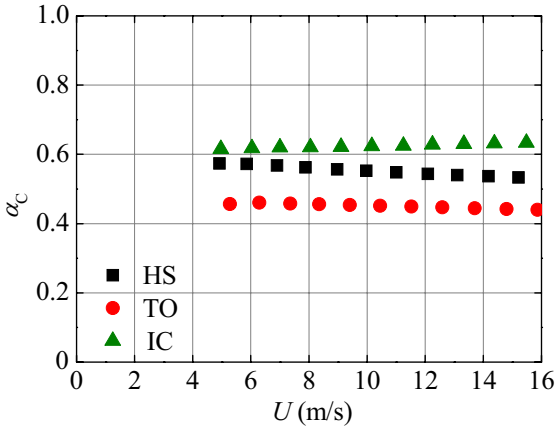

Figure 10. Relative height of aerodynamic centers

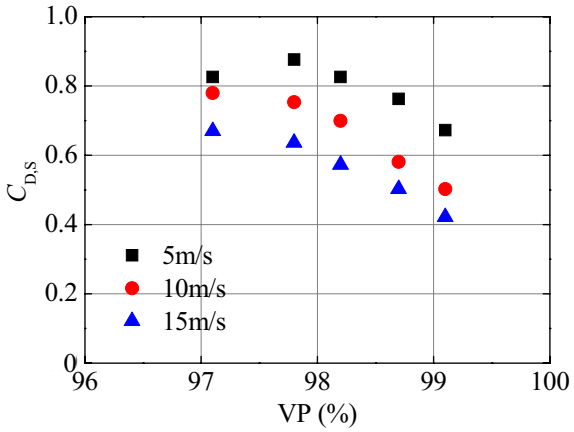
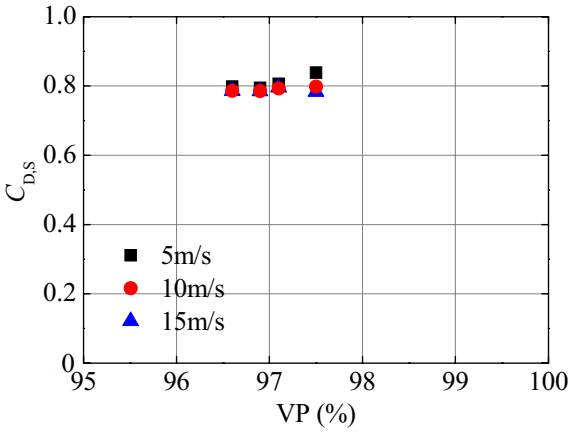


(a) TO



(b) IC

Figure 11. Effect of crown porosity on mean drag coefficients

3.5 *Aerodynamic center*

Results of overturning moment coefficients calculated based on frontal area in still air and relative height of the aerodynamic center are shown in Figures 9 and 10, respectively. The relationships between overturning moment coefficients and wind speeds for the three species were similar to the results for drag coefficients.

Aerodynamic center was mainly affected by the distribution of the crown structures and differed among tree species. Among the three experimental trees, the maximum value of α_C, 0.62, was recorded for IC, since the main crown was located at the upper part of the tree and left trunk only at half the bottom. TO has the smallest value of aerodynamic center, 0.45, since the crown has a conical shape and the main crown was distributed at the lower part of the crown. For HS which has a relatively uniform distribution in branch and leaves from top to bottom compared with the previous two species, the values ranged from 0.53 to 0.57.

3.6 *Effect of crown porosity*

Figure 11 shows the effect of crown porosity on drag coefficients of the tree in terms of the crown porosities and the values for the wind speeds of 5m/s, 10m/s and 15m/s were chosen. For TO, when the wind speed was low (5m/s), the drag coefficients first increased with increase in crown porosity and then decreased. This tendency never took place and drag coefficients gradually decreased with increase in crown porosity for high wind speed (10m/s and 15m/s). For IC, although the values at different wind speeds slightly changed, values for the same wind speed did not differ with change in crown porosity.

4 CONCLUDING REMARKS

Aerodynamic characteristics including drag and over-turning moment coefficients and plant forms of three trees, suitable for green roofing system were investigated through wind tunnel experiments. Variations of drag, frontal area, tip displacement and drag and over-turning moment coefficient due to mean wind speed were mainly discussed. The effect of crown porosity, view angle and turbulence intensity were investigated. The main conclusions are summarized as follows:

(1) The Vogel exponents were -0.36 and -0.29 for HS and TO, and -0.01 for IC. The power exponents fitting the relationship between wind-specific frontal areas and wind speed were -0.20, -0.07 for HS and TO, and 0 for IC. The discrepancy between Vogel exponents and power exponents for frontal areas indicated that there were parameters other than area reduction due to reconfiguration that affected the reduction of drag forces. The power exponents for the curve fitting of tip displacements of the three trees were 1.58, 1.57 and 3.78, respectively. Pure bending theory for a rigid body seems to be appropriate for IC since the value was close to 4.

(2) Even considering area reduction due to wind speed, mean drag coefficients decreased with increase in wind speed from 0.61 to 0.49 for HS, from 0.83 to 0.73 for TO, which were comparable to those of previous researches. Values for IC kept constant at around 0.79. The aerodynamic center was mainly affected by the distribution of the crown structures and differed among tree species.

(3) The effect of crown porosity differed among tree species and wind speeds. For TO, unfavorable porosity occurs with maximum drag coefficients with low wind speed while porosity has little effect on IC.

ABSTRACT: The study is to establish a numerical model, capable of correctly predicting flows past discrete coniferous trees so as to provide a handy tool for pedestrian wind analysis during the preliminary design for local wind environments. Besides numerical computations, wind tunnel measurements were also performed to guide and confirm the numerical simulations. Results showed that the tree factor, to be applied in the numerical flow computations, generally increased with increases of the volume ratio and horizontal thickness of the tree body. Based on a calibrated relationship of the tree factor, numerical computations were further performed to simulate flow past an isolated tree and dual trees. The predicted downstream wind speed profiles showed good agreements compared to the measurement results.

KEYWORDS: numerical simulation, wind tunnel measurement, pedestrian wind, coniferous tree.

1 INTRODUCTION

Planting trees in building areas can not only upgrade the local landscape but to some extent improve the wind environment, particularly regarding the reduction of wind speed at the pedestrian level. Therefore, how to analyze the wind flow in areas with discrete trees becomes an important task for the designers during the planning stage. Physically, the flow pattern around a tree may appear somewhat different from that around a solid (impermeable) body due to its porous nature. As a portion of wind passes through the tree, the shedding vortices can interact with the penetrating flow and disturb the formation of the downstream wake. Intuitively, the extent of this interaction effect may depend on the porosity and thickness of the tree.

To analyze the flow past discrete trees, wind tunnel model experiments are mostly employed. Besides the amount of human labor and time required in the execution of experimental work, however, technical difficulties (such as the scale effect) are generally encountered. In contrast, the adoption of numerical simulations can be another alternative for the flow analysis. Due to significant advancements of computer hardware and software, the application of numerical simulations becomes more and more popular in dealing with such flow problems as it is considered relatively more economical. Although it is presently impractical to simulate the flow around porous trees by taking into account the detail geometry of leaves and twigs since it involves a great deal of computing time, a second choice may be to find out a factor that physically reflect their existence in the computations.

Accordingly, the goal of the study is to establish a numerical model, capable of adequately predicting flows past discrete trees so as to provide a handy tool for pedestrian wind analysis during the preliminary design for local wind environments. Besides numerical computations, wind tunnel measurements were also performed to confirm and guide the numerical simulations.

2 RELATED STUDIES

Most of the previous related work concentrated on the studies in the research areas of forestry and meteorology. The main focus was to investigate the global wind flow characteristics around group trees in forest territories. Based on a global approach, the three-dimensional wind flow analyses were generally simplified into a two- or even one-dimensional problem depending on the spatial distributions of local group trees. Typically, Finnigan [1] stated that the surface wind flow region could be divided into a canopy and a surface sublayer. By field investigations, Raupach *et al.* [2] indicated that the pattern of turbulent flow characteristics within the canopy sublayer was close to that of a mixing-layer flow. A description of wind speed profile was then proposed by Raupach *et al.* [3] based on wind tunnel results. Similar profiles in forest territories were also brought out by Mihailovic *et al*. [4]. Based on the wind tunnel results, Massman [5] proposed a leaf area index (LAI) and discussed its influence on the associated wind speed profiles, surface shear velocities and roughness heights. Additionally, Novak *et al.* [6] found that a change of the spatial density of trees in a forest could affect the local mean and turbulent flow characteristics, mainly dominated by large-scale turbulence eddies. Further results of wind tunnel experiments of wind flow past a single layer and a double layer of plants by Boldes *et al*. [7] revealed that mixing flows occurred in the wake region and produced bleed flows due to the effect of large-scale eddies. Moreover, Flesch & Wilson [8, 9] carried out wind tunnel experiments to investigate the protected area as well as the extent of wind speed reduction downstream of group trees.

There are also several typical studies related to wind past trees by using numerical analysis. For instance, Shaw & Schumann [10] proposed an inclusion of a source term in the momentum equations to physically reflect the tree effects. The introduced drag term was the product of the drag coefficient (c_D), leaf density (a) and combined velocity (V). Wilson and Flesch [11] used a two-dimensional numerical model to simulated the flow past forests. The predicted wind speed profiles were in good agreements with the in-field results by Raynor [12]. By performing large eddy simulations, Su *et al*. [13] predicted neutrally stratified flows past forests. Patton & Davis [14] also carried out large eddy simulations to investigate the dispersion mechanism of chemicals in forests. Watanable [15] performed large eddy computations to examine the turbulence structure above forests. Moreover, Sládek *et al*. [16] investigated numerically the two- and three dimensional wind fields of boundary-layer flows past forests in complicated land territories.

3 NUMERICAL METHOD

In the study, a weakly-compressible-flow method [17] together with large-eddy-simulations is used in the numerical simulations. To simulate turbulence effect in the flow, a subgrid-scale turbulence model by Smagorinsky [18] is applied. In the computations, a finite-volume approach is adopted. For spatial volumes wholly occupied by air, the governing continuity and momentum equations in index forms are respectively as

$$\frac{\partial \overline{p}}{\partial t} + \frac{\partial}{\partial x_j}(\rho c^2 \overline{u_j}) = 0 \tag{1}$$

$$\frac{\partial \overline{u_i}}{\partial t} + \frac{\partial \overline{u_i}\,\overline{u_j}}{\partial x_j} = -\frac{\partial}{\partial x_j}\left(\frac{\overline{p^*}}{\rho}\right) + \frac{\partial}{\partial x_j}\left(\frac{\tau_{ij}}{\rho}\right) \tag{2}$$

where t and x indicate time and spatial coordinates; c, ρ , u and p denote respectively sound speed, air density, flow velocity and pressure; “bar” means spatial average and the subscripts in-

dicates spatial indices; $p^* = p + (\rho/3)\overline{u_i' u_i'}$; τ is the combination of the viscous and subgrid-scale stress, in which the subgrid-scale diffusion coefficient is expressed as [18]

$$v_t = (C_S \Delta)^2 (\frac{S_{ij}}{2})^{0.5} \qquad \text{with} \qquad S_{ij} = (\frac{\partial \overline{u_j}}{\partial x_i} + \frac{\partial \overline{u_i}}{\partial x_j}) \tag{3}$$

where Δ denotes the characteristic length of the computation cell and C_S is the Smagorinsky constant.

For the computational cells partially occupied by leaves and twigs, by neglecting sway motion of the tree body the momentum equation is modified by adding a source term as [10]

$$\frac{\partial \overline{u_i}}{\partial t} + \frac{\partial \overline{u_i}\,\overline{u_j}}{\partial x_j} = -\frac{\partial}{\partial x_j}(\frac{\overline{p^*}}{\rho}) + \frac{\partial}{\partial x_j}(\frac{\tau_{ij}}{\rho}) + (f_D)_i \tag{4}$$

$$\text{with} \quad \overrightarrow{f_D} = \left[-C_D a u \left|\overrightarrow{V}\right|, -C_D a v \left|\overrightarrow{V}\right|, -C_D a w \left|\overrightarrow{V}\right| \right]^T \tag{5}$$

where C_D is the drag coefficient and a is the leaf surface area per unit volume.

4 WIND TUNNEL EXPERIMENTS

Since the factor of leaf surface area per unit volume (a value) cannot not be easily measured, a new parameter is proposed and is defined as

$$C_{Da} = C_D a \tag{6}$$

To investigate how C_{Da} varied with the conditions of trees, wind tunnel experiments were performed. In the experiments, a rectangular panel (D = 0.28 m) with a number of parallel coniferous leaf strings was set in the direction perpendicular to the uniform approaching flow (see Figs. 1 and 2； U_0 = 10 m/s). Hot-film anemometry was adopted to measure the downstream cross-sectional mean and root-mean-square velocity profiles. On the other hand, a series of numerical simulations with a number of guessed C_{Da} values were performed in parallel. By comparing with the measurement profiles corresponding to a prescribed thickness (B) and volume density of trees (γ), the C_{Da} value that lead to the best agreement between the measurement and calculated profiles was then obtained. Figure 3 illustrates a typical example of the velocity profile comparisons.

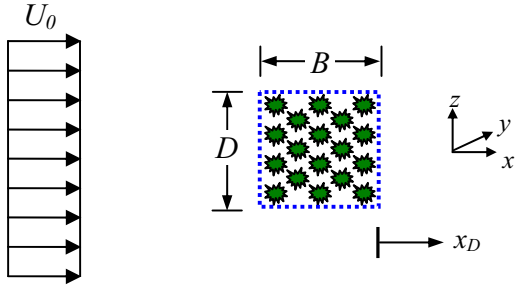

Figure 1. Schematic of experiments.

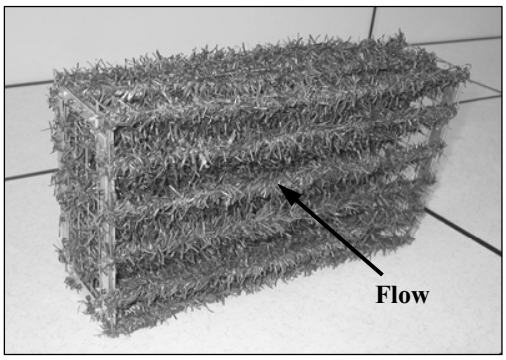

Figure 2. Panel of tree strings.

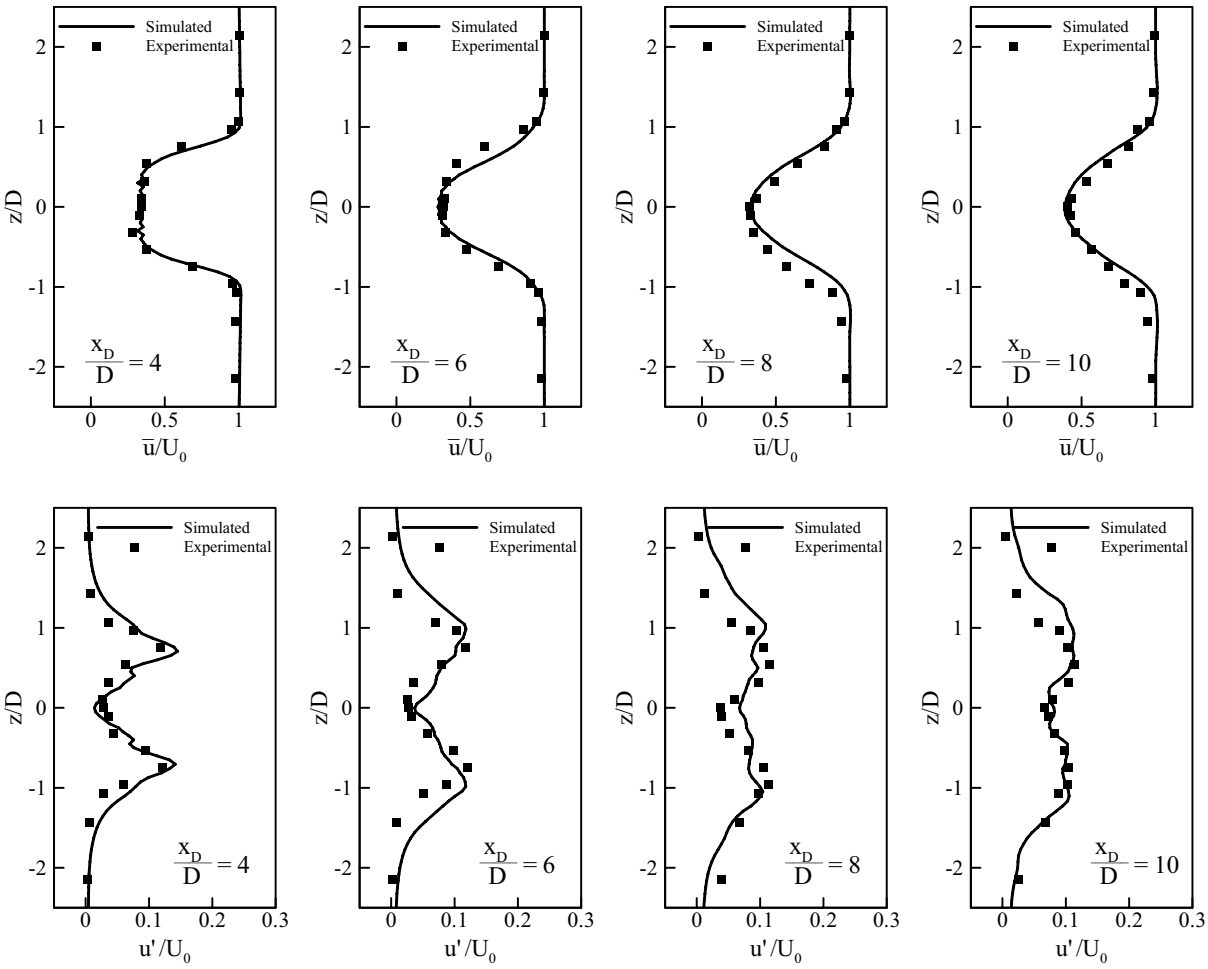

Figure 3. Comparison of cross-sectional mean and root-mean-square velocity profiles behind a square tree panel. (B/D = 0.5, γ = 0.3%, C_{Da} = 1.75)

Accordingly, Fig. 4 depicts the contour plot of the C_{Da} value in relation to the panel thickness (B) and volume ratio of tree body (γ). The general tendency shows that an increase of the

panel width or the volume ratio results in an increase of the C_{Da} value, except when B and γ are about 0.3D and 0.75%. In addition, the variation of C_{Da} appears insignificant as B is greater than $2D$.

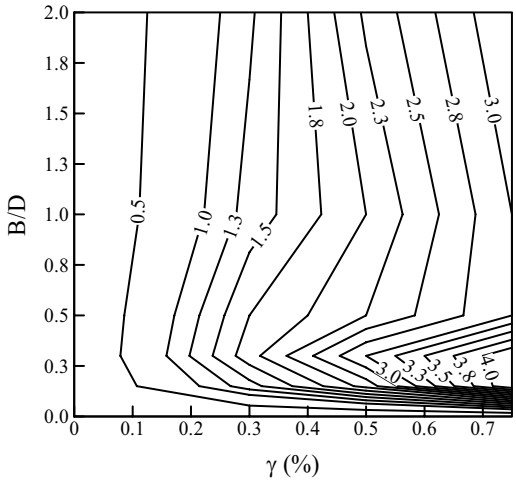

Figure 4. Contours of C_{Da}.

5 FLOW SIMULATIONS

Based on the result in Fig. 4, simulations were conducted further to examine the validity of the calibrated C_{Da} variations. In the computations, a uniform approaching flow is selected (U_0 = 10 m/s). Parallel wind tunnel experiments were also carried out to measure the downstream velocity profiles for comparisons.

5.1 *Uniform flow past an isolated coniferous tree with a conical shape*

Figure 5 depicts the schematic of the three-dimensional problem. In the computation, the tree body was divided into several layers, and the C_{Da} values associated with the grid cells in each layer were taken from the calibration contour plot (Fig. 4) according to the horizontal thickness and volume ratio of the tree body.

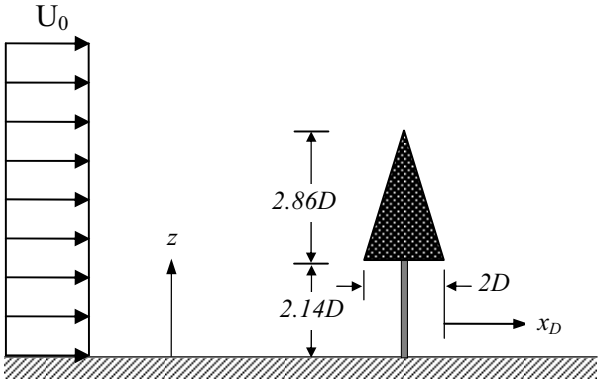

Figure 5. Schematic of flow past an isolated tree body with a conical shape.

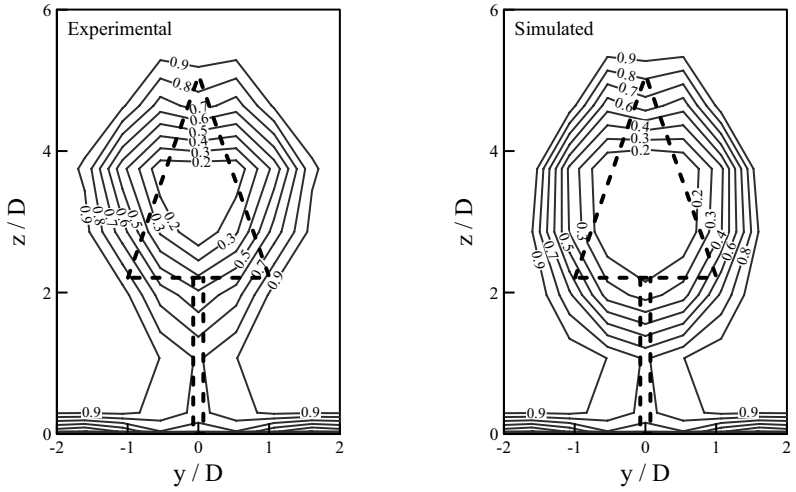
The comparisons of mean and root-mean-square velocity profiles at a typical downstream cross-section (x_D = 6*D*) are shown in Fig. 6. The spatial correlation coefficient of the cross-sectional velocity variations between the experimental and calculated results are respectively 0.976 and 0.916, indicating that the simulations well predicted the flow.

(a) Mean profiles (correlation coefficient = 0.976)



(b) Root-mean-square profiles (correlation coefficient = 0.916)

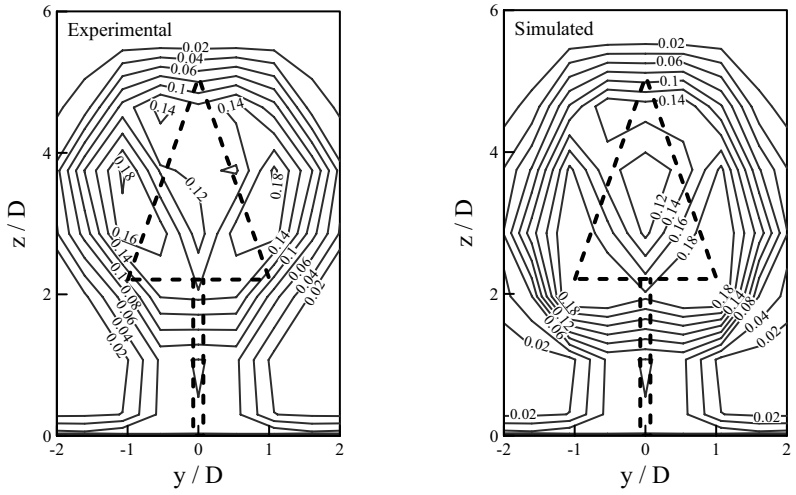


Figure 6. Comparison of cross-sectional mean and root-mean-square velocity profiles of an isolated tree (x_D = 6*D*).

5.2 *Uniform flow past dual coniferous trees in a tandem arrangement*

An additional flow computation was conducted to simulate a uniform flow past dual coniferous trees in a tandem arrangement with an edge-to edge distance of 2*D* (see Fig. 7). The comparison shows in Fig. 8 that the agreement between the measurement and the predicted results at a typical cross-section (x_D = 6*D*) appears fairly good. The spatial correlation coefficients are respectively 0.976 for the mean profiles and 0.916 for the root-mean-square profiles.

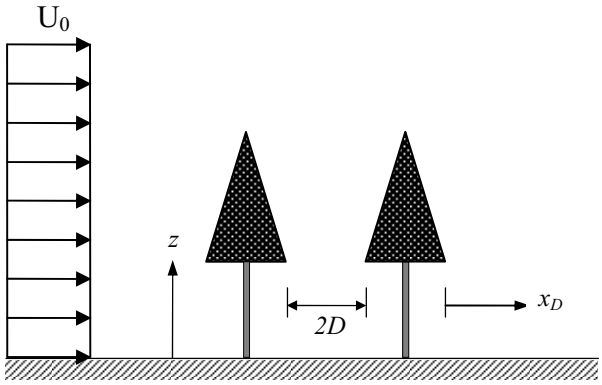

Figure 7. Schematic of flow past dual trees in a tandem arrangement.

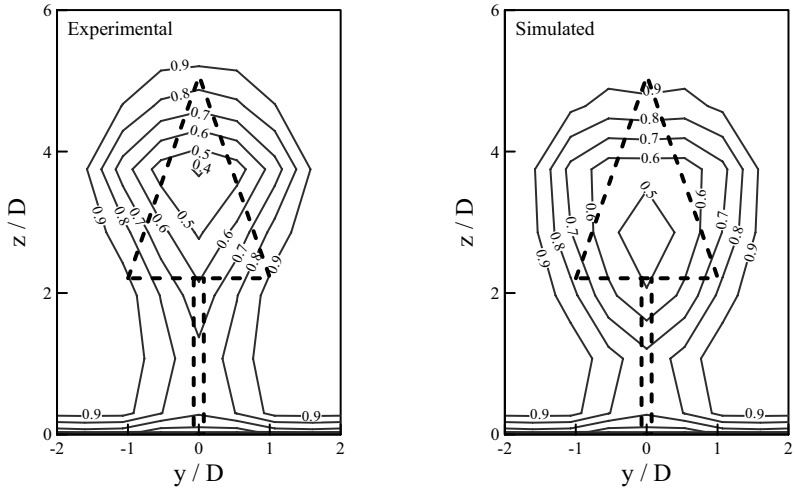
(a) Mean profiles (correlation coefficient = 0.985)



(b) Root-mean-square profiles (correlation coefficient = 0.901)

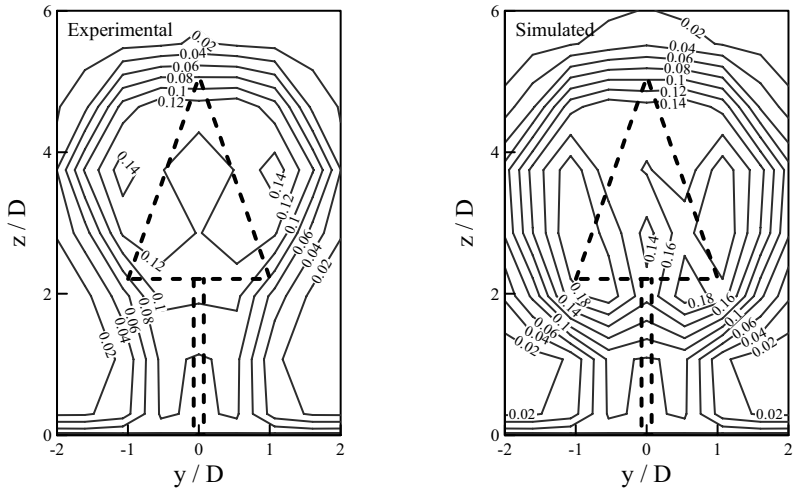


Figure 8. Comparison of mean and root-mean-square velocity profiles of dual trees in a tandem arrangement ($x_D = 6D$).

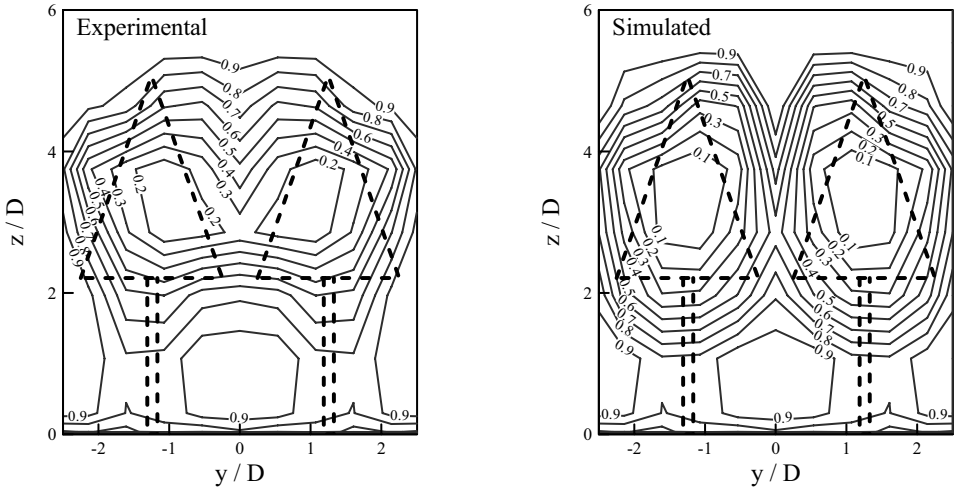
5.3 *Uniform flow past dual coniferous trees in a side-by-side arrangement*

A uniform flow past dual coniferous trees in a side-by-side arrangement with an edge-to-edge transverse distance of *0.5D* was further simulated numerically. The comparisons in Fig. 9 show that at a typical downstream cross-section (x_D = *0.6D*), again, the predicted mean and fluctuating velocity profiles are predicted with acceptable accuracy.

(a) Mean profiles (correlation coefficient = 0.939)



(b) Root-mean-square profiles (correlation coefficient = 0.854)

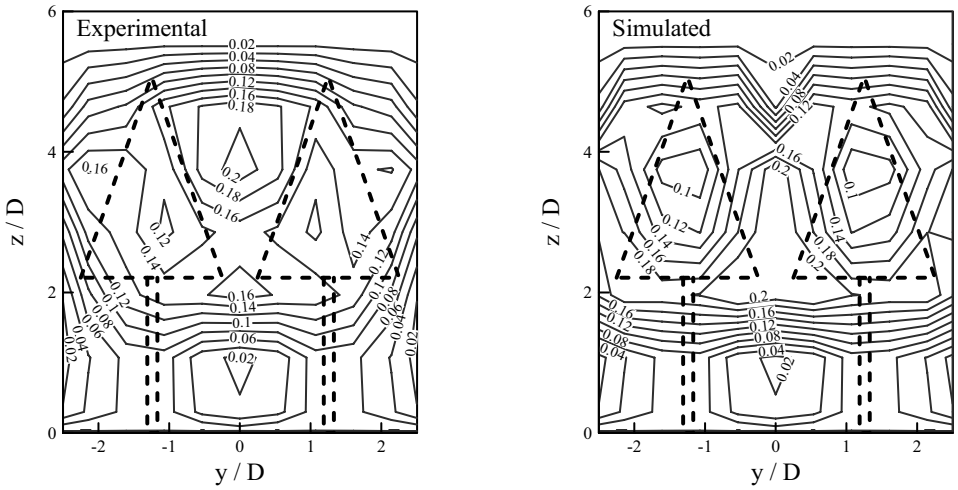


Figure 9. Comparison of mean and root-mean-square velocity profiles of dual trees in a side-by-side arrangement (x_D = 6*D*).

6 DISCUSSIONS

Different from the analysis of flow past group trees, the present study attempted to investigate the effect of discrete trees in more detail so as to provide extensive information regarding the local tree characteristics. Although the sway motion of trees due to wind action could affect the neighboring flow behavior [8, 9, 11], it was not considered in the study to simplify the analysis.

The basic concept of the proposed procedure to determine the C_{Da} variation is that as the wind flow impinges the tree body, the effect of the tree is mainly controlled by the volume ratio of local leaves and twigs as well as the horizontal thickness. As the numerical flow simulations in the three examples were successfully applied, it indicates that the C_{Da} variation (Fig. 4) can be used to simulate flows past discrete trees with adequate accuracy.

The result in Fig. 4 also indicates that as the thickness of the tree body exceeds $2D$(D = 0.28 m), the variation of C_{Da} appears insignificant. It reveals that the relation can be adopted in cases with a larger size of discrete trees.

Finally, it interesting that C_{Da} varies significantly when B and γ are near $0.3D$ and 0.75% . In the wind tunnel experiments, however, the range of the volume density (γ) was limited up to 0.75%. Additional studies will be needed to investigate this issue in a more extensive manner.

7 CONCLUSIONS

A method of identifying the tree factor was proposed. By comparing with the measurement results of the velocity profiles downstream of rectangular tree panels, the C_{Da} value associated with the thickness (B) and volume ratio (γ) of the tree body was calibrated numerically by a try-and-error procedure. Accordingly, the variation of C_{Da} in relation to B and γ was presented.

Based on the calibrated contour plot of C_{Da}, simulations of uniform flows past an isolated tree, and dual trees in a tandem and a side-by-side arrangement were performed to examine the validity of the numerical method. The comparisons, in terms of the downstream mean and root-mean-square velocity profiles indicated that the flows were well predicted. Several conclusions are drawn as follows:

1. The general tendency shows that an increase of the thickness or the volume ratio results in an increase of the C_{Da} value, except when B and γ are about $0.3D$ and 0.75% respectively.
2. When B exceeds $2D$, the variation of C_{Da} appears insignificant.
3. As the sway motions of trees can be neglected, the calibrated variation of C_{Da} can be readily applied to simulate flows past discrete trees with adequate accuracy.

Aerodynamics of high-speed trains in confined spaces

Tim Gilbert, Chris Baker, Andrew Quinn, Mark Sterling

School of Civil Engineering, University of Birmingham, Edgbaston, Birmingham, UK

ABSTRACT: In confined spaces the air movements around high speed trains may be amplified. Moving-model aerodynamic experiments were undertaken to identify the fundamental changes to train-induced air movements by firing a 1/25th scale high-speed train past instrumented walls and through box-shaped tunnels. The effect of confinement on velocities in the boundary layer and wake are assessed. Moreover the peak gusts are analysed using a prescribed European methodology to determine whether confined spaces cause the flow to exceed acceptable criteria. All results showed significant increases in velocity in the near wake, with the gusts exceeding allowable limits of velocity at positions extending far from the train side. The pressure transient increased in magnitude with increasing confinement, although the increases were lower than those predicted by European standards.

KEYWORDS: High-speed trains, aerodynamics, confined spaces, pressure, slipstream.

1 INTRODUCTION

This paper will analyse the flow around a German ICE-2-style high-speed train passing through confined spaces formed by various combinations of walls and ceilings, both at a fundamental and an applied level. This information is useful for assessing resilience and safety on routes where confined sections may amplify the flow. Tests were undertaken at the TRAIN Rig moving-model aerodynamic facility in Derby (UK), owned and operated by the University of Birmingham. It has 150m long tracks and can propel reduced scale model vehicles to speeds of up to 75m/s. A large dataset was collected, from which a small subset will be analysed in this paper.

The methodology is described in Section 2. Slipstream and wake velocities will be presented in Sections 3 and 4, with emphasis placed on the fundamental changes caused by the confined cases. Section 5 examines the peak gusts at 'human height' at the trackside, using the European slipstream methodology set out by the 'Technical Specification for Interoperability' (TSI) for high-speed rolling stock ([1]). The TSI rules apply to any train operator seeking regulatory acceptance for operating high-speed services between national borders, so it is very relevant to the developing trans-European interoperable high-speed rail network. Section 6 builds on a recent observation by [2] that the predictive equations for loading on objects caused by train-induced pressure changes in [3] may need revising. A revision would have a direct impact on the structural engineering costs of trackside infrastructure ([4,5]).

2 METHODOLOGY

Experiments were commissioned at the TRAIN Rig moving-model facility. A four-coach ICE-2 shaped train was used, pictured in Figure 1 below. It was built to 1/25 scale with equivalent full-scale length 106m. The test Reynolds number was 9 million based on the train model length and test speed of 32±1m/s.

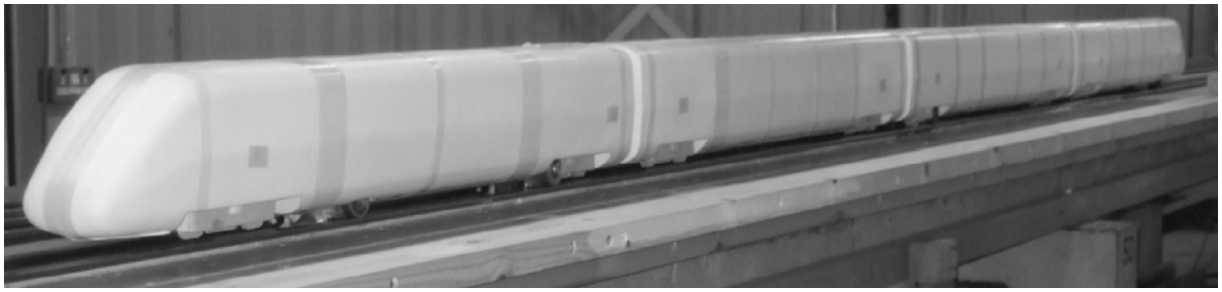

Figure 1: Photograph of the ICE-2 shaped model train.

The choice of facility was inspired by the need to measure velocities in areas within which such concerns as space for equipment, logistical issues, and health and safety considerations would be limiting factors for commissioning full-scale tests. The ability to account for relative movement between the train and the walls is a particular strength of the TRAIN Rig over wind tunnels. Other benefits of the facility compared to full-scale tests include the ability to control the speeds with little deviation between runs, to obtain data quickly and inexpensively, and to prevent changes in the background environment from occurring unpredictably and suddenly.

The ICE-2 train was selected as there is a wealth of empirical data against which to validate the results. There are several unique flow features related to the geometry, making the results specific to the train. An often crucial area is the nose and tail since the pressure and wake depend on the tail geometry. [6] discusses the flow differences between train geometries in detail.

Figure 2 below shows a general arrangement of structures, probes and pressure tappings. All measurements in this paper are written as full-scale equivalent dimensions (scale factor 25). There are three coordinate systems: ‘y’ originates from the surface of the train at its widest point; ‘y(r)’ from the top-centre of the nearest rail; ‘y(c)’ from the track centre; ‘z’ from the top of the rail. The ‘x’ axis extends through the page, with the origin aligned to the train nose (predicted to ±15cm accuracy at full-scale). Table 1 explains the structure configurations. The photographs in Figures 3 (a) and (b) show the structures as built. Every probe has a corresponding open air ‘reference case’ for comparative purposes. The probes were repositioned for Case W2 so its own reference case called ‘OA2’ is provided.

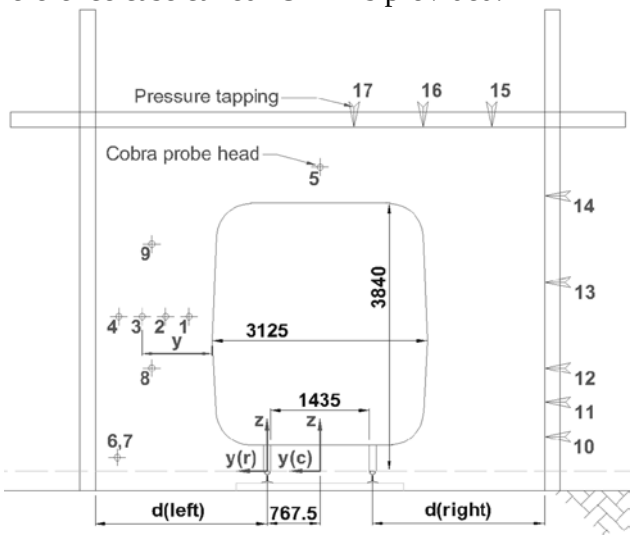

Figure 2: General arrangement of structures and instrumentation.

Table 1: Details of the test cases and structure geometries.

Case	Name	d(left) (m)	d(right) (m)	z (m)	Length[(1)] (m)	Ref. Case
OA1	Open air characterization for cases W1 W3 B1 B2.					
W1	2.5m walls	2.5	2.5	*No roof, walls 6.75m high*	8	OA1
W3	Asymmetrical walls		1.5			
B1	8m long box[(2)]		2.5	5		
B2	2m long box[(2)]		2.5		2	
OA2	Open air characterization for case W2					OA2
W2	2m walls	2	2	*No roof, walls 6.75m high*	8	

Notes:
(1) The structure length is written in model scale metres.
(2) The box edges are sealed.

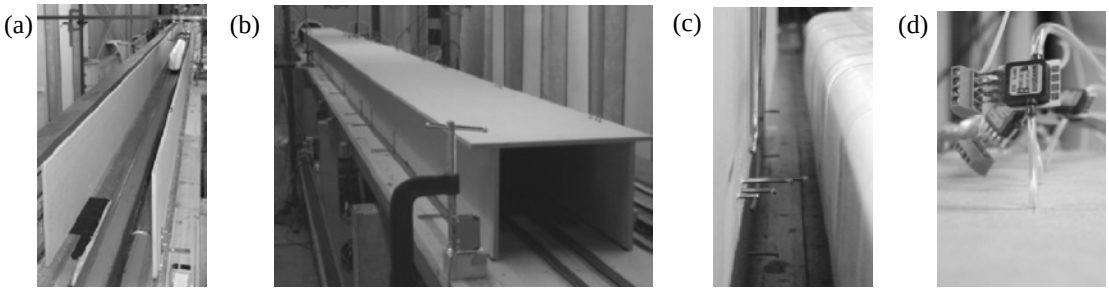

Figure 3: (a) Case W1, (b) Case B1, (c) Pressure tappings, (d) Cobra Probe heads

The probes which provide results relevant to this paper are included in Table 2 which describes their geometries. 'TFI' Cobra Probes (Figure 3(c)) measured the slipstream and wake velocities in three dimensions, and the static pressure. They were chosen because of their suitability for model-scale testing; their calibrated frequency responses are greater than 2000Hz; their accuracies are ±2%, and their 2.54mm head diameters are small and unobtrusive. The drawback is the 45 degree 'cone of acceptance' which limits the range of detection. If flow goes outside the range the data for that scan is replaced with zeros. The size of the ensemble (i.e. number of nonzero values per x-position) thus varied with distance, meaning that the ensemble was low around the first carriage where the flow was highly three-dimensional but rose to 80-100% in the wake where the flow was mainly longitudinal. For this reason the paper will not plot slipstream velocities upstream of the nose where data retention was poor. Pressure tappings were installed on the structure surfaces (Figure 3(d)). For all instruments the data were sampled at 5000Hz and low-pass filtered depending on the analysis requirements. Table 2 only describes the most relevant dimensions, but Figure 2 provides the necessary measurements to transfer geometries between coordinate systems.

Table 2: Description and positions of the instrumentation.

Probe	Type	Description	Case OA1/W1/W3/B1/B2				Case OA2/W2		
			y (m)	y(r) (m)	y(c) (m)	z (m)	y (m)	y(r) (m)	z (m)
1	Cobra	Boundary layer 1 $y_{wall}/5$ [(1)]	0.34			2.25	0.24		
2	Cobra	Boundary layer 2 $2y_{wall}/5$	0.69			2.25	0.48		
4	Cobra	Boundary layer 4 $4y_{wall}/5$	1.36			2.25	0.97		
6	Cobra	Trackside gusts			3	0.2		1.5	0.5

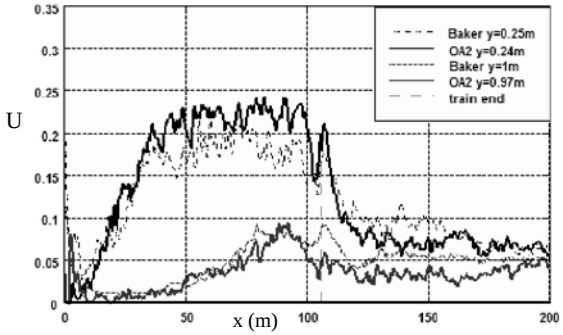
10-15	Tapping	Wall		2.5, 2, 1.5 (from right rail)		0.5, 1, 1.5, 2.75, 4			

Notes:
(1) The measurement y_{wall} represents the distance between the 'y' axis origin and the left wall, i.e. the gap between the train side and the wall. The probes are positioned in one fifth increments of y_{wall}.

3 THE BOUNDARY-LAYER

It is important to first validate the data. Figure 4 below plots the open air slipstreams (from OA2) against empirical data, closely following the analysis techniques used in the empirical tests. The data referred to as 'Baker' in Figure 4 (a) was reported in [7]. Hot-wire anemometers were used, and the positions differed very slightly (see legend for y-values); otherwise the test parameters were identical. The RAPIDE data in Figure 4 (b) was reported in [8] and comprised seven passes of an eight-car ICE-2 train measured by Gust anemometers, and seven passes of an ICE-2 model at the TRAIN Rig measured by Hot-wire anemometers. The train end at x=106m is denoted by a vertical dashed line. In Figure 4 (b) there are two 'train end' lines which represent the four and eight car trains respectively.

(a) Comparison with [7] (z=2.25m)



(b) Comparison with [8] (y(r)=1.5m, z=0.5m)

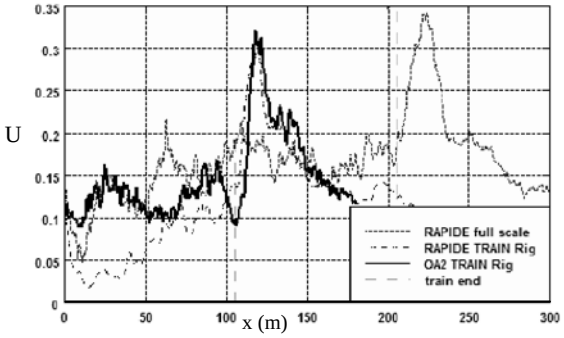


Figure 4: Comparisons of slipstream velocities with empirical data.

The Cobra Probes detect higher boundary layer velocities than previous model-scale tests, but this appears to be valid because agreement with the full-scale boundary layer in Figure 4 (b) is closer. The peak gust behind the tail is 6% lower than full-scale and has a shorter duration.

Moving on to the new results, a selection of boundary layer resultant velocities at half-train-height is shown in Figures 5-6 for a range of experimental configurations, and featuring Probes 1, 2 and 4. The slipstream data were low-pass filtered to 1000Hz using a Butterworth filter. They were non-dimensionalised by dividing by train speed (32m/s). The boundary layer extends from x=0-106m with the train end bounded by a vertical dashed line. A small section of the wake is shown. As stated previously the probe positions in Figures 5 and 6 differ, so comparisons may be made with the reference cases but not between Figures.

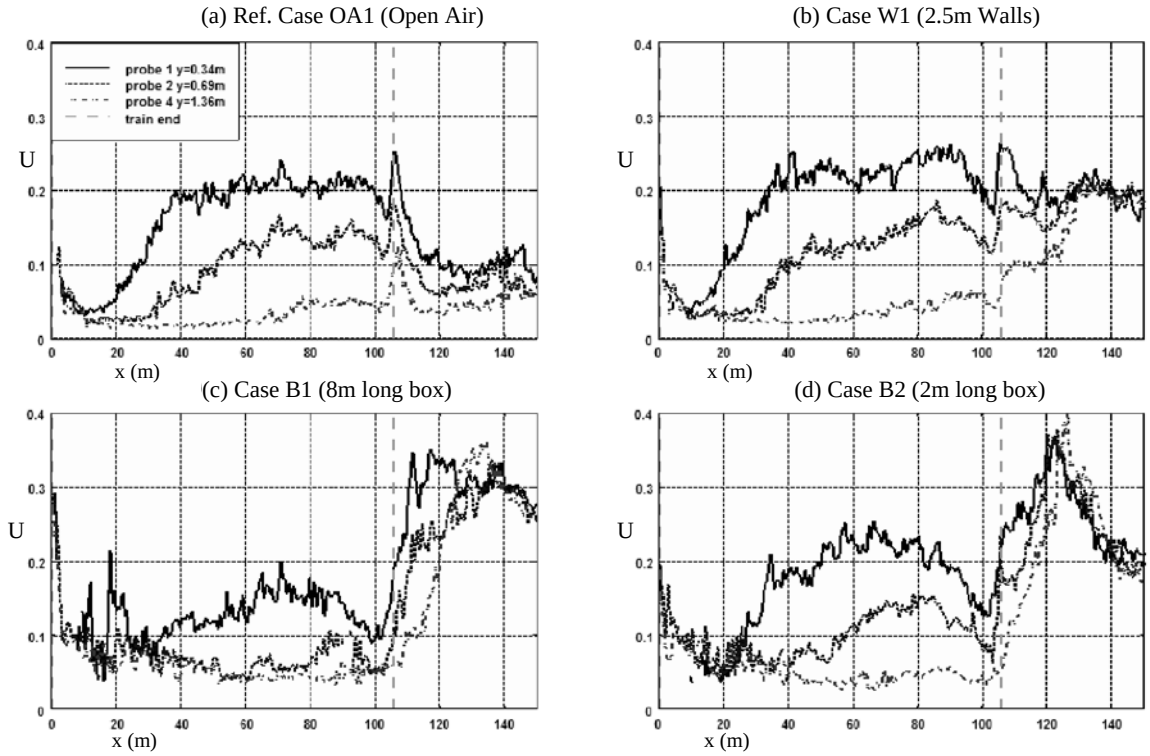

Figure 5: Boundary layer resultant velocities at z=2.25m. Reference case is OA1.

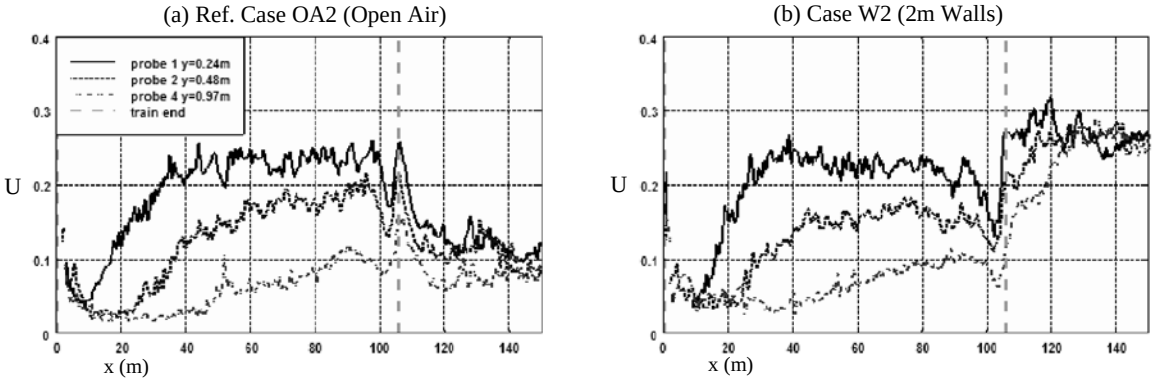

Figure 6: Boundary layer resultant velocities at z=2.25m. Reference case is OA2.

The results show that the boundary layer grows towards an equilibrium velocity, before falling off just upstream of the peak in the tail. For the wall cases the boundary layers develop very similarly to the open air cases. When the flow is enclosed by sealed boxes B1 or B2 it does not reach equilibrium because there are strong pressure gradients along the whole train length. In the short box the pressure gradients are more localized to the train ends so the velocity more closely resembles the results from unsealed configurations. The velocity gradient with respect to y (distance from train side) differs between the long and short boxes, which is likely related to the reduced cumulative effect of wall friction on the flow.

4 THE WAKE

A selection of resultant wake velocities is shown in Figures 7-8. The slipstream data were low-pass filtered to 1000Hz using a Butterworth filter. Only Probes 1 and 6 are shown. Probe 1 is quite representative of the z=2.25m group of boundary layer probes as Section 3 showed them collapsing into one curve. Probe 6 represents the wake at a low height further from the train side. Velocities are non-dimensionalised by dividing by train speed.

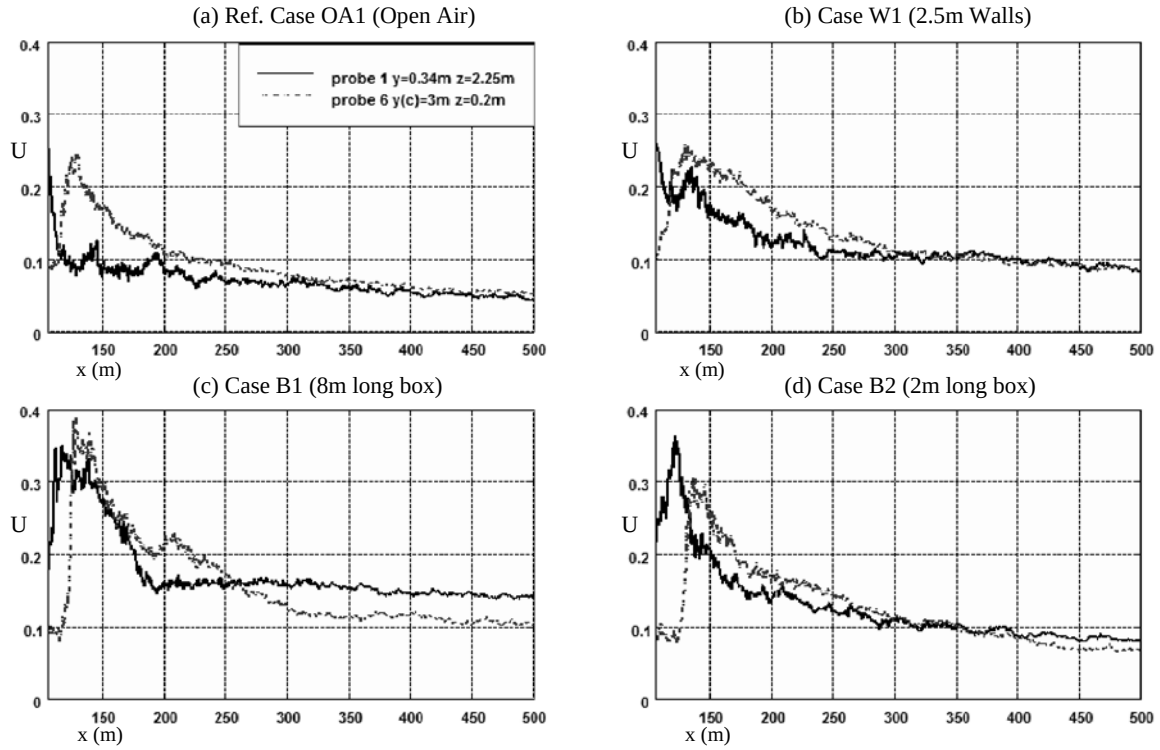

Figure 7: Wake resultant velocities. Reference case is OA1.

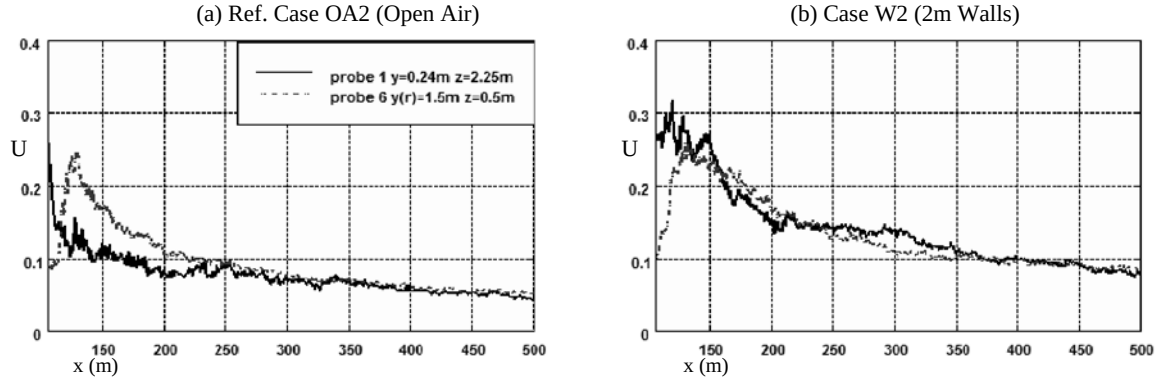

Figure 8: Wake resultant velocities. Reference case is OA2.

The results show the gust magnitudes significantly increasing relative to open air gusts in all confined cases except W1. In all cases the duration of the gust is greatly increased, which is likely due to containment of the trailing vortices behind the train which reduces their spatial

dissipation. Even at 500m the velocities are still higher than the open air cases. The signals from Probes 1 and 6 converge, suggesting the flow becomes somewhat one-dimensional and fills the space. They decay together exponentially. Case B1 (Probe 1) does not fit this description, as it seems that the decaying velocity is met by a continuous flow of air being drawn through the box long after the train has passed. It is not known if this effect is as pronounced at full-scale.

Probe 6 is laterally further from the train side than Probe 1, so predictably the near wake peak gust occurs later. We may also examine height effects by comparing Probe 6 and Probe 4 as they are at nearly the same lateral position. For reader reference Probe 4 is plotted in Figures 5-6 above. In the open air Probe 6 captures higher gusts due to the proximity to the 'trailing edge' of the tail, where the large-scale vortices are released. In the Wall and Box cases Probes 4 and 6 show closer agreement with each other, suggesting that the vortex structure fills more vertical space with increasing confinement.

5 LOW HEIGHT GUSTS

Probe 6 at y(c)=3m and z=0.2m (in Cases OA1, W1, W3, B1, B2) could be taken to represent a trackside worker standing at a continuous walkway as trains pass, with the probe roughly at the position of their centre-of-gravity. When Probe 6 is at y(r)=1.5m and z=0.5m (in Cases OA2, W2) it could represent a worker standing on the edge of a ballast shoulder. Note that for these tests the ballast itself was not simulated, meaning the ground profile was flat.

The aforementioned TSI [1] rules will be used to assess low-height gusts. It specifies an acceptable limit on the slipstream of 22m/s (by the trackside). Assessment requires ≥20 measurements to be made with the train speed very close to the design speed, and at full scale next to straight, ballasted track. Each run must be measured at ≥10Hz then filtered with a 1 second window moving-average filter. The maximum velocities of each run form an ensemble from which the mean $\bar{u}$ and standard deviation σ may be calculated. The overall U(TSI) gust value is obtained by summing $\bar{u} + 2\sigma$ of the peak values.

The TSI method is designed and optimized for ideal running conditions. One of these idealized test requirements is that the train must be running in the open air with no obstructions. This means excessive velocities may occur in certain confined spaces. These results will provide an insight into how much the limits might be exceeded in confined spaces, but this paper will not go as far as recommending actions.

The chosen analysis method emulates that used in AeroTRAIN [9]. The data was low-pass filtered and re-sampled down to 1250Hz (50Hz * model scale). A moving-average filter then smoothed the runs to 25Hz (1 second * model scale). The assumption is that the characteristic lengths and durations of the gusts are exactly 1/25th of full scale. This is obviously not the case as Reynolds number effects are non-linear, so there will be some over- or under-smoothing caused by the filter, compared to the full-scale equivalent filter.

Peak gust values from individual runs are plotted in Figure 9 and separated by test case. Note that Figures 7-8 above show the corresponding ensemble average time histories as dotted lines. Table 3 summarizes the results of the analysis.

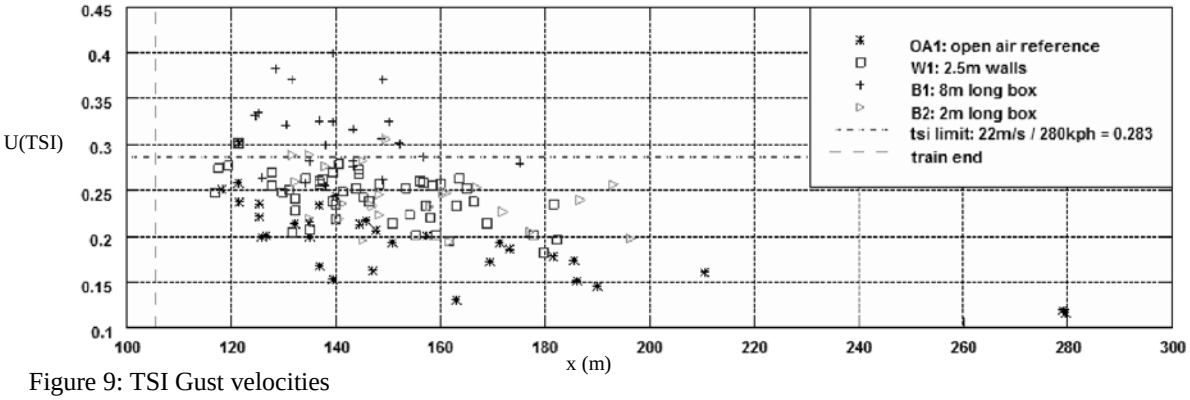

Figure 9: TSI Gust velocities

Table 3: Results of the TSI analysis applied to slipstream gusts at low heights.

Test case	Number of runs (n)	Mean ($\bar{u}$)	Standard deviation (σ)	U(TSI) ($\bar{u} + 2\sigma$)	Increase on open air (%)	Position of U(TSI) from x=0 (m)	Runs exceeding 22m/s limit (%)	Standard error of U(TSI) ($2\sigma/\sqrt{n}$)[(1)] (%)
Probe at y(c)=3m, and z=0.2m. Conforms to TSI. Plotted in Figure 9.								
OA1	32	0.20	0.04	0.28	--	157	3%	1.42
W1	50	0.24	0.03	0.29	4% on OA1	146	2%	0.84
B1	25	0.31	0.04	0.39	39% on OA1	129	60%	1.6
B2	25	0.24	0.03	0.3	7% on OA1	155	13%	1.2
Probe at y(r)=1.5m, and z=0.5m. Not plotted.								
OA2	36	0.23	0.06	0.34	--	139	*No prescribed limits*	2
W2	50	0.33	0.03	0.4	18% on OA2	122	*No prescribed limits*	0.84

Notes:
(1) The standard error is multiplied by two because U(TSI) is calculated by $\bar{u} + 2\sigma$.

Before drawing any conclusions the open air U(TSI) value should be validated. Unfortunately there aren't any directly comparable empirical tests, but the most similar is reported in [10]. Full-scale measurements of 16-car double-unit ICE-2 trains were undertaken at a position corresponding to OA1, providing a dataset of 32 passes (exactly the same as OA1), with a U(TSI) of 0.28. Although the values agree, one would expect the moving-model value to be slightly lower due to the shorter train model length. Nevertheless we may conclude that the combined mean and standard deviation of the gusts give close enough values to what would be measured at full-scale.

Moving on to the confined cases, all found higher U(TSI) values than the open air reference cases. The U(TSI) value for Case W1 was above the allowable limit of 0.283, but interestingly just 2% of the individual runs had exceeded this limit, i.e. fewer of them than OA1. On closer inspection this is because σ is lower than OA1 whilst $\bar{u}$ is higher. This is a curiosity of the TSI method. The 8m long Box (B1) found greater gust magnitudes than the 2m long box (B2). Table 3 also shows how the position of the peak gust varies; the gusts generally occur closer to the train tail as confinement increases, although this is less-so for short structures.

6 THE PRESSURE TRANSIENT

The final point of discussion addresses transient pressure loads on stationary structures. [2] recently showed that a moving-model Class 390 UK train caused pressure loads on low, short vertical walls that were significantly lower than the Eurocode ([3]) predicted loads when they were close to the side of the train. This was mainly because UK trains have smaller cross-sectional areas than the continental trains that the code equations were derived from. The code equations originated from CFD 'Panel method' simulations. The data is shown in Figure 10 (a). the paper proposed a less conservative 'National Annex' to the code for British infrastructure, based on this and other results. It was also recommended that further experiments are carried out at the TRAIN Rig on continental gauge trains to replace "the less reliable data in the current code", referring at least to the CFD-derived data.

These new experimental results allow an early indication to be made on how the pressure varies with lateral distance, and whether the current code accurately predicts the loads for larger continental rolling stock in this situation. The pressure is presumed to be scalable and sufficiently Reynolds number independent, as proven in [11]. In what follows the analysis method set out in [2] will be performed on just the vertical wall data. These experiments represent a worst case scenario; the walls are little-affected by end and edge effects, the train is distinctly wider than most high-speed trains, and it has a wedge-shaped nose, so overall the ICE-2 produces higher pressure transients than modern 'streamlined' rolling stock. The analysis involves first obtaining the maximum and minimum pressures by averaging the pressure 5m in front of and behind the nose location where the pressure crosses zero. For consistency with [2] the mean wall pressure is calculated by measuring the bending moment about the base of the maximum and minimum pressures at each of the five tapping positions, and rearranging the cantilever bending moment equation so that $\omega = 2M/L^2$, in which L=4m, and ω is the non-dimensional uniformly distributed load (Cp/m). This 'moment method' predicts slightly higher loads than a 'normal' integration of pressure tappings but agrees to one decimal place. Figure 10 (b) below shows the maximum and minimum pressures plotted against the predictive curve from [3]. Note that the predictive curve does not extend closer than y(c)=2.3m.

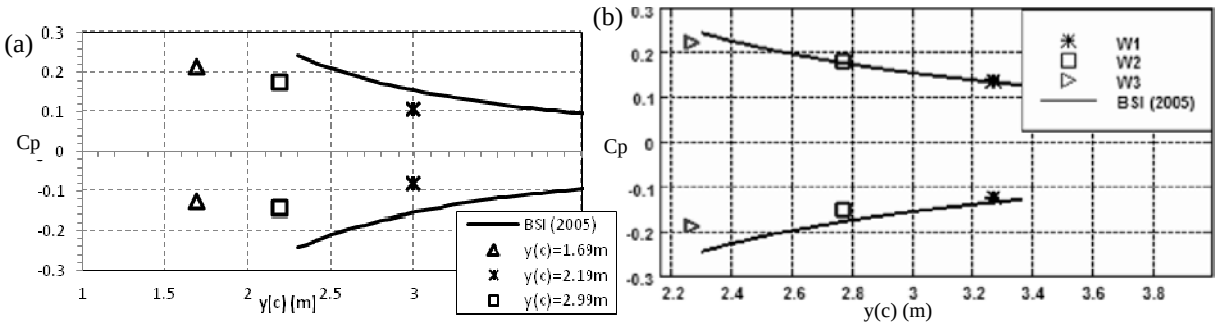

Figure 10: Wall surface pressures plotted against BSI (2005) ([3]) predictive curves, (a) Class 390, Baker et al (2012a), (b) ICE-2, Current tests.

It is clear that despite the worst case scenario the predictive curve for high-speed trains still predicts higher loads than it should for close wall distances, although the agreement is better at greater distances. Cost-savings may be possible through revising and updating the code. Please note this paper is not assuming cost savings are linked only with relaxations of standards. It may emerge that 'dynamically sensitive' structures or similar might require more stringent standards in a revised code, which may save money through reduced failures.

7 CONCLUSIONS

- The TRAIN Rig can measure slipstreams which compare well with full-scale values.
- Boundary layer velocities do not increase significantly with confinement. When sealed box cases were tested the boundary layer growth was suppressed due to steep pressure gradients along the boundary layer.
- Walls 2.5m or closer from the nearest rail increase the durations of the peak gusts behind the tail of the train, and in some cases their magnitudes.
- The addition of a ceiling to form a box further increases the durations of the gusts, as well as their magnitudes. The box represents a worst case.
- The peak-to-peak pressure change increases with confinement, with implications on the transient loads on structures.
- This paper presents just a small subset of the data that were collected. More detailed analysis of the data will be disseminated in the future, along with the results from follow-up experiments and CFD simulations.

8 ACKNOWLEDGEMENTS

Many thanks to RSSB who gave us authorization to use their pressure data. Tim would like to thank his co-authors for their support for this paper and his ongoing PhD. Thanks also to our colleagues David Soper, Sarah Jordan, and Francesco Dorigatti for their various roles in making these tests convenient and possible.

Wind loads and coupling vibration of wind-vehicle-bridge system in the process of two trains passing each other

LI Yongle, XIANG Huoyue, Wu Mengxue, QIANG Shizhong

(*Department of Bridge Engineering, Southwest Jiaotong University, Sichuan Chengdu 610031, China*)

ABSTRACT: Under lateral wind action, wind loads on vehicles and bridge can be changed dramatically when two trains pass each other. Taking a long-span suspension bridge as a practical example, the aerodynamic coefficients of vehicles and bridge were measured by wind tunnel tests with section models of vehicle and bridge. The coupling vibration of wind-vehicle-bridge (WVB) system was simulated for the process of two trains passing each other. The responses of vehicles and bridge were investigated to demonstrate the effects of the spacing of two trains, wind speed and vehicle speed. The analysis results indicate that the sudden change of wind loads on leeward vehicles can considerably increase the lateral response of leeward vehicles.

KEYWORDS: two trains passing each other; wind-vehicle-bridge system; coupling vibration; wind load; wind tunnel test.

1 INTRODUCTION

Lateral wind is one of the most important influencing factors on train running performance. Many wind-induced accidents of rail vehicles have been reported all over the world. With higher train speed and lighter vehicle body, train is more sensitive to strong lateral winds. In the process of high speed train running along a flexible bridge under lateral winds, there is the interaction among wind, vehicle, and bridge, which represents the coupling vibration of WVB system.

Diana and Cheli[1] studied the interaction of wind, vehicle and bridge, in which the wind force was simplified as additional transverse force. Xia[2]and Guo[3] et al. further studied the effect of fluctuating wind. Ge et al[4-5]. developed above works by measuring aerodynamic coefficients, which considered the interaction between bridge and vehicle. Li et al. [6-9] presented a relatively better WVB system model, which well reflected the aerodynamic coupling relationship between wind, vehicle and bridge, and considered the geometric and mechanical coupling relationships between bridge and vehicle.

High-speed vehicles running on bridge deck are subjected to side force and overturning moment under strong lateral wind. The wind loads of leeward vehicles are abruptly decreased due to the wind-shielding effect of windward vehicles at the beginning of two trains passing each other. When leeward vehicles are out of the shelter of windward vehicles at the end of two trains passing each other, the wind loads on leeward vehicles are suddenly increased. In the process of two trains passing each other, the leeward vehicles experience a sudden wind loads reduction and loading again, which is dangerous for vehicle safety. In addition, leeward vehicles change the aerodynamic ambient flow around windward vehicles and bridge, so the wind loads on windward vehicles and bridge also have a sudden change. The sudden change of wind loads in the process of two trains passing each other could result in the increase of responses of vehicle and bridge, and would become a controlling factor for the safety of WVB system.

In the present study, the bridge and vehicle aerodynamic coefficients in the process of two trains passing each other were tested by wind tunnel testing to study the effect of sudden change of wind loads. The responses of vehicle and bridge were calculated by BANSYS (Bridge Analysis System), addressing the effects of distance between two trains, wind speed and vehicle speed.

2 WIND TUNNEL TEST FOR WIND LOADS ON VEHICLES AND BRIDGE DECK

At the present time, bridge and vehicles are regarded as two separate subsystems in the most vehicle-bridge coupling vibration analysis, so respective wind loads on the two subsystems must be determined with consideration of aerodynamic interaction between them[9]. Crossed Slot System[10] was employed to measure aerodynamic coefficients of bridge deck and vehicle. The wind tunnel tests included two kinds of track arrangements on deck (shown in Figure.1), i.e., the space of 3.5m between two trains in case 1, and 29.5m in case 2, and three different angles of attack (-3°, 0°, +3°). Both vehicle and bridge section models are in scale of 1:55, with length of 2.1m. The aerodynamic coefficients at angle of attack of 0°are shown in table 1.

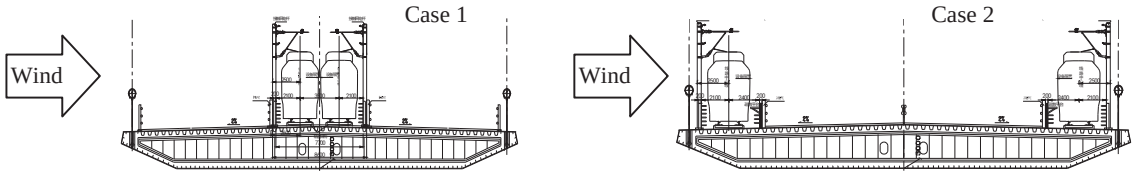

Figure.1 Two kinds of track arrangements on deck

The table 1 shows that local wind field of bridge deck determines the real aerodynamic forces of vehicles as a result of the vehicles submerged in the aerodynamic ambient flow of bridge, leading to obvious differences of aerodynamic coefficients of vehicle and bridge in various combination. The drag and lift coefficients of leeward vehicles decrease dramaticlly when the two trains are passing each other, meanwhile, the aerodynamic coefficients of windward vehicles and bridge also have a certain degree of change. The influence of two trains passing each other on wind loads of bridge and vehicle is more significant in the case 1 of track arrangement.

The bridge structure form has an effect on the aerodynamic forces of vehicle, at the same time, the vehicle has an influence on the aerodynamic forces of bridge, because the interaction between them is significant.

Table.1 Aerodynamic coefficients of box section in 0°

		Track arrangement case 1 (3.5m)			Track arrangement case 2 (29.5m)		
		C_D	C_L	C_M	C_D	C_L	C_M
One train passing	Leeward vehicle	0.5859	0.4398	——	0.5225	0.3207	0.0151
	Windward vehicle	0.6669	0.5160	——	1.0404	0.2629	-0.0151
	Bridge I	0.8913	-0.1026	-0.0564	0.9119	-0.2617	-0.0320
	Bridge II	0.8585	-0.0251	-0.0552	0.7361	0.1742	-0.0261
Two train passing each other	Leeward vehicle	0.0790	0.1757	0.0151	0.2536	0.0405	——
	Windward vehicle	0.7254	0.4718	——	1.0252	0.2383	——
	Bridge	0.9069	-0.0841	-0.0620	0.7992	0.0093	-0.0340

Note: ‘Bridge I’ means aerodynamic coefficients of bridge with leeward vehicle, ‘Bridge II’ means aerodynamic coefficients of bridge with windward vehicle, ‘——’means the aerodynamic forces are too small to measure.

3 ANALYSIS METHOD OF COUPLING VIBRATION OF WVB SYSTEM

Random cross-wind velocity field is usually simulated as a stationary Gaussian stochastic processe by spectral representation method. Vehicle can be modeled as a mass-spring-damping system with 23 degrees of freedom. Bridge analysis model can be established by the finite element method. Bridge and vehicle can be regarded as two subsystems. The motion equations of wind-vehicle-bridge system are as follows.

$$\mathbf{M}_b\ddot{\mathbf{u}}_b + \mathbf{C}_b\dot{\mathbf{u}}_b + \mathbf{K}_b\mathbf{u}_b = \mathbf{F}_{stb} + \mathbf{F}_{bub} + \mathbf{F}_{seb} + \mathbf{F}_{vb}$$

$$\mathbf{M}_v\ddot{\mathbf{u}}_v + \mathbf{C}_v\dot{\mathbf{u}}_v + \mathbf{K}_v\mathbf{u}_v = \mathbf{F}_{stv} + \mathbf{F}_{buv} + \mathbf{F}_{sev} + \mathbf{F}_{vv}$$

Where the subscript b and v indicate the bridge and vehicle, respectively; $\mathbf{F}_{st}$, $\mathbf{F}_{bu}$, and $\mathbf{F}_{se}$ are the static wind loads, buffeting wind loads and self-excited loads, respectively; $\mathbf{F}_{vb}$, $\mathbf{F}_{bv}$ denote the interaction forces between vehicle and bridge. The displacement response of bridge under static wind loads is equivalent to change the track irregularity, thus affecting the vehicle vibration. The equilibrium position of bridge under static wind loads should be treated as the initial state in the direct integral calculation of system motion equation. The expression of static and buffeting wind was refered to the literature [9].

The aerodynamic coefficients of one train passing are used before and after the two trains passing each other, and the aerodynamic coefficients of two trains passing each are adopted in the process of two trains passing each other, the specific aerodynamic coefficients are shown in table 1. The lateral and vertical fluctuating wind speeds are determined by the position of the vehicle. In the calculation of the buffeting force of vehicle and bridge, the fluctuating wind of vehicle is similar to the bridge. The self-excited force of train is ignored in WVB system because the width of vehicle is lesser, and the section is bluff body. The wind loads of bridge are accordingly changed with the motion of vehicle in the process of two trains passing each other in addition to the vehicle wind loads.

4 ANALYSIS OF TWO TRAINS PASSING EACH OTHER

4.1 *Engineering example*

A suspension bridge which have three-spans continuous steel box girder is investigated in the process of two trains passing each other, and the combination of span is 212m++600m+212m (as shown in Fig.2). The track layout form on the deck is shown in Fig.3. The width of deck is 35.5m, and the height is 3.0m. The aerodynamic coefficients in table 1 were adapted.

The fluctuating wind velocity was simulated by using spectral representation method. The horizontal and vertical fluctuating wind velocity field which included 105 wind speed simulation points evenly distributed along the girder were simulated respectively. The space of wind speed simulation points is 10m, and the space in tower is similar to girder, but the horizontal and crosswise fluctuating wind velocity field along towers included 15 wind speed points. The wind velocity spectrum comes from literature [12].

The B type vehicle of urban rail transit was employed, and the composition of the train is 2× (M+T+T+M). The rail irregularities was simulated by American level 6 spectrum, and the dynamic time history analysis of spatial step is 0.2 m, the damping ratio is 0.5% [12].

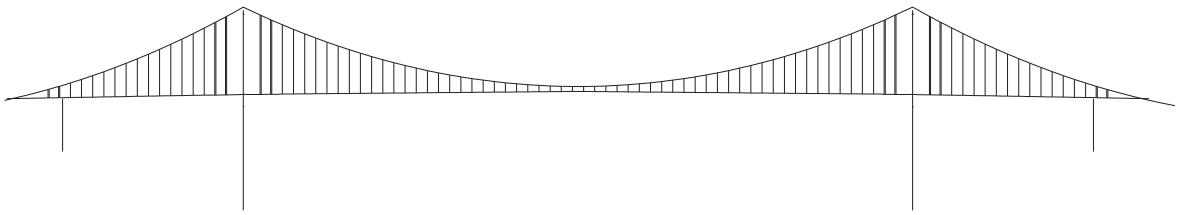

Figure.2 Overall Structure arrangement

4.2 *Effect of vehicle speed*

Two trains entering into bridge at the same time in opposite directions at various vehicle speeds were analyzed by method of coupling vibration of WVB according to case 1 (as shown in figure.1) under the wind speed of 30m/s. The lateral acceleration of 1st vehicle and 8th vehicle of the leeward trains at different speeds for two trains passing each other is shown in Figure.2 and Figure.3. It shows that there are two peaks at the beginning and end of two trains passing each other in the mid-span due to the effect of sudden change of wind loads. The maximum acceleration of vehicle at different speeds is shown in table 2. The effect of sudden change of wind loads in leeward vehicle is larger than windward vehicle, leading to the larger acceleration of leeward vehicle. The lateral acceleration of vehicle increases with increasing speed of leeward and windward vehicle, it suggests that the higher speed is, the stronger effect of sudden change of wind loads is.

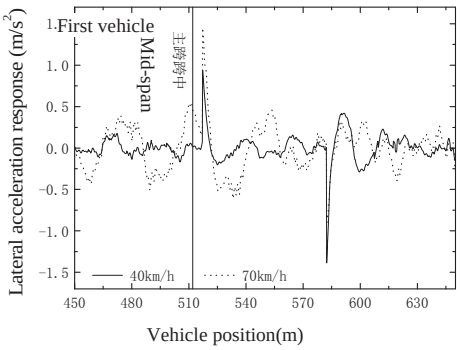

Figure.3 Response of lateral acceleration of first vehicle

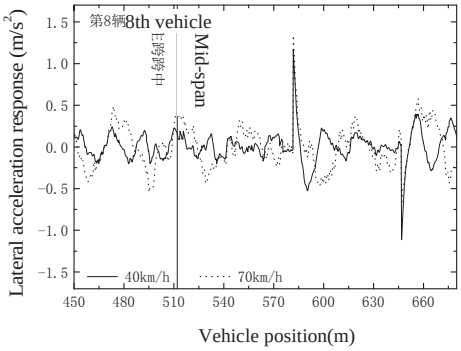

Figure.4 Response of lateral acceleration of 8th vehicle

Table.2 Response of acceleration at various vehicle speeds

Vehicle speed(/km/h)		40	50	60	70	80
Leeward vehicle	Lateral acceleration(m/s^2)	1.566	1.488	1.258	1.840	1.793
	Vertical acceleration(m/s^2)	1.841	1.869	1.693	1.861	1.710
Windward vehicle	Lateral acceleration(m/s^2)	0.472	0.534	0.680	0.854	0.995
	Vertical acceleration(m/s^2)	1.809	1.850	1.692	1.831	1.812

4.3 *Effect of wind speed*

Two trains entering into bridge at the same time in opposite direction at various wind speeds were analyzed by method of coupling vibration of WVB according to case 1 (as shown in Figure.1) under the vehicle speed of 80km/h. The acceleration of windward vehicle at wind speed of 20m/s is shown in figure 4. From the Fig. 4 we can see that the lateral and vertical acceleration don't have a remarkable change, which suggests that the effect of sudden change of wind loads of windward vehicle is limited with two trains passing each other (about 23s). The lateral and vertical displacements in the two trains passing each other at various wind speed is shown in figure 5, the figure shows lateral and vertical response bridge increased with higher wind speeds, the bridge response did not happen significant mutations at the two trains passing each other(about 510m～650m).

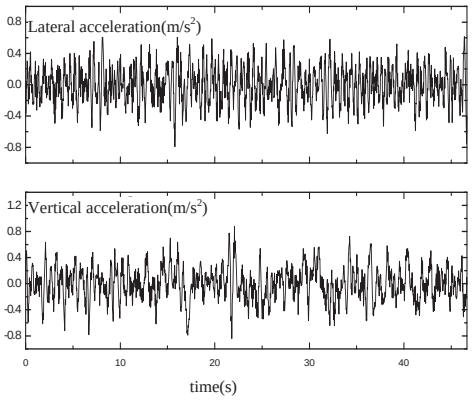

Figure.4 Acceleration of windward vehicle

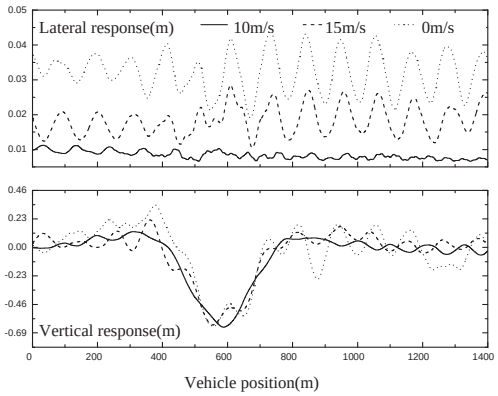

Figure.5 Response of displacement in midspan

The responses of vehicle and bridge at different wind speeds is shown in the table 3, the lateral acceleration of leeward vehicle is increased significantly with increasing wind speed, but the lateral acceleration of windward vehicle is only increased slightly, although the acceleration of bridge was accompanied with the wind velocity increased and bigger, the acceleration value is small. For this reason, the effect of sudden change of wind loads was a controlling factor for the leeward vehicle, the lateral vibration of bridge is limited devoted to the response of vehicle. The vertical acceleration is increased significantly with increasing wind speed, corresponding to the acceleration of vehicle is significant increased, but the vertical acceleration of vehicle (as shown in Table 3) wasn't significantly changed with increasing speed. Therefore, the vertical vibration of bridge under the strong cross-wind has a great contribution to the vertical acceleration of vehicle, but the vehicle speed is limited.

Table.3 Response of acceleration for vehicle and bridge in various wind speed

Wind speed(m/s)		10	15	20	25	30
Leeward vehicle	Lateral acceleration(m/s^2)	0.837	0.836	0.810	1.017	1.793
	Vertical acceleration(m/s^2)	0.743	1.022	0.999	1.561	1.710
Windward vehicle	Lateral acceleration(m/s^2)	0.806	0.806	0.850	0.886	0.995
	Vertical acceleration(m/s^2)	0.948	1.036	0.916	1.412	1.812
Maximum lateral acceleration in midspan(m/s^2)		0.054	0.064	0.063	0.065	0.142
Maximum vetical acceleration in midspan(m/s^2)		0.133	0.215	0.441	0.773	1.180

4.4 *Effect of the distance between two trains*

Another type of track arrangement (in Fig.1 case 2) was analyzed by method of coupling vibration of WVB under the vehicle speed of 80km/h, the responses of vehicle and bridge at different wind speeds were shown in the table 4, the vertical acceleration of vehicle and vertical acceleration of leeward vehicle in the two cases was similar in table 3 and table 4, but the transverse acceleration of leeward vehicle has significant difference with increasing wind speed, the lateral acceleration of leeward vehicle was slowly increased with the wind velocity increased, this suggested that the effect of sudden change of wind loads in the two trains passing each other is more weaker with the intervals of two trains as a result of effect of covering for windward vehicle.

Table.4 Acceleration of vehicle under different wind speed

Wind speed(m/s)		10	15	20	25	30
Leeward vehicle	Lateral acceleration(m/s^2)	0.838	0.837	0.811	0.873	1.201
	Vertical acceleration(m/s^2)	0.764	0.975	0.914	1.437	1.645
Windward vehicle	Lateral acceleration(m/s^2)	0.807	0.821	0.841	0.867	0.949
	Vertical acceleration(m/s^2)	0.897	1.002	0.984	1.591	1.779

CONCLUSION REMARKS

Some conclusions are drawn in this section on basis of wind tunnel tests and above calculation analysis.

1. the vehicle and bridge aerodynamic coefficients have an obvious effect on different combination of vehicle and bridge, the drag and lift coefficients in leeward vehicle are abruptly decreased when the two trains passing each other, and the aerodynamic coefficients of vehicle and bridge in windward have a change to some degree, the alteration of vehicle and bridge should be considered in the coupling vibration of WVB system for the process of two trains passing each other.
2. The vehicle speed and wind speed is higher, the effect of sudden change for horizontal acceleration of vehicle is stronger. The horizontal response in leeward is a controlling factor when the two train passing each other.
3. The vertical wind-induced vibration of bridge has a significant influence on the vertical response of vehicle in windward and leeward, but the effect of vehicle speed is limited.
4. The shielding effect of windward vehicle could be reduced with the increase of horizontal distance between two vehicles when the two trains passing each other.

Wind tunnel test study the influence of wind screen on wind pressure distribution above railway tracks

Xiang Huoyue, Li Yongle, Chen Ning, Liao Haili

Department of Bridge Engineering, Southwest Jiaotong University, Chengdu 610031, China

ABSTRACT: In order to investigate the wind screen to effects of distribution on wind pressure above tracks, the wind pressure coefficients profile were tested by the wind tunnel testing used the wind pressure row tube, and numerical simulation was carried out at the same time to contrast with wind tunnel testing, the effects of wind screen arrangements, heights of wind screen, the line structure types such as the ground roadbeds, high embankments and bridges were discussed about the distribution of wind pressure on tracks, and the mechanism of aerodynamics was analyzed. It shows that the wind pressure value above tracks are significant decreased by wind screen in windward; the wind screens in leeward increased the negative pressure above tracks; in the three line structure forms, the wind pressure value above tracks on bridge are maximum, the energy dissipations are minimum, and the energy dissipations in high embankment are maximum, meanwhile, the wind pressure coefficients on catenary are decreased when the wind screens installed on high embankment.

KEYWORDS: wind screen; wind pressure coefficients; wind tunnel testing; line structure forms

1 INTRODUCTION

In recently, wind-induced accidents of trains have been reported around the world from time to time. For instance, there have been more than 30 wind-induced accidents of trains since 1872 in Japan[1, 2] (statistics to 2006). In 2005, Shinkansen train “Rice 14”of East Japan Railway Company was derailed as a result of encountering cross-wind which was much lower than the warning wind speed[3]. In China, more than 110 rail vehicle (statistics to 2002) rollover accidents by cross winds have been reported on the Lan-Xin Railway since 1959[4], in 2007, a 5807 times train from Urumchi to Aksu was derailed by 13 class gale leaded to four deaths and more than 30 injured. Beijing-Shanghai (or Jing-Hu) high-speed railway has been built along the annual maximum wind speed greater than 20m/s, the number of occurrences is about 19.2[5]. In summary, it is very necessary for gale district railway to set up the precautions such as wind screens, it’s one of the efficient measures for vehicle safety, wind screens were installed one or two sides along the railway to create a local environment of relatively low wind speed for trains.

Wang et al.[4] indicated that the heights of windbreak wall should be 2.4m above rail top, the construction cost per kilometer will be decreased by 33%. Ge and Jiang[6] studied the wind velocity reduced ratio in Lan-Xin railway by full-scale measurements, their results showed that the speed of the wind behind the 3m high windbreak is smaller than that outside the windbreak and the shielding scope of windbreak exceeds 38m when wind speed is 20m/s. A series of wind tunnel testing are conducted in Japan, the result shows that the effects of wind screen on the reduction of aerodynamic forces depends on the heights of wind screen, solidity ratios, configurations of vehicles and infrastructures[7, 8]. Numerical simulations were also conducted to understand the wind shield effect of wind screen. Bobi et al.[9] used the method of Navier-Stokes simulation to study the different wind screen shapes, obtained global values of efficacy greater than 90% in both viaduct and embankment situations. Jiang and Liang[10] studied the effects of the vehicle

aerodynamic performance caused by the change of height and position of wind-break wall, the result shows that position vs. height was approximately cubic polynomial relations.

In conclusion, the related research in China focused on the heavy windbreak wall in Nan Xing railway, researched on light wind screen and its mechanism is relatively limited, and the research results of foreign is difficult of direct reference. The Jing-Hu high-speed railway located in the eastern coastal of china where is vulnerable to the attack of typhoon and strong monsoon, so it is necessary to set up wind screen in the high wind speed regions. Three line structure types were chosen from Jing-Hu high speed railway: the ground roadbed, high embankment and 32m span bridges, were respectively made the wind tunnel test model. The wind pressure coefficients in different wind screens were tested, discussed the effects of arrangements, heights, line structure types, and analyzed the aerodynamic mechanism of wind screen.

2 WIND TUNNEL TESTING

Strong lateral wind can affect substantially the performance of the running train, the wind screen can change the ambient flow field above the railway, furthermore influence the wind loads acting on vehicles. Three types of infrastructure forms are adopted in this study, bridge, high embankment and ground roadbed.

The test of wind pressure distributions was conducted in XNJD-3 wind tunnel with a scale of 1:15, the end-plate was set up along the side of models to reduce the effect of flow around, because the width of the model is 3m while the width of the wind tunnel is 22.5m. The wind pressure pipe was vertical to flows installed in columns, and was vertical extended 0.05m to reduce the disturbing effect of pillar. There are 16 measuring points in the center of tracks with a measuring spacing of 0.03m below height of 0.25m, other spacing was 0.04m (shown in figure 1). The wind pressure coefficient profile of the center of tracks can be obtained by the synchronous acquisition system.

A pitot tube was placed in undisturbed flows to test the static pressure and velocity, if the static pressure in upper stream was considered as a reference point, then the wind pressure coefficient can be expressed as:

$$C_{pi} = (P_i - P_\infty) / 0.5\rho V_\infty^2 \qquad (1)$$

Where P_i is value of wind pressure in ith wind pressure pipe (total pressure); P_∞ is static pressure in reference point of upper stream; V_∞ is velocity of upper stream; ρ is the air density; It should be noted that wall pressure coefficient is relative to the shape of the structure reflecting the surface wind load distribution on the structure, but C_{pi} is the relatively wind pressure coefficient reflecting distribution of the flow field and the total energy.

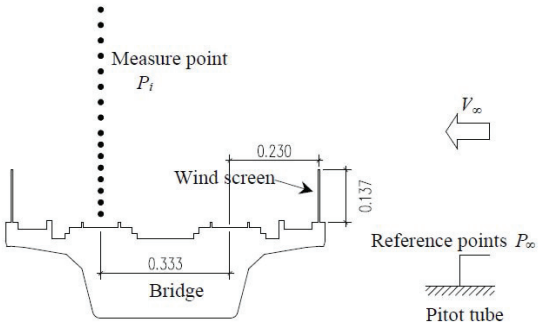

Figure.1 Schematic diagram of wind pressure profile test schemes on bridge (unit: m)

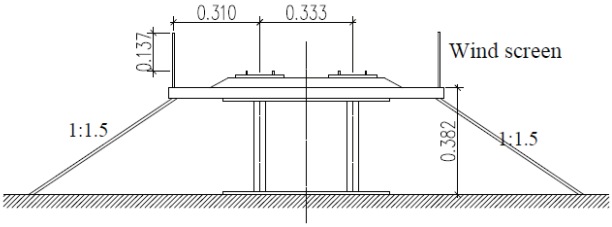

Figure.2 Wind tunnel test model of high embankment (unit: m)

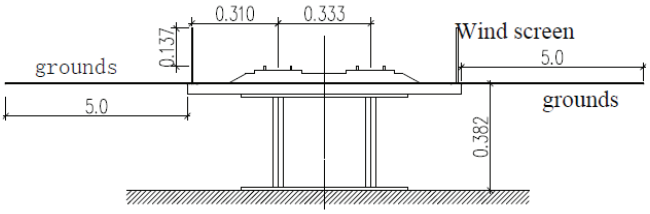

Figure.3 Wind tunnel test model of ground roadbed (unit: m)

the wind pressure coefficient profile in the center of tracks on windward side and leeward side was tested with different wind screens height and arrangement on three typical line construction forms (as shown in figure.1～figure.3) for the Beijing-Shanghai high-speed railway, the specific case is shown in table 1.

Table.1 Wind tunnel test cases

infrastructure scenario	height of wind screen(unit:m)	Arrangement of wind screen
bridge	0.0、1.72、2.05	one side, both side
high embankment	0.0、1.60、2.05	one side, both side
ground roadbed	0.0、1.60、2.05	one side, both side

Noted: the height above orbital plans is the wind screen height, 0.0 is no wind screen, and one side is no windward wind screen.

3 RESULT ANALYSIS

The numerical simulation was firstly conducted at the same time for typical case, compared the results of wind tunnel test and CFD, and on that basis, the mechanism of aerodynamics was analyzed, the wind pressure distributions above tracks were discussed in different arrangements, heights and line structure types.

3.1 *Comparison of the wind tunnel test and CFD*

A 2D wind pressure distributions with a scale of 1:15 was simulated using CFD with a 2.05m height wind screen set on the bridge (as shown in figure 1) to validate this paper test method, the turbulent model is the SST k-ω, boundary layer thickness refer to the literature [11], the grid number is approximately 76 thousand, the comparison of numerical simulation by steady analysis and wind tunnel test is shown in figure 4, which shows that the CFD simulation results well agree with the wind tunnel test in windward tracks, although there has certain differences in the leeward side tracks, but the law are similar; In addition, the wind pressure coefficient in scope of

shading is smaller than external flow by the reason of energy dissipation of turbulence according to the ideal fluid Bernoulli Equation. Therefore, the wind pressure distributions tested by row tube is feasible.

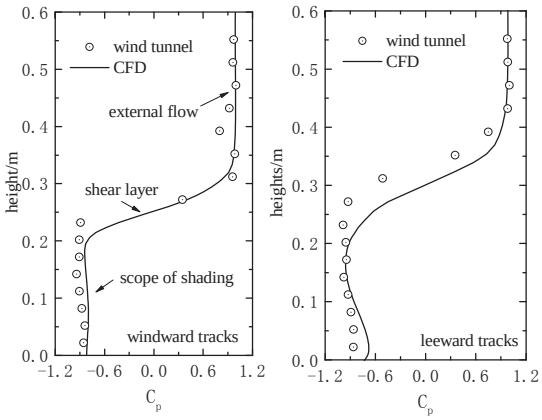

Figure.4 Comparison of wind tunnel test with CFD

3.2 *Effects of windscreen arrangement*

Comparison of wind pressure coefficient profile, setting one side, both side and without wind screen with a height of 2.05m on the bridge is shown in figure 5 to investigate the effect of windscreen arrangement. The value of pressure in the center of tracks was reduced as the wind screen was set on one side or both sides. Compared the wind pressure coefficients with one side and both side cases, it is easy to learn that both side case were increased with respect to one side case in the scope of shading. Because the leeward wind screen blocked the around flow coming from windward wind screen, which increased the backflow above tracks, increased the pressure coefficient, and reduced the energy dissipation in scope of shading.

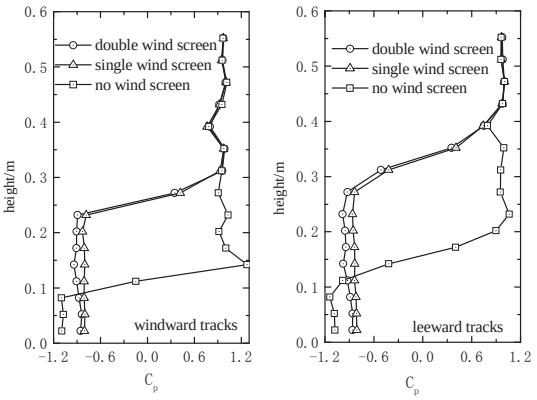

Figure.5 Effects of position of wind screen

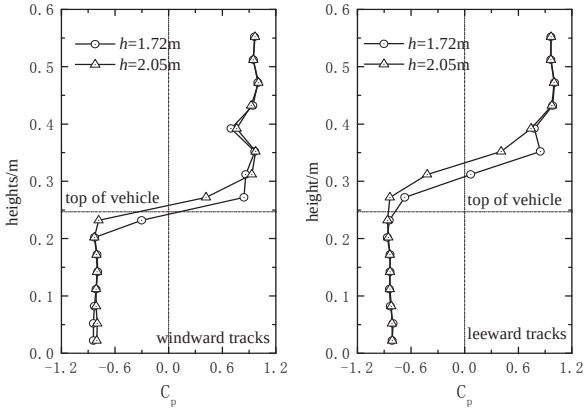

Figure.6 Effects of height of wind screens

3.3 *Effects of height*

The wind pressure profile of two heights of wind screens (1.72m and 2.05m) on one side is shown in figure 6 to investigate the effects of height. It shows that the change law of wind pressure coefficient profile is similar, and the height of the shear layer increased with the height of wind screen increasing. The height of vehicles in practice is generally in 3.5m to 4.0m such as

the vehicle of CRH2 is 3.7m above orbital plane with a value of 0.247m after scale. There is negative pressure in the windward tracks beneath the height of vehicles when the heights of wind screen are 2.05m. But the vehicles are partly subjected to positive pressure when the heights of wind screen are 1.72, and smaller than 2.05m. The shear layer of wind pressure coefficients in leeward wind screen are above the top of vehicle, and there has little difference in the scope of shading. Therefore, the wind shield of 1.72m wind screen is better than 2.05m if the wind pressure coefficient is considered as evaluation index.

3.4 *Effects of line structure type*

The profile of wind pressure distributions in bridges (shown in figure 1), high embankment (shown in figure 2), grounds roadbed (shown in figure 3) was tested to check the effect of line structure type. The wind pressure distributions for three kinds of infrastructure forms with wind screen set on one side are shown in figure 7. It shows that the wind pressure coefficient in bridge is largest, while the high embankment is smallest, it because the effect of slope in high embankment leads to change the attacks of wind, and improved the height of shear layer, meanwhile, the wind pressure coefficients on catenary was decreased when the wind screens is installed on high embankment.

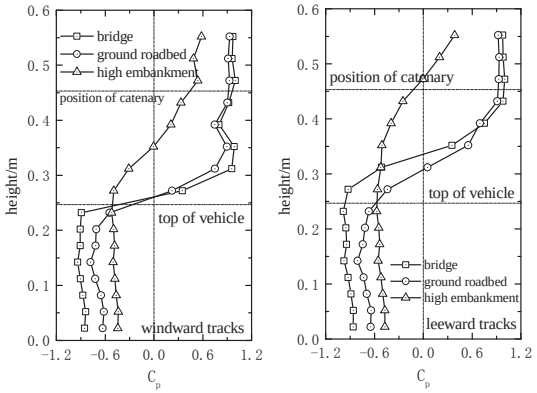

Figure.7 Effects of line structure types with wind screens

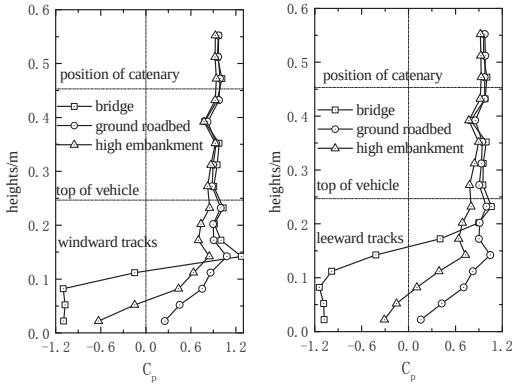

Figure.8 Effects of line structure types without wind screens

The wind pressure coefficient above tracks in different line structure types without wind screen were compared from the perspective of energy dissipation as shown in figure 8. Combined with figure 7, it is easy to learn that that the line structure types have a significant effect on the wind shield of wind screen, the distribution of wind pressure above tracks without wind screen have a remarkable difference, the energy dissipation in high embankment is maximum, the bridge is minimum. Therefore, it should be pay attention to the adverse effect of sudden change of vehicle wind load as a result of the change of line structure types.

4 CONCLUSION

The wind tunnel test has been performed investigating the effects of the wind screen on the three line structure types as well as an analysis of the flow field distribution, and derived the following conclusions.

1. The existence of windward wind screen reduced the wind pressure value, and the shear layer height increases with the height of the wind screen.

2. the wind pressure distribution have a significant difference in varied lines structure type, and the difference of energy dissipation is obvious, the energy dissipation is minimum on the bridge, is maximum on high embankment which can reduce the wind pressure coefficients on catenary.

Evaluation of crosswind effects on rail vehicles through moving model experiments

F. Dorigatti [a], A.D. Quinn [a], M. Sterling [a], C.J. Baker [a]

[a] *School of Civil Engineering, University of Birmingham, Birmingham, UK*

ABSTRACT: This paper presents the results obtained from two series of tests on scale-model rail vehicles, one in static and the other in moving model conditions. The experiments were carried out at the TRAIN (TRansient Aerodynamic INvestigation) rig using the recently developed crosswind generator. A 1:25 scale model of a Class 390 Pendolino train was tested on a flat ground scenario in correspondence of a 30° yaw angle. The Reynolds number was of the order of 2×10^5. The surface pressure on the train leading car was monitored in correspondence of 110 tapping points using a novel onboard stand-alone measuring system. An evaluation of the mean values for the local pressure coefficient shows limited differences between static and moving model tests only in correspondence of a restricted number of tapping points. A comparison in terms of overall mean aerodynamic coefficients indicates a good agreement between the two sets of results.

1 INTRODUCTION

A train travelling through a natural turbulent crosswind is surrounded by a complex flow field which leads to a series of steady and unsteady aerodynamic forces and moments. These aerodynamic loads may induce significant changes in the vehicle dynamic behaviour in comparison to a no-crosswind condition and, in the presence of strong winds, serious accidents may happen because the train stability has been compromised [1]. To prevent the occurrence of such events, in the last two decades a series of specific methodologies have been developed for assessing the stability of trains in crosswinds [2, 3]. These methodologies are currently applied within the rolling stock certification process [4, 5] and rely on a numerical-experimental approach. While the vehicle dynamics and the characteristics of the natural wind are simulated numerically, the information regarding the wind-vehicle interaction is provided as an external input to the model in form of dimensionless aerodynamic coefficients. Such parameters depend on the train geometry and are typically obtained through wind tunnel experiments on static scale models, which represent the standard technique of investigation [4, 5]. These type of experiments have the significant advantage that they can be treated as conventional wind tunnel tests and, as such, can be carried out in traditional environmental wind tunnel facilities. However, by their very nature they do not simulate the movement of the train relative to the ground; the importance of this on the overall forces/moments acting on the train still remains largely unresolved [6].

Different studies have been undertaken in the past for evaluating the impact that the vehicle movement simulation has on the crosswind loads on trains. Since the mid 1980's the problem was approached from an experimental perspective and a number of moving model test campaigns were carried out [7, 8, 9, 10]. Despite the differences in these experiments, three common elements can be identified. Firstly, a test methodology based on carrying out series of multiple

runs was adopted. This was essential in order to collect a proper amount of data for enabling stable ensemble averages of the time histories to be calculated. Secondly, in the vast majority of the cases, the tests took place in existing wind tunnel facilities, where specifically designed propulsion systems (either mechanical [7, 8, 10] or gravity based [9]) had been integrated for providing the vehicle movement. Finally, the measuring systems employed during the tests all measured the overall forces and moments acting on the moving vehicle through the use of internal strain gauge balances. The outcomes from these previous moving model test campaigns do not appear to be entirely consistent. Bocciolone *et al.* [9] found no relevant discrepancies between aerodynamic loads on a train measured in stationary and moving model conditions, whereas Baker [7] and Humphreys [8] found the opposite. However, a close examination of data which did show an effect of the vehicle movement simulation yielded no definitive trends. Such inhomogeneity suggests a limited level of reliability associated with the results and was one of the motivations for the current work.

Considering the numerous issues associated with a moving model test campaign, recently, an alternative approach based on CFD analyses has been used [11]. However, before quantitative conclusions can be drawn based on numerical results, it is essential to assess the level of accuracy of CFD when applied to moving vehicles. Such a comparison requires detailed and reliable experiment data, some of which will be outlined below.

This paper presents the results obtained from a measurement campaign on scale-model rail vehicles in crosswinds, which was undertaken as part of the EU-funded AeroTRAIN project. Two series of experiments were carried out, one under static conditions and the other in moving model conditions. Contrary to previous moving model campaigns, the measuring system used for these tests monitored the local pressure distribution on the train surface rather than the overall aerodynamic loads on the vehicle. This approach enables a first comparison between static and moving tests results to be made with consideration to local values of the mean pressure in different areas of the train. By integrating the pressure distribution, a further comparison can be arranged in terms of steady overall aerodynamic loads. In what follows, the details of the examined test case, together with the characteristics of the facility, as well as of the measuring system and of the methodology, are described in section 2. Section 3 illustrates the results in terms of local values of the mean pressure coefficient and also of overall steady aerodynamic loads. Side force, lift force and rolling moment coefficients are considered and a comparison between static and moving tests is discussed. Finally, some concluding remarks are drawn in section 4.

2 EXPERIMENTAL CAMPAIGN

All of the experiments outlined below were carried out at the University of Birmingham's TRAIN (TRansient Aerodynamic INvestigation) rig (the distinctive features of which are outlined in section 2.1). A 1:25 scale model of a Class 390 Pendolino train was used for the tests. It comprised a full reproduction of the leading car followed by a dummy half trailing car: the leading vehicle was the object of investigation, while the partial second coach was provided to ensure realistic flow around the length of the train (Fig. 1a). For the purpose of the present work a Flat Ground (FG) scenario (i.e. no representation of the ballast was included) and a yaw angle (i.e. the angle between the direction of travel and the relative impacting wind) of 30° were examined. An onset turbulent crosswind characterized both series of tests, static and moving. Such flow simulation was provided by a crosswind generator that has been developed as part of this project. A more in depth description of this apparatus, as well as of the flow characteristics, is reported in what follows. The Reynolds number, based on the train height and the wind speed relative to the vehicle, was of the order of 2×10^5.

2.1 *The TRAIN rig*

The TRAIN rig is a research facility specifically dedicated to undertaking moving model tests on scale model vehicles in open-air, crosswinds and tunnels [12]. It is situated in Derby (UK) and was designed and built by British Rail Research at the end of 1980's [13]. The rig consists of a series of three straight parallel tracks, 150 meters long, equipped with a mechanical propulsion system that can catapult a 1/25 scale model up to 75 m/s. The acceleration mechanism employs a series of pre-tensioned elastic ropes driven by pulleys, while the brake is based on the use of a piston deformable tube. The facility was acquired by the University of Birmingham Centre for Railway Research and Education (BCRRE) in 2009. Since then, the capability of performing moving model experiments in crosswinds has been improved through the design and installation of a new crosswind generator.

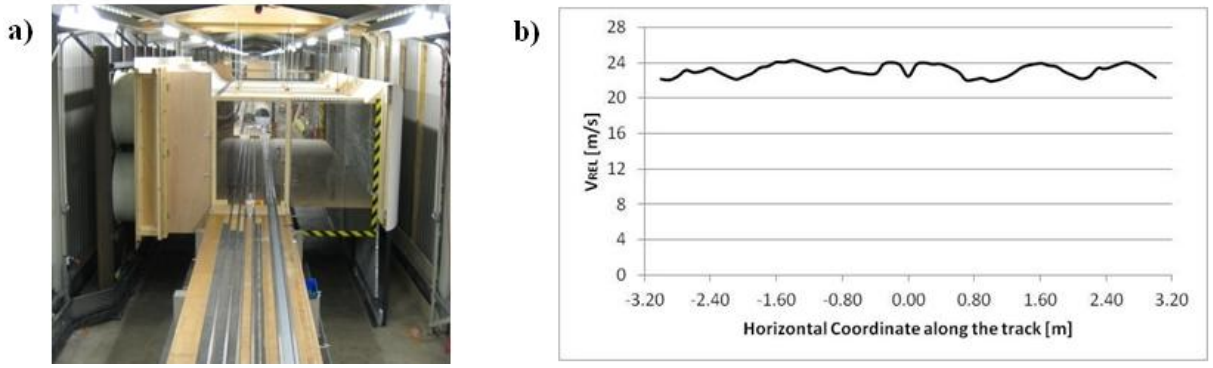

Figure 2. a) TRAIN rig internal view: new crosswind generator. b) Mean wind velocity relative to a train travelling at 20m/s c.a. and experiencing a 30° yaw angle: horizontal profile at 3m full scale equivalent height.

The new system, consists of a series of 16 axial flow fans positioned at the trackside and arranged in two rows of eight units each. The fans operate in sucking-mode and generate an airflow directed perpendicularly to the direction of travel. Such flow is enclosed in a tests section spanning a portion of the tracks 6.4m long (indicated in what follows as L_{CW}). A photograph of the new crosswind generator is shown in Figure 2a. Before the static and moving model test campaigns started, a dedicated session was carried out in order characterize the properties of the simulated crosswind in terms of mean speed, turbulence intensity and static pressure. The spanwise average of the mean wind speed (U) and turbulence intensity (I_U), measured at 3m full

scale equivalent height, are approximately 12m/s and 16%, respectively. The mean velocity profile of the relative wind, as seen by a train travelling through the crosswind section at approximately 21 m/s (thus in correspondence to a 30° yaw angle) is illustrated in Figure 2b.

2.2 *Measuring Instrumentation*

The experimental data collected during the tests comprised of both trackside and onboard measurements. The trackside measurements included the data regarding the ambient conditions (temperature, barometric pressure and relative humidity), the crosswind properties (velocity and static pressure within the air-channel) and the train speed (for moving model tests only). The ambient conditions were monitored using an Oregon Scientific BAR208HGA weather station and a GBP3300 digital barometer. Localized measurements of the flow speed and static pressure within the crosswind section were recorded using a set of Series 100 cobra probes (by Turbulent Flow Instrumentation Ltd) and a Pitot-static tube in combination with differential pressure transducers HCLA02X5PB (by Sensortechnics GmbH). An acquisition system run by a laptop computer was employed and data were sampled at 1KHz over a time interval of 60s. During moving model tests, the vehicle speed at the entry and exit of the crosswind generator was measured by two sets of photoelectric position finders and reflectors.

The onboard measurements consisted mainly of the surface pressures detected on the train model. For moving model tests, they included also the output signal from a light detector. The employment of an onboard stand-alone measuring system is essential in order to enable moving model experiments. Unlike what had been done in the past, the system used for these tests monitored the local pressure distribution on the train surface rather than the overall aerodynamic loads on the vehicle. It is a purpose-built measuring system, which employs a series of miniaturized ultra-low differential pressure transducers HCLA12X5PB (by Sensortechnics GmbH) in combination with a stand-alone data logger. The data logger has a 16-bit resolution, is capable of monitoring 16 channels at a maximum sampling rate of 4KHz and presents an extremely compact design that makes it suitable to be accommodated inside the scale train model. The surface pressure was measured only on the first vehicle, which was equipped with eight loops of pressure taps distributed along its length for a total of 110 measuring positions (Fig. 1b). A series of silicon tubing connected the tapping points to the pressure ports of the transducers. Having 15 channels of the data logger available to pressure measurements, the same number of transducers was used. This enabled the pressure taps of each single loop to be monitored simultaneously. A light detector was connected to the sixteenth channel of the data logger. Having set a series of light sources at specified locations along the track, during the moving model tests the signal from such sensor provided a number of ‘position markers’. They were used while post-processing the data for trimming the records from the raw data and thus isolate the portion of time histories associated to the train travelling within the crosswind section.

2.3 *Experimental setup and test methodology*

The test procedure for static tests was similar to the standard methodology commonly adopted for wind tunnel experiments. The train model was mounted statically inside the air-channel and rotated with respect to the oncoming wind in order to simulate the required yaw angle (30°). Time histories of the surface pressure on the train were recorded during a time window of 60s at a sampling rate of 4KHz. It is worth noting that, having the design of the crosswind generator optimized for moving model tests, a number of restrictions were imposed on the static tests. The dimensions of the model coupled with the limited extension of the air-channel in the along-wind direction (i.e. transversally to the track) meant that the nose of train was positioned close to the

channel inlet (i.e. at a distance of approximately 0.2m). This positioning compromised the possibility of a freestream flow upstream the model and determined a high sensitivity of the pressure field on the nose of the train to minor alterations in the environment external to the air-channel. In addition, a gradient in the along-wind direction was identified by the experimental data collected during the flow characterization, either for the streamwise mean wind velocity (negative gradient) or for the static pressure (positive gradient). All these aspects were taken into account during the data processing and also within the uncertainty analysis. They led to an estimate of the experimental error for the static tests slightly larger than in moving model conditions (Fig. 6).

During the moving model experiments the train was run through the crosswind section at approximately 20.8m/s (±0.6m/s). For analysis purposes the wind velocity was doubled averaged, i.e., both in time (averaged over the measurement time) and spatially (spanwise) along the measurement domain, yielding a value of 12m/s. Hence, the required yaw angle was 30° ±1°. Considering a total span of the air-channel (L_{CW}) of 6.4m, a train travelling at the specified speed spent approximately 0.3s within the crosswind section. With an acquisition data rate of 4 KHz, this corresponded to approximately 1200 samples. A high variability was observed in the time histories of the surface pressure associated to different runs (Fig. 3b). This suggesting that no reliable indication could be obtained from the analysis of individual runs, a data analysis method based on ensembles of runs was adopted for the moving model tests [14]. For the experiments reported in this paper, a sensitivity study indicated that 15 runs were required for obtaining stable ensemble averages. Figure 3 presents an example of the results obtained by applying this moving model test procedure, with consideration of one single pressure tap on loop 2 (on the nose of the train according to Figure 1b).

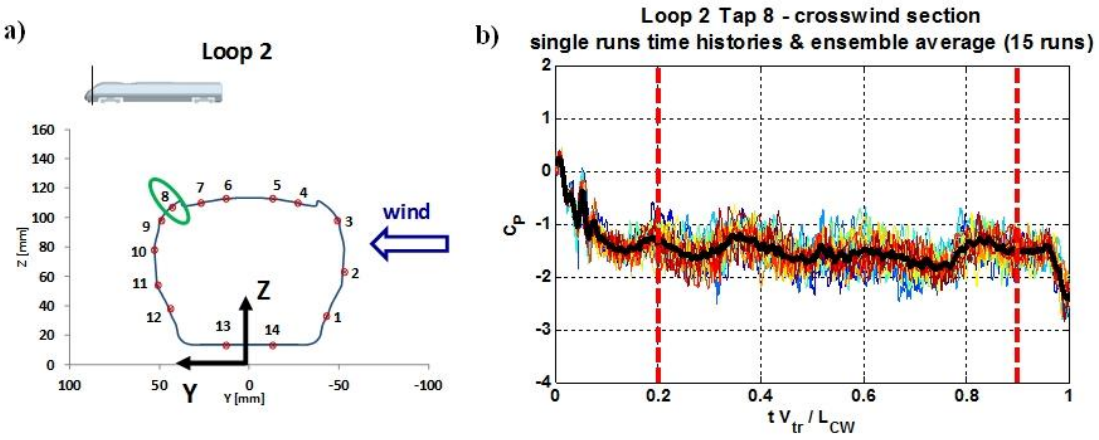

Figure 3. a) Loop 2: cross-section and taps' distribution. b) Single runs time histories (thin lines in grey colors) and ensemble average time history (thick line in black) trimmed within the crosswind section: C_P with respect to non-dimensional time (the vertical dotted lines denote the portion of time history considered for calculating the mean pressure coefficient).

3 RESULTS AND DISCUSSION

3.1 *Stationary pressure distribution*

In this section the data concerning the pressure distribution on the train are presented in terms of non-dimensional pressure coefficients. Considering each tapping point *i* on the train surface, the

instantaneous value of the pressure coefficient at a generic time t is indicated as C_{Pi} and defined as:

$$C_{Pi}(t) = \frac{P_i(t) - P_0}{0.5\rho V_{rel}^2} \quad (1)$$

where $P_i(t)$ is the instantaneous value of the actual pressure, measured at the tapping point i, P_0 is the reference pressure, ρ is the crosswind air density and V_{rel} is the reference wind velocity relative to the train.

The reference pressure (P_0) adopted in this study, either in static or moving conditions, consists in the estimated double average static pressure: during any single run, the wind static pressure at a number of measuring positions were recorded over a 60s time interval. Selecting one of these positions as a reference, and averaging the data over the entire time interval, a local mean value for the static pressure during each run was calculated. The reference pressure P_0, as defined in the above, corresponds to the spanwise average extrapolated from such local mean value. It was obtained using a spanwise average-to-local ratio based on data obtained during the full flow characterization. For static tests only, an additional correction was applied to the reference static pressure calculated as explained in the above. Considering that different loops of tappings were at considerably different distances from the inlet, such correction was adopted to take into account the along-wind static pressure gradient (see Section 2.3). For the moving model experiments, the Cobra probe used for monitoring the reference wind conditions was positioned 0.2m upstream the track centreline, at 3m full scale equivalent height. During the static tests, although still at the same height, the probe was set close to the channel inlet and on the side with respect to the model.

For static tests, the relative wind corresponds to the absolute crosswind. Hence, the reference relative wind velocity (V_{rel}) coincided with the reference crosswind streamwise velocity, indicated as U. Both the definition and the process according to which U was calculated were consistent with those for the reference pressure. A local mean was calculated time averaging the 60s velocity time history recorded by the reference Cobra probe (the same that provided the data for the crosswind static reference pressure). The reference crosswind streamwise velocity (U) is the spanwise average extrapolated from such local mean velocity. Once again it was based on a spanwise average-to-local ratio obtained from the flow characterization data. An along-wind velocity gradient correction was applied when processing the data from static tests.

The results reported in what follows are relative to a stationary aerodynamic condition. Hence, they are expressed in terms of a mean pressure coefficient, $\bar{C}_{Pi}$, where i corresponds to a particular tapping point. For the static tests, the average was calculated over the entire 60s time interval, which corresponded to the full length of time histories recorded for the surface pressure. For the moving model tests, it was obtained considering only the central portion of the ensemble average time history relative to the crosswind section (noted by vertical dotted lines on Figure 3b). The transitions experienced by a running train at the entry and exit of the crosswind section determined a series of unsteady fluctuations respectively in the initial part and in the tail of the ensemble average time history. As not representative of a stationary aerodynamic condition, such effects were not taken into account in the analysis reported here.

Figures 4 and 5 present the mean pressure coefficient distribution in correspondence of two loops of pressure taps, loop 2 on the train nose and loop 6 approximately in the centre of the leading car. A comparison between static and moving tests results is outlined. Error bars are included in the figures to represent the experimental error that has been estimated through an uncertainty analysis (not discussed in the current paper). As specified above, experimental data for the surface pressure were collected for all the eight loops of tappings shown in Figure 1a. For

purposes of discussions, however, two cross-sections were selected to provide a significant example of different surface pressure conditions experienced along the vehicle.

On the nose of the train (Fig. 4) positive values of $\bar{C}_P$, which indicate a stagnation region, are shown on the windward side and also on the roof windward corner. Negative values of $\bar{C}_P$, which instead indicate suction, characterize the leeward side, the underbody region and also the roof leeward corner, with an evident suction peak arising in correspondence of the latter. Significantly reduced magnitudes of $\bar{C}_P$, for both positive and negative values, and also a partially different trend are outlined at the centre of the train leading car (Fig. 5). Similarly to what observed for loop 2, the results relative to loop 6 show areas of suction that embrace both the leeward side and the underbody region. A stagnation region is still present on the windward side, within which a uniform surface pressure is indicated by the very similar $\bar{C}_P$ values in correspondence of taps 1 and 2. The pressure distribution on the roof presents the main variations with respect to what found on the train nose: in the centre of the leading car the roof is entirely characterized by an area of suction, which shows a peak in correspondence of the windward corner.

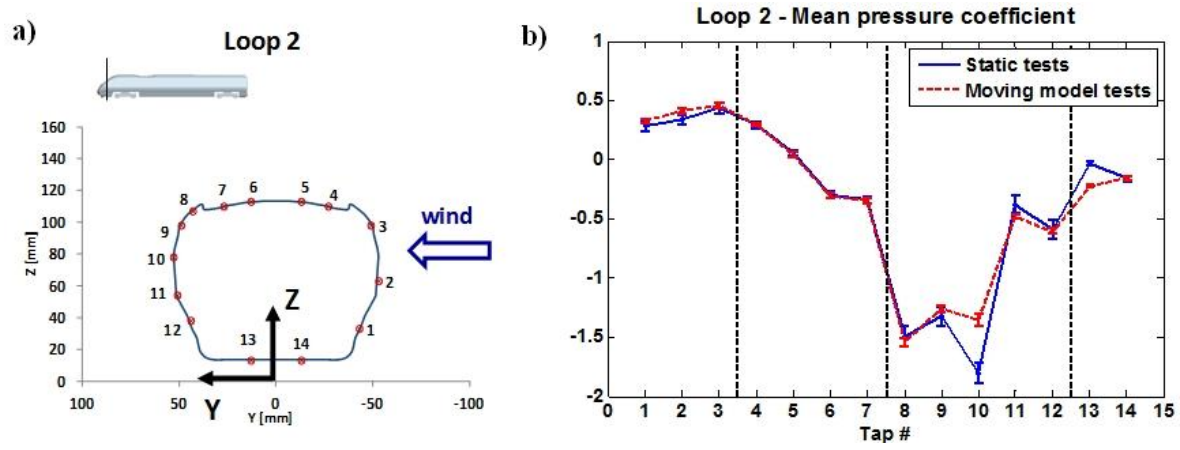

Figure 4. Mean pressure distribution over loop 2 on the nose of the train: Static vs Moving model tests comparison (Class 390 Pendolino, 1:25 scale, 30° yaw angle, FG scenario)

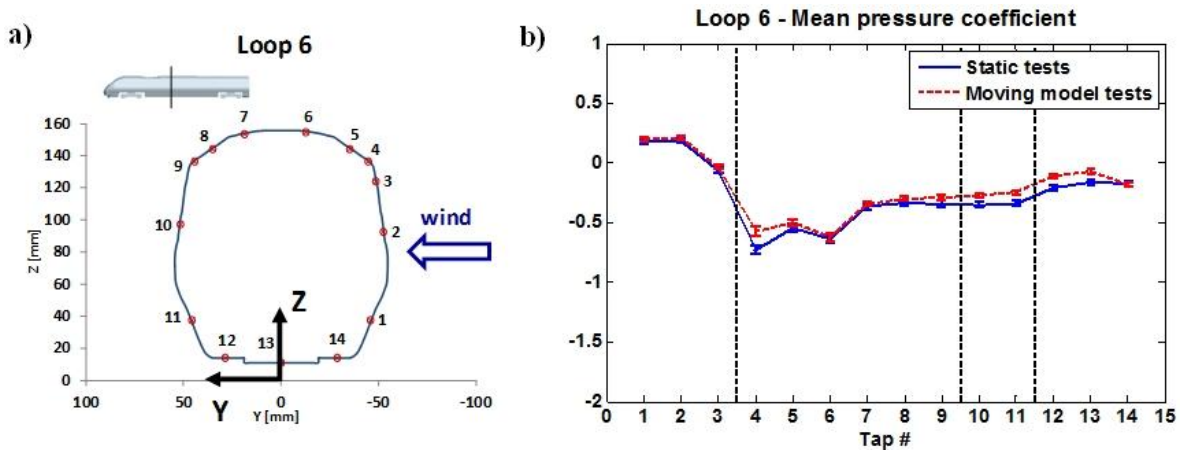

Figure 5. Mean pressure distribution over loop 6 in centre of the leading car: Static vs Moving model tests comparison (Class 390 Pendolino, 1:25 scale, 30° yaw angle, FG scenario)

These results appear consistent with those reported by previous studies on trains which presented similar streamlined designs and were investigated at a 30° yaw angle [11, 15]. The stagnation on the windward side, which on the nose extends also to part of the roof, is determined by the relative crosswind directly impinging the train surface. The suction peak on the nose leeward side is compatible with the presence in that area of one (or more) vortex attached to the train surface. This being supported not only by the magnitude of the suction highlighted in Figure 4 on tap 8, 9 and 10, but also by the fluctuations observed in the time histories of the surface pressure and reflected by high values of standard deviation (not shown here). Moving towards the rear of the train, the data for the adjacent loops of tappings (not shown here) denotes a progressive attenuation in the intensity of this low pressure peak. Such a trend supporting the hypothesis of the vortices mentioned in the above progressively rolling up and moving away from the train surface. A smooth pressure distribution on the leeward side, still associated to a suction region but showing no peak, is reached already in correspondence of loop 4 (Fig. 1a) by where, hence, a complete detachment of the vortical structures seems to have occurred. A region of uniform low pressure is maintained on the leeward side from that section up the rear of the leading vehicle, as reflected by the results relative to the centre of the first car (Fig. 5). The suction peak observed on loop 6, in correspondence of the roof windward corner, suggests in that area the presence of a further vortex. The data from adjacent measuring sections seems to indicate that this vortex is rolling up on the roof. While moving towards the rear, it is drifting progressively from the windward edge to the centerline of the roof, and then it detaches from the train.

The comparison between static and moving model tests indicate good correspondence between the two cases. If the estimated measurement accuracy is taken into account, the majority of the data show a level of agreement that appears somehow remarkable. There are local differences that do not fall within the margin of experimental error. They tend to occur in correspondence of the suction peaks. Nevertheless, it is worth noting that they can be found only for a limited number of tapping points. The trend of the pressure distribution shows a good agreement between static and moving model test results. In correspondence of all the examined loops of pressure taps, the position and extension of the stagnation regions and of the suction peaks are very similar, and also the magnitude of such peaks is comparable. No major differences, hence, can be inferred with regard to the characteristics of the flowfield surrounding the train.

3.2 *Mean aerodynamic load coefficients*

The mean aerodynamic load coefficients for the side and lift forces, and for the rolling moment are presented in this section. Such coefficients are indicated in what follows as $\bar{C}_Y$, $\bar{C}_Z$ and $\bar{C}_{Mx}$, respectively. They were calculated by discrete integration of the pressure distribution over the entire leading car, according to the following equations:

$$\bar{C}_Y = \frac{1}{A_{ref}} \Sigma_i \bar{C}_{Pi} A_i \left(\mathbf{n}_i \bullet \mathbf{y} \right); \quad \bar{C}_Z = \frac{1}{A_{ref}} \Sigma_i \bar{C}_{Pi} A_i \left(\mathbf{n}_i \bullet \mathbf{z} \right); \quad \bar{C}_{Mx} = \frac{1}{A_{ref} H_{ref}} \Sigma_i \bar{C}_{Pi} A_i \left| \mathbf{d}_i \times \mathbf{n}_i \right| \tag{3}$$

In Equation 3, $\bar{C}_{Pi}$ is the mean pressure coefficient as defined in the previous section. A_i and $\mathbf{n}_i$ represent, respectively, the area and the normal unit vector associated to each flat surface into which the train geometry has been discretized. The discretized geometry adopted for the integration was the same for both the static and moving model tests pressure data. **d** is the vector directed from the longitudinal axis X to the center of such flat surfaces *i*, while **y** and **z** are the unit vectors associated to the Y and Z axes, respectively (Fig. 1b). A_{ref} is the reference area, assumed as the nominal side area of the leading car and equivalent to 77m^2 at full scale, while H_{ref} is the reference height and corresponds to a full scale equivalent of 3.1m. The convention for positive

directions defined in accordance to the reference system specified in Figure 1a (for the rolling moment following the 'right-hand screw rule').

A comparison between the results obtained from static and moving model tests is illustrated in Figure 6. The differences appear to be very limited. In particular, whereas the experimental accuracy is taken into consideration (i.e. by specifying error bars on the figure), it can be appreciated how the discrepancies fall well within the estimated margin of error.

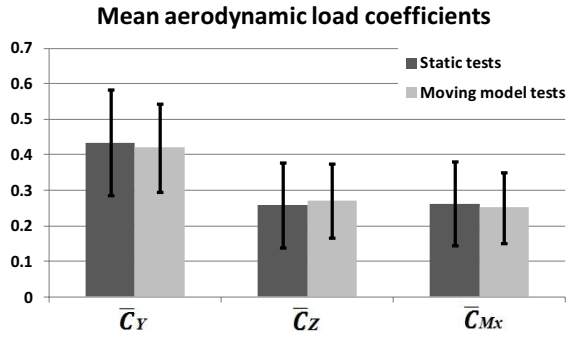

Figure 6. Mean aerodynamic load coefficients for the side force, lift force and rolling moment: Static vs Moving model tests comparison (Class 390 Pendolino, 1/25th scale, 30° yaw angle, FG scenario)

4 CONCLUSIONS

This paper has presented the results from an experimental campaign aimed to assess the effect of the vehicle movement simulation on the train aerodynamics in crosswinds. The existing TRAIN rig moving model test facility was updated by installing a new crosswind generator. A novel test methodology based on the use of an onboard pressure measuring system was developed. The combination of such factors enabled a rather extensive set of data to be collected through both static and moving model experiments. A Class 390 Pendolino scale model was tested on flat ground scenario at a 30° yaw angle. A first comparison, concerned with the mean pressure coefficient on the train leading car, shows limited differences between static and moving model tests. A second analysis, focused on the mean aerodynamic load coefficients, indicates non-significant impact of the vehicle movement on such parameters. Additional studies are ongoing. A further data analysis is investigating the unsteady aerodynamic effects. Also, the experimental results are being shared and used within the AeroTRAIN consortium for CFD benchmarking.

5 ACKNOWLEDGEMENTS

This paper describes some work undertaken in the context of the AeroTRAIN project, Aerodynamics: Total Regulatory Acceptance for the Interoperable Network (www.triotrain.eu).
AeroTRAIN is a collaborative project –medium-scale focused research project supported by the European Commission under the 7th Framework Programme, contract number: 233985, and coordinated by UNIFE, the European Rail Industry. CFD aerodynamic assessment of deck alternatives for a cable-stayed bridge

Felix Nieto [a], Santiago Hernández [a], Ibuki Kusano [a], José Á. Jurado [a]

[a] *School of Civil Engineering – University of La Coruna, Campus de Elviña s/n, Spain*

ABSTRACT: The present document reports the CFD analyses carried out for a set of four different deck cross-sections considered at the preliminary design of the Forth Replacement Crossing: a single box girder with and without wind shields and a twin box girder with and without wind shields. In order to assess the aerodynamic performance of these alternative designs the force coefficients, the shelter provided by the wind shields and the low-speed vortex shedding response of the static deck have been computed. The results obtained are compared with experimental data available in the literature for similar cross-sections finding a good general agreement. It can be concluded that CFD can provide designers with valuable qualitative information at an early design stage for the set of alternative designs considered.

KEYWORDS: CFD, force coefficients, wind shields, vortex shedding, cable-stayed bridges.

1 INTRODUCTION

Focusing on the wind action response, at the early design stage of long span bridges several alternatives for the deck are usually considered. The expected aerodynamic and aeroelastic response must be assessed in order to choose the most feasible alternative for each specific project. Usually engineers rely on previous experiences with similar cross-sections and only in the most challenging projects it is possible to test in the wind tunnel some of the considered preliminary designs. On the other hand, the use of computer-based aerodynamic analysis in real cases is scarce in spite of the growing number of applications in recent times [1, 2].

The aim of the present work is to employ CFD tools to assess the aerodynamic response of two deck types considered at the early design stage of the Forth Replacement Crossing. In order to recreate the constraints in the real design process, where the available resources are limited, 2D models with a limited size are employed. In the absence of published experimental data of the considered cross-sections the results are partially validated using experimental results of similar decks available in the literature. It must be remarked that this application aims to qualitatively evaluate the aerodynamic response of the set of cross-sections and to identify potential problems to focus on in a comprehensive wind tunnel campaign of a candidate design. It is out of discussion the requirement of extensive experimental campaigns to ascertain the performance of any bridge final design. Finally, it is worth recalling that the alternative selected by Transport Scotland for the final design of the Forth Replacement Crossing was the single box girder with wind shields [3].

2 ANALYSIS STRATEGY

2.1 *Deck types*

Two different deck types, from the ones considered for the Forth Replacement Crossing two corridor functional cross section, have been chosen as the specimens for this study: namely, single

box girder (SBG) and twin box girder (TWBG). The data required for the geometric definition of the cross sections of the aforementioned deck types have been obtained from published documents [4, 5] while the geometric definition of the 50% porosity wind shields has been obtained from Ozkan et al. [6] .

In the forthcoming sections the results obtained computationally for the two different deck types, with and without wind shields (WS standing for wind shields and BD standing for bare deck respectively), are going to be presented. This means that a benchmark of four different configurations will be analysed. In figure 1 the geometric definition of the cross sections studied suited with wind shields can be inspected (dimensions in m at real scale). It can be remarked that the purpose of the simulations has been to reproduce numerically the real sectional model wind tunnel tests at a 1:80 geometric scale.

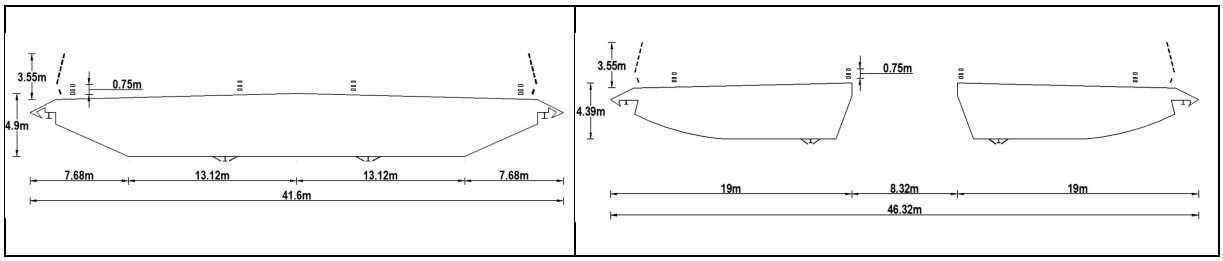

Figure 1. Geometry of the deck types

2.2 *Aerodynamic assessment approach*

The first step to ascertain the aerodynamic response of the set of considered deck types has been the computation of the force coefficients.

$$C_d = \frac{D}{\frac{1}{2}\rho U^2 B}; \quad C_l = \frac{L}{\frac{1}{2}\rho U^2 B}; \quad C_m = \frac{M}{\frac{1}{2}\rho U^2 B^2} \tag{1}$$

In fact, force coefficients play a very significant role because to avoid one degree of freedom instability the first derivative of lift and moment coefficients must be positive according to the criteria of figure 2; additionally, the greater the value of those derivatives is the lower the flutter critical wind speed of the structure is [7, 8]. Moreover, the force coefficients allow the quantification of the effect caused by the wind shields in the overall aerodynamic performance of each particular cross-section, for instance in the increase of the drag coefficient or the changes in the slope of the lift and moment coefficients.

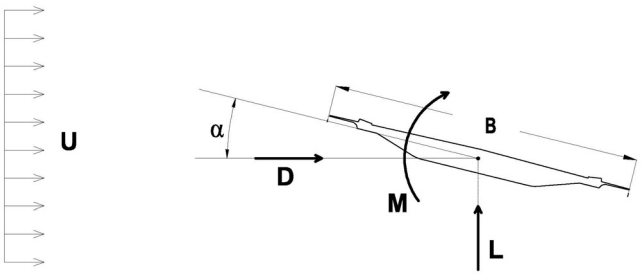

Figure 2. Sign criteria for the force coefficients

Besides this, the computer simulations also allow the evaluation of the level of shelter created by the wind shields in the vehicles' circulation zone on the deck.

Another critical issue to be addressed in the conceptual design stage of a cable supported bridge is the risk of low-speed vortex shedding excitation. In this study a number of flow velocities are considered in the unsteady simulations carried out, and the effect of the wind shields in the oscillatory lift forces suffered by the deck has been analysed.

In this work the CFD simulations for the single box girder are in the Reynolds number range (4.33e+04, 5.3e+05) based on the girder width, while for the twin box girder deck the Reynolds number based on the one box chord length is in the range (1.19e+04, 2.37e+05). It has been assumed that the deck is static throughout the simulations.

3 COMPUTATIONAL MODELLING

The flow around the deck has been computed using the incompressible, unsteady Reynolds averaged Navier-Stokes equations in 2D and the $k-\omega$ SST turbulence model has been chosen. Dirichlet conditions are imposed at the inlet and outlet while no-slip boundary condition has been imposed at the deck surface and the upper and lower limits of the fluid domain as the purpose of the simulations is to reproduce real sectional wind tunnel tests. The corners are modelled as perfectly sharp. The turbulent intensity prescribed at the inlet is 1.1% while the turbulent length scale is about 0.1 times the width of the single box girder design [9]. The flow domain considered in this work is 26.9*B* by 3.8*B* (being *B* the single box girder width), similar to existing wind tunnel facilities.

A commercial finite volume solver has been used to numerically evaluate the flow field. A quadrilateral mesh using the map scheme near walls, and pave scheme in the main part of the flow domain, was utilised. As the target of this study is the preliminary analysis of a set of tentative designs it has been intended to avoid high density meshes. Additionally it has been intended to employ only one mesh for each deck type with similar temporal and spatial discretization, thus the boundary layer grid resolution has been a compromise between the requirements associated to each Reynolds number. As a consequence the ratio of the height of the first grid layer attached to the deck and the single girder width is δ_1/B =5.8e-5 for all the cases analyzed, which is close to the value prescribed by Ribeiro [10] and one order of magnitude higher than the values adopted by Mannini and co-workers [11] and Fransos and Bruno [12]. In tables 1 and 2 the time averaged values of $y^+ = \delta_1 u_\tau / \nu$ ($\overline{y^+}$) averaged along the boxes, the traffic barriers and the windward wind shield are presented along with the time averaged maximum value of y^+ ($\overline{y^+_{max}}$) for the same parts of the deck.

4 GRID AND TIME-STEP REFINEMENT

As a first step in the verification of the numerical simulations a grid and time-step refinement study has been carried at *Re*=5.3e5 and 0º angle of attack for both single box girder arrangements and at *Re*=2.4e5 for the twin box girder with and without wind shields, in order to analyze the changes in several variables.

Regarding the spatial discretization study, in tables 3 to 6 the main characteristics of the set of grids considered are presented along with the results obtained for the mean force coefficients (C_d, C_l and C_m) and the standard deviation of the fluctuating force coefficients (C'_d, C'_l and C'_m). The number of cells is increased by a factor of 1.5 while the characteristics of the structured layer attached to the deck, described in the previous section, are the same in all the cases.

From the results presented in the tables above it can be concluded that there are not substantial differences in the mean values of the force coefficients obtained with the medium and fine grids for the single box girder with wind shields, and the twin box girder deck with and without wind shields. Therefore the medium mesh will be used in the simulations hereafter. It is worth remarking that for the single box girder without wind shields there is a non-negligible difference in the value computed for the mean lift coefficient as a 20% discrepancy exists between the medium and fine mesh results, furthermore the standard deviation of both lift and moment coefficients is about one order of magnitude lower when the fine grid is adopted. Further studies are required to set an accurate spatial discretization for the single box girder case without wind shields, nevertheless at the present stage of the investigation it has been decided to adopt the medium mesh to keep coherency with the other cases studied, in the understanding that the level of accuracy can be compatible with the purpose of this work, which is the preliminary assessment of a set of alternative designs. The twin box girder without wind shields shows a strong vortex shedding; thus the Strouhal number (St) has been included in table 5 for comparison.

For the ascertaining of the time step adequacy, the mean values and standard deviation of the force coefficients are computed using the medium grid, considering two different non-dimensional time steps: 2.88e-03 and 1.44e-03, for the single box girder cases, and 2.53e-03 and 1.23e-03 for the twin box girder cases. The results are presented in tables 7 to 10.

For the twin box girder without wind shields a 17% difference in the mean lift coefficient along with a 5% difference in the mean drag coefficient have been found while the Strouhal number and the standard deviation of the three force coefficients are in good agreement. These differences are considered assumable at the present stage for the intended purposes of the investigation. For the other three deck types, no substantial discrepancies are presented. As a consequence 2.88e-03 and 2.53e-03 non-dimensional time steps are selected for the computation of the complete set of mean force coefficients which are going to be presented next. However for the low-speed vortex shedding simulations 1.44e-03 and 1.26e-03 non-dimensional time steps have been chosen for the sake of higher accuracy in evaluating this unsteady response.

5 NUMERICAL EVALUATION OF THE FORCE COEFFICIENTS

5.1 *Single box girder with and without wind shields*

In figure 4 the computed mean force coefficients of the single box girder deck with and without wind shields at *Re*=5.2e5 are presented along with the experimental force coefficients of section H4.1 of the candidate cross-sectional shapes considered in the early design of the Great Belt Bridge [13] for validation.

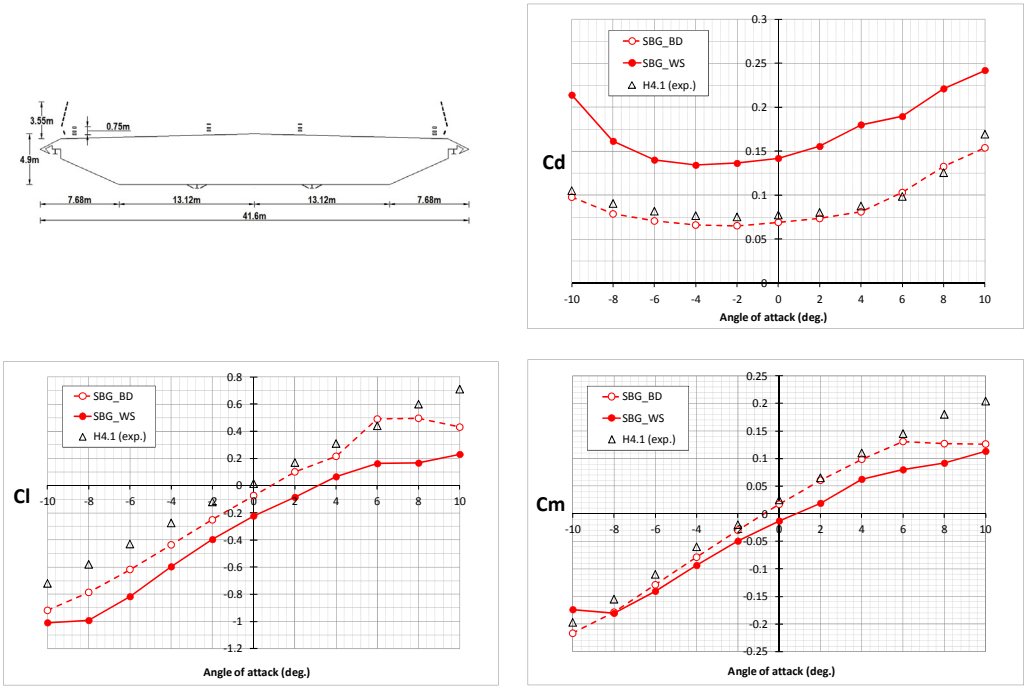

Figure 4. Force coefficients of the single box girder with and without wind shields

From figure 4 it can be concluded that mean force coefficients of the single box girder without wind shields are in good agreement with the experimental data of the H4.1 section. This is important due to the poor results of the grid convergence study for this particular deck type. Besides this the wind shields cause an important increment in the drag coefficient, which is about twice the drag coefficient for the bare section at 0º angle of attack. Furthermore the lift co-

efficient shifts down about 0.15 units keeping the same slope in the range of angles of attack (-8º, 6º) and the slope of the moment coefficient decreases slightly.

5.2 *Twin box girder with and without wind shields*

The computed mean force coefficients at *Re*=2.4e5 for the twin box girder deck types are presented in figure 5. In this case, the experimental force coefficients of two twin box girder decks as the Xihoumen Bridge [14], with a geometrical arrangement similar to the studied specimen, and the Stonecutters Bridge [15], with curved box lateral plates, are also included for the sake of indirectly validating the numerical results.

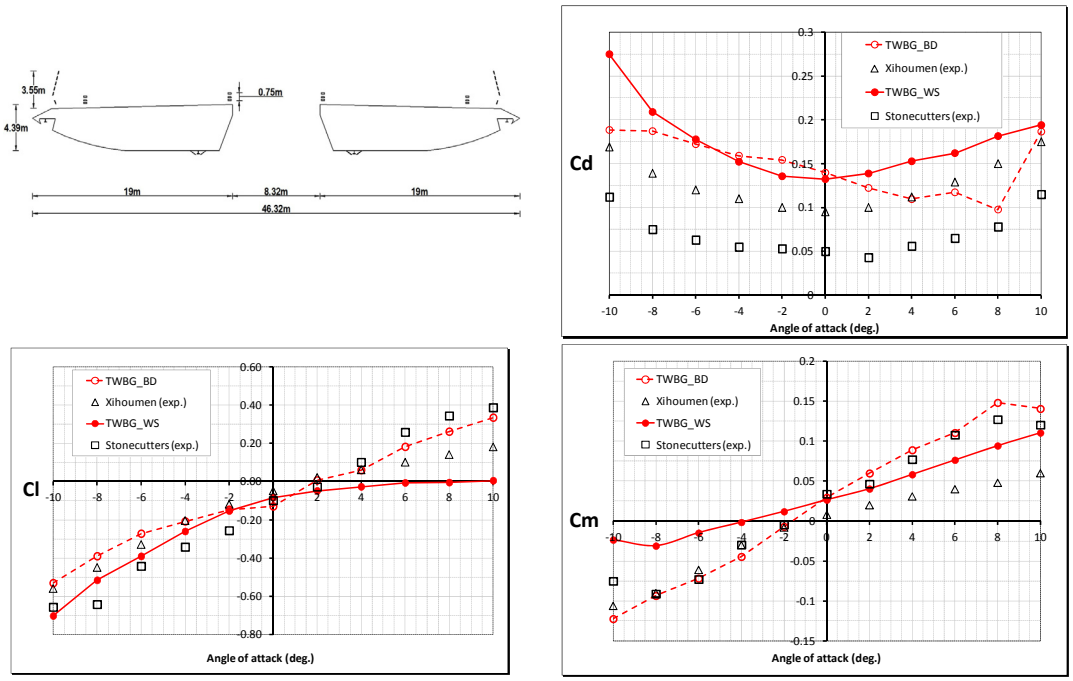

Figure 5. Force coefficients of the twin box girder with and without wind shields

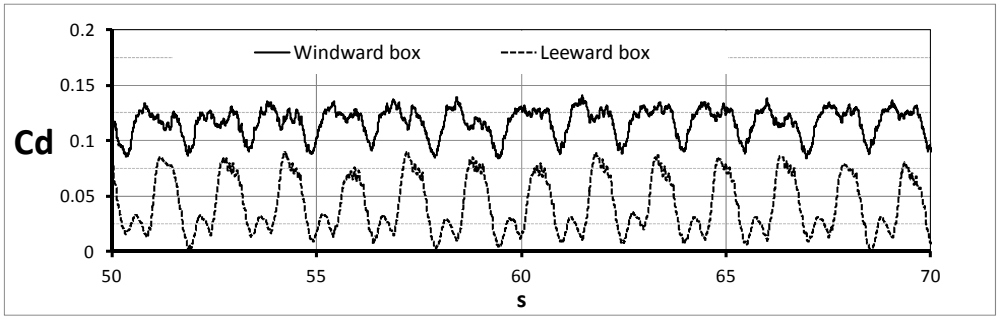

Figure 6. Time history of the disaggregated drag coefficient for TWBG without wind shields at -4º angle of attack.

The twin box girder without wind shields shows lift force coefficient close to the Xihoumen Bridge in the range of angles of attack between -10º and 4º and the differences increase for higher angles of attack. The computed moment coefficient shows good agreement with the Xihoumen Bridge experimental data from -10º to -2º angle of attack. Besides this, for the positive angles of attack the computational results are in agreement with lift and moment coeffi-

cients of the Stonecutters Bridge. Nevertheless it must be remarked the abnormal patter of the drag coefficient which is far from the parabolic shape typical of this force coefficient. Another important characteristic is the high value of the drag coefficient which is similar to the values of the wind shield configuration for the angles of attack between -8º and 2º. Analyzing the computed disaggregated drag forces acting on the windward and leeward boxes it has been found that they are nearly in phase as it can be perused in figure 6. In the absence of a precise experimental validation, this result must be taken as a work hypothesis to be confirmed in the experimental wind tunnel tests to carry out in case of this alternative progressing along the design process.

On the other hand the drag coefficient computed for the twin box girder with wind shields shows a parabolic shape, with values higher than those corresponding to the Xihoumen Bridge. The effect caused by the wind shields in the lift coefficient is the decrement in the slope of the Cl for the positive angles of attack. Regarding the moment coefficient, the wind shields cause the decrement of the coefficient slope for the complete range of studied angles of attack.

6 SHELTER EFFECT OF WIND SHIELDS

The purpose of windshielding in bridges is to provide shelter to vulnerable vehicles, in order to avoid restrictions in bridge operation such as the imposition of lane closures [16].

For the single box girder and the twin box girder alternatives for the Forth Replacement Crossing, computational simulations were carried out for a 3.0 m/s flow speed, which corresponds to a 26.3 m/s free stream velocity at real scale, which is above the wind speed values triggering restrictions in the operation of long span bridges. In figure 7 the normalized wind velocities (ratio of the velocity magnitude to the reference velocity at any point) fields between wind shields are presented for both the single box girder and the twin box girder deck types. The origin of coordinates x and y is set at the connection between the windward wind shield and the box deck. In the charts the horizontal and vertical coordinates are normalized employing the height of the wind shield (H)

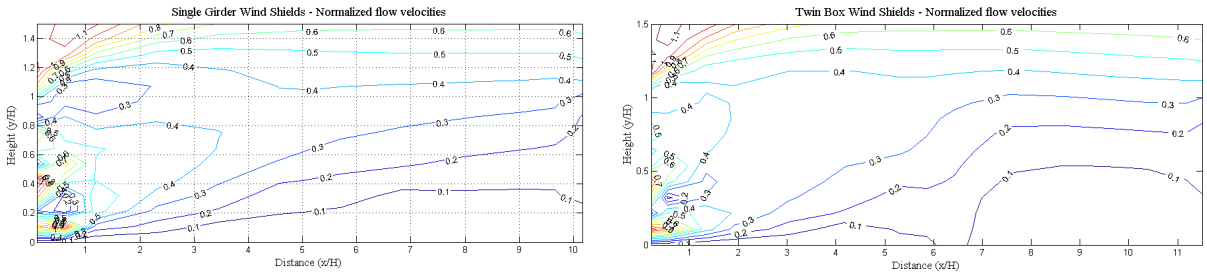

Figure 7. Normalized flow velocities at 0º angle of attack.

The numerical results are compared with the experimental tests reported by Kwon and coworkers [17] who tested an expanded metal barrier with a porosity ratio of 53.7% and a folded porous plate with a porosity ratio of 50% at a 1:10 geometric scale. The numerical results are about a 15%-20% lower that the normalized velocities obtained in the wind tunnel. This can be due to several causes: in the experimental tests the size of the mesh and the holes of the porous plate were not scaled to prevent scale effects, furthermore in the wind tunnel tests only a windward barrier was considered, nevertheless in the present computation both windward and leeward barriers along with the four traffic barriers have been included in the model, which justifies an additional decrement in the flow velocities. Additional studies are required for an accurate as-

sessment of the shelter provided by the wind shields as Reynolds number effects cannot be dismissed beforehand.

7 VORTEX SHEDDING RESPONSE

The preliminary assessment of the vortex-induced vibration risk of the different deck types proposed for the Forth Replacement Crossing at the early design stage has an obvious interest as it would allow the identification of potential aerodynamic concerns. Special attention must be paid to the twin box girder arrangement as bridges with this configuration such as the Stonecutters [18] or the Xihoumen [19] Bridges required mitigation strategies to tackle this phenomenon.

Several simulations considering a static deck have been carried out at low speed and 0º angle of attack for the set of deck types considered in this work. The fluctuating lift coefficient has been analyzed in order to identify strong peaks on the spectrum, indicative of vortex shedding excitation risk. For the single box girder with and without wind shields the fluctuating lift coefficient does not show important peaks on the spectrum. However for the twin box configuration without wind shields a single and extremely high pick has been identified at a *St* between 0.152 and 0.160 for all the flow velocities considered (0.75 m/s, 1.25 m/s, 1.75 m/s, 2.25 m/s and 3 m/s) which clearly indicates a vortex excitation risk and is in agreement with the experimental results reported in the literature. On the other hand, when the twin box girder is fitted with wind shields, it does not show a single strong peak in the spectrum of the lift coefficient for the same set of wind speeds. This indicates a beneficial effect of the wind shields in the vortex shedding response of twin box decks as it has been reported by Ge and co-workers [19].

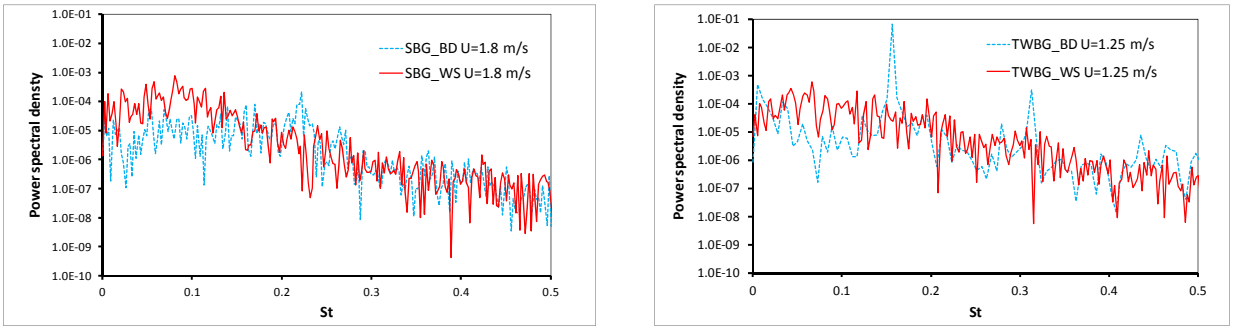

Figure 8. Power spectral density of the fluctuating lift coefficient at 0º angle of attack for the single box girder and the twin box girder with and without wind shields.

8 CONCLUSIONS

CFD techniques have been employed to study the aerodynamic response of two different deck types, with and without wind shields. The force coefficients have been computed, along with the shelter provided by the wind barriers and the vortex shedding response at low-speed.

The verification studies have shown a poor grid convergence for the single box girder without wind shields and some discrepancies were found for the twin box girder without wind shields refining the time step. On the other hand both decks fitted with wind shields showed a good grid and time step convergence.

The force coefficients for the decks without wind shields presented results close to other designs whose experimental data are available in the literature, except for the drag coefficient of the twin box which must be further studied. The decks fitted with wind shields showed a strong increment in the drag coefficient and a slight decrement in the slopes of lift and moment coefficients.

The shelter provided by the 50% porosity wind shields is higher than the existing results in the literature. However, the presence of the leeward wind shield and the traffic barriers justifies lower wind speeds at deck level.

Vortex shedding excitation risk was detected for the twin box girder without wind shields which is in agreement with the published literature. Also the beneficial effect of the wind shields has been pointed out, which is also in agreement with the results published for the Xihoumen Bridge.

ABSTRACT: Two dimensional numerical simulations of vortex-induced vibration response of H-shaped bridge deck with 2DOF was conducted with the techniques of dynamic mesh and UDF in Fluent software. The energy of the vertical vibration mode and torsional vibration mode were also calculated to investigate to the energy transition mechanism from one vibration mode to another vibration mode. Numerical results show that the drag coefficient and Strouhal number of the stationary H-shaped bridge deck agree well with the results reported by Larsen. The lock-in of the vertical vibration mode of the H-shaped bridge deck was found when the reduced wind velocity is in the range from 1.23 to 2.43. The flutter critical reduced wind velocity of the H-shaped bridge deck is about 5.26, which corresponding to flutter critical wind velocity of 12.5m/s for the original H-shaped bridge deck. When the reduced wind velocity is 5.26 and 6.31 separately, the energy of the H-shaped section with 2DOF is dominated by the vertical vibration mode firstly, then the energy of it in the torsional vibration mode increase dramatically and the flutter instability occurred.

KEYWORDS: numerical simulation; vortex-induced vibration; H-shaped bridge deck; energy of vibration mode; dynamic mesh; UDF

1 INTRODUCTION

Vortex-induced vibrations (VIV) are motions induced by the vortex shedding behind the bluff bodies. VIVs can occur in many engineering situations, such as large span bridge decks, offshore structures, and other engineering structures. The famous first Tacoma Narrows Bridge main deck exhibited the vortex-induced vibrations after opening to the traffic, which was finally destroyed by wind (Billah K.Y., et al., 1991). With the development of computational performance of computers, the numerical methods on VIVs of structures with sample geometry shapes, such as circular section, square section and rectangular section are used by many researchers (Murakami S., et al., 1997; Owen J.S., et al., 2007; Placzek A., et al., 2009; Sarwar M.W., Ishihara T., 2010, Liu Z.W., 2011). The aerodynamics and structural responses of four generic cross-section shapes developed from the well-known plate girder section of the first Tacoma Narrows bridge were investigated by Larsen with discrete vortex methods (Larsen A., 1998). The aerodynamic performance of the main deck of the first Tacoma Narrows bridge was investigated by many researchers (Matsumoto M., et al., 2008).

In present paper, a new gird generation method was developed to simulate vortex-induced vibrations of H-shaped bridge deck of Tacoma Narrows Bridge with two-degree-of-freedom (2DOF). The energy of the vertical vibration mode and torsional vibration mode were also calculated to investigate to the energy transition mechanism from one vibration mode to another vibration mode.

2 NUMERICAL METHODS

2.1 *Governing equations*

The fluid flow computation is in the framework of the finite volume method (FVM). The Reynolds-averaged Navier-Stokes (RANS) equations can be written as

$$\frac{\partial u_i}{\partial x_i} = 0 \tag{1}$$

$$\frac{\partial}{\partial t}(\rho u_i) + \frac{\partial}{\partial x_j}(\rho u_i u_j) = -\frac{\partial p}{\partial x_i} + \frac{\partial}{\partial x_j}(2\mu S_{ij} - \rho\overline{u'_j u'_i}) \tag{2}$$

where u, p present the time-average value of velocity and pressure; μ is the molecular viscosity, and S_{ij} is the mean stress tensor. The small-scale fluctuations of velocity relating to the turbulence are reduced as $\overline{u'_j u'_i}$, which is referred to as the Reynolds stresses.

The shear stress transport (SST) $k-\omega$ turbulence model was used in the present work. It models the Reynolds stresses with two transport equations for the turbulent kinetic energy k and the specific dissipation rate ω. The SST $k-\omega$ model shows good performance in predicting the adverse pressure gradient flows. The unsteady segregate solution was adopted in the calculations. The SIMPEC algorithm was used to solve the pressure-velocity coupled equations. The implicit first-order scheme was used for the unsteady terms. The PRESTO algorithm was used for pressure terms. The third-order upwind difference scheme QUICK was applied to the convection terms in the momentum equations and the k and the ω transport equations.

2.2 *Modeling of fluid-structure interaction*

The elastically mounted cylinder with 2DOF under the vortex-induced forces can be idealized as shown in Figure 1. The differential equations governing the vortex-induced vibration of the 2DOF system with damping are given as follows,

$$m\ddot{y} + c_y\dot{y} + k_y y = F_y(t) \tag{3}$$

$$I_m\ddot{\alpha} + c_\alpha\dot{\alpha} + k_\alpha\alpha = M_\alpha(t) \tag{4}$$

where m is the mass of the structure, c_y is the vertical damping, k_y is the vertical stiffness of the structure, y is the vertical displacement, respectively. I_m is the inertial moment of mass, c_α is the torsional damping, k_α is the torsional stiffness of the structure, α is the rotational displacement. $F_y(t)$ is the lift force in y direction, and $M_\alpha(t)$ is the torque around the z axis, which can be obtained by conducting fluid analysis around the structure section.

To analyze the structural response of the two-degree-of-freedom system, the equations of structural motion were integrated using Newmark-β method. The computational flow chart of numerical simulation of VIV of H-shaped bridge deck with 2DOF used in present paper is given in Figure 2.

2.3 *Geometry and mesh generation*

The original Tacoma Narrows bridge deck was chosen to investigate the wind-induced vibration responses with numerical methods given in present paper. The geometry and structural data of the original Tacoma Narrows bridge deck were taken from the paper by Larsen (Larsen A., 1998). The main parameters of the main deck are given in Table 1.

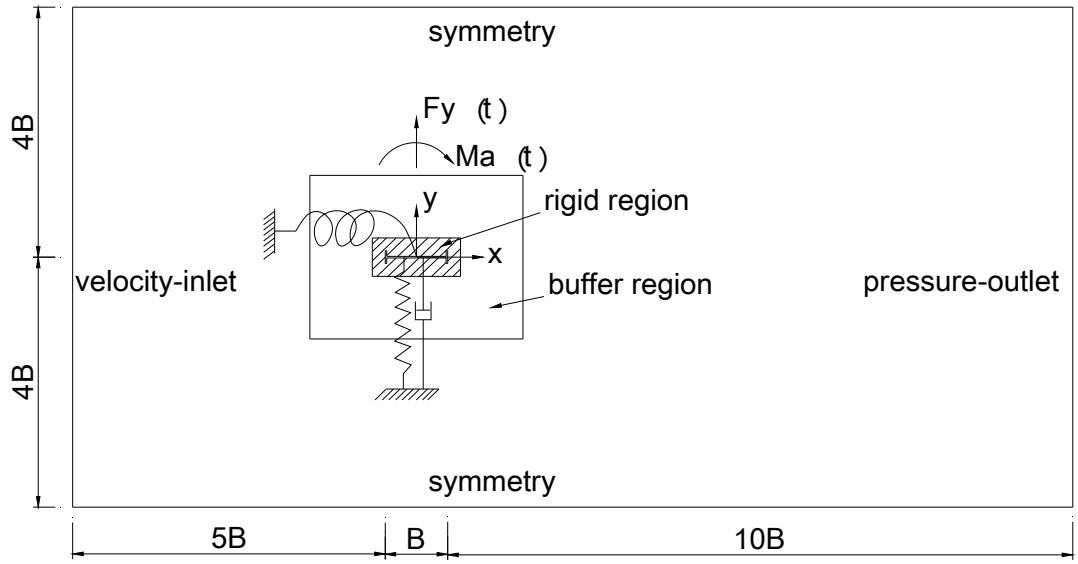

Figure 1 VIV model, computational region and boundary condition of the H-shaped bridge deck

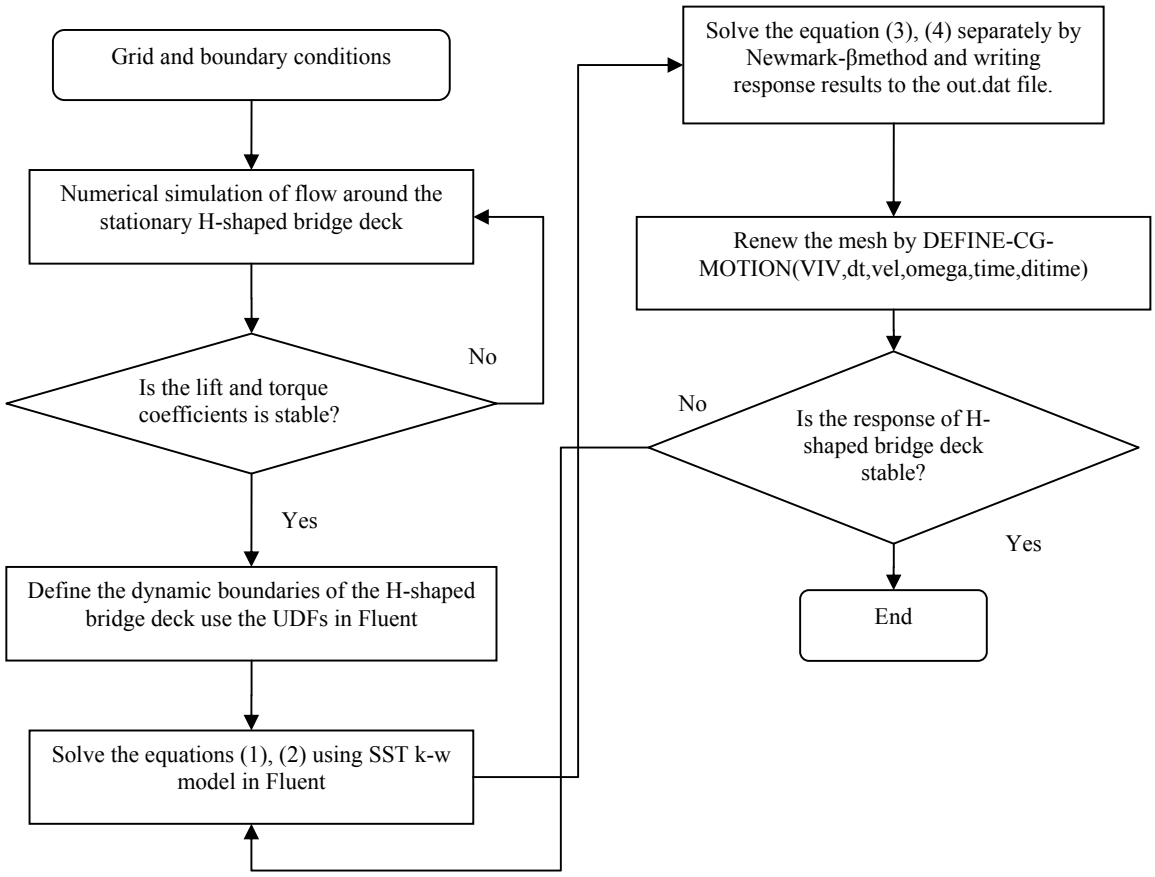

Fig. 2 Flow chart of numerical simulation of VIV of H-shaped bridge deck with 2DOF

Table 1 Main parameters of H-shaped deck of 1st Tacoma Narrows Bridge (Larsen A., 1998)

Parameters	Unit	Original value	Scale	Model value
The width of the deck, B	m	11.887	1/50	0.23774
The height of the deck, H	m	2.40	1/50	0.048
The mass per meter of the deck, m	kg/m	4.25×10^3	$1/50^2$	1.70
The inertial mass per meter of the deck, I_m	$kg\cdot m^2/m$	177.73×10^3	$1/50^4$	0.02844
The first asymmetric vertical vibration frequency, f_h	Hz	0.13	10/1	1.3
The first asymmetric torsional vibration frequency, f_α	Hz	0.20	10/1	2.0
Ratio of wind velocity, λ	/	/	1/5	/
The damping ratio, ξ	%	0.005	1.0	0.005

The computational region and boundary conditions of the H-shaped bridge deck are shown in Figure 1. As shown in Figure 1, the whole computational domain was divided into three different blocks, namely, rigid region, buffer region and stationary region. The displacements and velocities of the rigid region are same as that of the H-shaped bridge deck. The region between the rigid region and the stationary region was modeled as buffer region in which the mesh can be renewed at each time step. The turbulence intensity was of the order of 0.5% at the velocity inlet boundary. And the inlet velocity was in the range from 0.38m/s to 3.0m/s, which corresponding to the reduced wind velocity V/f_hB from 1.23 to 9.71. Symmetry condition was used for the top and bottom sides of the computational domain. The outflow condition was used for the right side of the outlet boundary of the computational domain. The no-slip wall condition was used for the H-shaped bridge deck.

A block-structured grid was used with coarser structured mesh in the stationary region, and the unstructured mesh was used for the buffer region between the stationary region and the rigid region of the computational domain, whereas fine structured mesh was used for the rigid region near the H-shaped bridge deck. The height of the first layer of the mesh near the H-shaped bridge deck is $\delta = 0.0017B$. An overview of the grid of the region is shown in Figure 3(a), and the local view of the mesh around the H-shaped bridge deck is shown in Figure 3(b).

3 NUMERICAL RESULTS

3.1 *Numerical simulation of flow around the stationary H-shaped bridge deck*

To verification the accuracy of the mesh, the numerical simulations of flow around the stationary H-shaped bridge deck were conducted firstly. The inlet velocity was 10m/s, and symmetry condition was used for the top and bottom sides of the computation domain. The pressure outlet condition was used for the right side of the outlet boundary of the computational domain. The no-slip wall condition was used for the H-shaped bridge deck. The aerostatic coefficients and FFT of the lift coefficients of the H-shaped section are given in Figure 4.

From the Figure 4, it can be seen that the drag coefficient of it is 0.238 with the reference width of B, which is slightly less than the result of Cd=0.28 reported by Larsen (Larsen A.,1998). The Strouhal numbe is about St=fH/V=0.1219, which is slightly larger than the result of St=0.11 given by Larsen (Larsen A.,1998).

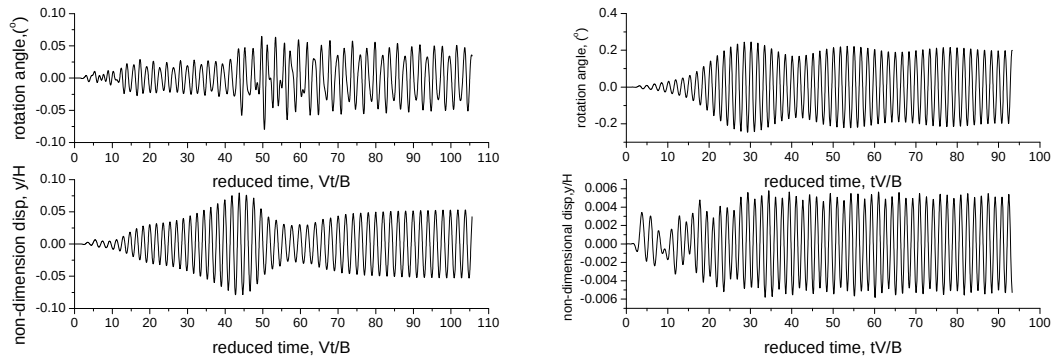
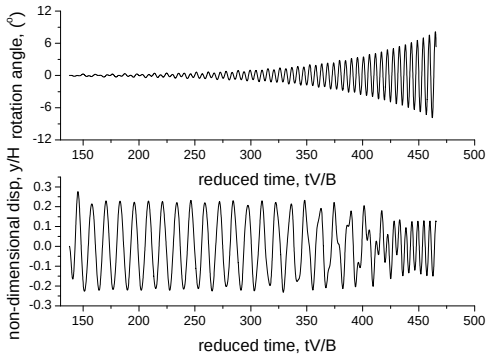
Figure 4 Aerostatic coefficients and FFT of the H-shaped section

3.2 *Numerical simulation of wind-induced vibration of the oscillating H-shaped bridge deck*

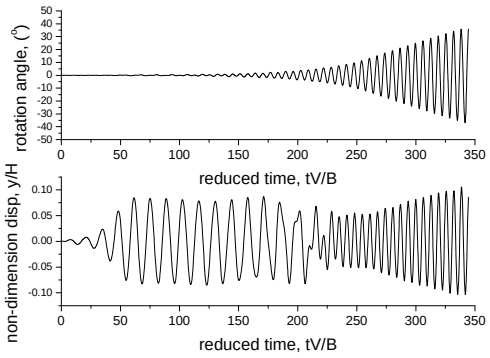
The numerical simulations of wind-induced vibration of the H-shaped section with 2DOF were conducted with the method given in present paper under the wind velocity of from 0.38 to 3.0m/s. Fig. 5 gives the time history of wind-induced vibration responses of the H-shaped bridge deck of the first Tacoma Narrows bridge for the wind velocity of 0.57m/s, 0.75ms, 2.50m/s, and 3.0m/s.



(a) $V_m = 0.57m/s$ (b) $V_m = 0.75m/s$



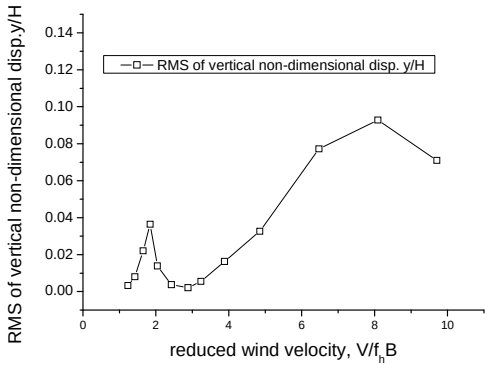
(c) $V = 2.5m/s$



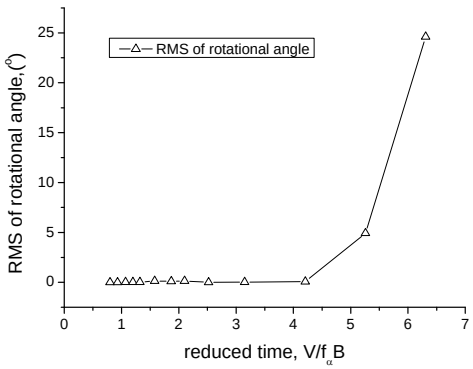
(d) $V = 3.0m/s$

Figure 5 Time history of wind-induced vibration responses of the H-shaped bridge deck with 2DOF

The wind-induced vibration responses of the H-shaped bridge deck with 2DOF are given in Figure 6. From the Figure 6(a), it can be seen that the VIV of the heaving vibration mode of the H-shaped bridge deck was found, and the lock-in reduced wind velocity located from1.23 to 2.43, which corresponding to the wind velocity from 1.90 to 3.75 m/s for the prototype bridge. The maximum RMS value of the non-dimensional displacement is about 0.04 when the wind velocity for the numerical model is 0.57m/s. At this wind velocity, the maximum amplitude is about 0.06H (H is the height of the H-shaped section). As shown in Figure 6(b), the torsional vibration angle of the H-shaped bridge deck increasing suddenly when the wind velocity is about 2.5m/s, which means that the flutter critical wind velocity is about 2.5m/s for the numerical model. The flutter critical wind velocity is about 12.5m/s for the original Tacoma Narrows bridge deck, which is less than the wind velocity of 18.7m/s (Matsumoto M., et al., 2008).



(a) Vertical responses of the H-shaped bridge deck



(b) Torsional responses of the H-shaped bridge deck

Figure 6 Wind-induced vibration responses of the H-shaped bridge deck with 2DOF

3.3 *Energy transformation of VIV of the H-shaped bridge deck*

The energy transformation from one vibration mode to another one was calculated to investigate the mechanism of VIV of the H-shaped bridge deck with 2DOF. The energy of the vertical vibration mode and rotation vibration mode of the VIV of the H-shaped bridge deck are defined as follows,

$$E_1 = (m\dot{y}^2 + ky^2)/2.0 \tag{5}$$

$$E_2 = (I_m\dot{\alpha}^2 + k_a\alpha^2)/2.0 \tag{6}$$

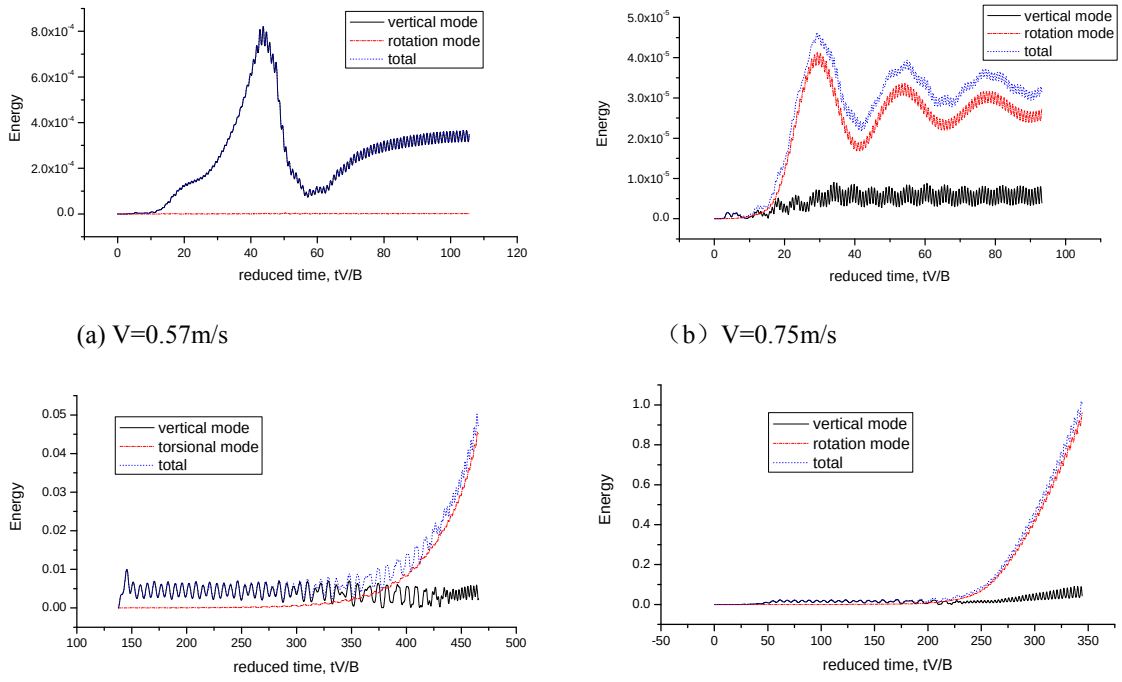
where m is the mass structure, k is the spring stiffness of the bridge deck in vertical direction, y and $\dot{y}$ are the vertical vibration displacement and velocity separately, E_1 is the energy of the structure system of the vertical vibration mode. I_m is the inertial moment of the mass of the bridge deck, k_α is the spring stiffness in torsional direction of the bridge deck, α and $\dot{\alpha}$ are the rotation angle and angular velocity separately, E_2 is the energy of the structure system of the torsional vibration mode.

The total energy of the VIV of the H-shaped bridge deck is given as follows,

$$E = E_1 + E_2 \tag{7}$$

where E is the total energy of the H-shaped bridge deck with 2DOF.

The time history of energy of the vertical vibration mode and rotation vibration mode of the H-shaped bridge deck for wind velocity of 0.51m/s to 3.0m/s are given in the Figure 7.



(a) V=0.57m/s　　（b）V=0.75m/s

（c）V=2.5m/s　　（d）V=3.0m/s

Figure 7 Time history of the energy of the H-shaped bridge deck with 2DOF

As shown in Fig.7, the energy of the H-shaped bridge deck with 2DOF is mainly dominated by the vertical vibration mode when the wind velocity is in the range from 0.38 to 0.63m/s. While the energy of it is mainly dominated by the torsional vibration mode when the wind velocity is in the range from 0.75 to 1.0m/s. The energy of the H-shaped bridge deck with 2DOF is mainly dominated by the vertical vibration mode when the wind velocity is in the range from 1.2 to 2.0m/s. When the wind velocity is 2.5m/s and 3.0m/s separately, the energy of the H-shaped bridge deck with 2DOF is dominated by the vertical vibration mode firstly, then the energy of it in the torsional vibration mode increase sharply and the flutter instability occurred.

4 CONCLUSIONS

The gird generation method and UDF (User defined function) program developed in present paper was used to simulate the wind-induced vibration of the H-shaped bridge deck with 2DOF. The wind-induced vibration responses of the H-shaped bridge deck with 2DOF were calculated to investigate the VIV responses and flutter instability of it. Numerical results show that the drag coefficient and Strouhal number of the stationary H-shaped bridge deck agree well with the results reported by Larsen. The lock-in of the vertical vibration mode of the H-shaped bridge deck was found when the reduced wind velocity is in the range from 1.23 to 2.43. The flutter critical reduced wind velocity of the H-shaped bridge deck is about 5.26, which corresponding to flutter critical wind velocity of 12.5m/s for the original H-shaped bridge deck. When the reduced wind velocity is 5.26 and 6.31 separately, the energy of the H-shaped section with 2DOF is dominated by the vertical vibration mode firstly, then the energy of it in the torsional vibration mode increase sharply and the flutter instability occurred.

ABSTRACT: This study used a Large Eddy Simulation (LES) model to investigate the hydrodynamic forces on fully submerged bridge decks. The numerical simulation was verified by comparing with the experimental results and was used to examine the influences of the deck Froude number and blockage ratio on the drag and lift coefficients of the bridge deck. The results demonstrate that the force coefficients are dependent on the deck Froude number. The drag coefficient increases as the blockage ratio increases for low Froude number, and dramatically increases, due to the wave induced drag, for high Froude number. On the other hand, the lift coefficient is a function of the submergence ratio of the deck. The downward velocity above the bridge deck and the asymmetric pressure distribution on the upper and lower sides of the deck generate a negative lift force on the bridge deck.

KEYWORDS: Bridge deck, Froude number, drag coefficient, lift coefficient, blockage ratio.

1 INTRODUCTION

The hydrodynamic loading on the bridge body is an essential parameter for evaluating bridge safety, especially when a bridge deck is entirely submerged in the river flow during flood events. The drag and lift forces can be calculated as:

$$F_D = C_D \frac{1}{2} \rho U_o^2 A \tag{1}$$

$$F_L = C_L \frac{1}{2} \rho U_o^2 A \tag{2}$$

where C_D is the drag coefficient, C_L is the lift coefficient, ρ is the density of water, U_o is the free-stream velocity of the undisturbed flow, and A is the frontal area of the bridge body. The drag and lift coefficients are functions of the bridge shape, attack angle and the Reynolds number of the flow (Hamill, 1999).

For fully submerged bridge decks, due to the presence of a free surface and the complicated interaction between the bridge structure and river flow, the drag and lift coefficients are difficult to determine. In previous studies, Naudascher & Medlarz (1983) measured the drag coefficient of a girder bridge and found that the wave motion and vortex formation between the girders generated a peak loading on the bridge deck. Malavasi & Guadagnini (2003) used dynamometers to measure the hydrodynamic forces on partially and fully submerged bridge decks with a rectangular cross-section. Their results revealed that the drag and lift coefficients were dependent on the Reynolds number and submergence ratio of the bridge deck. The submergence ratio is defined as:

$$h^* = \frac{H_o - h}{D} \tag{3}$$

where H_o is the water depth of undisturbed flow, D is the thickness of the bridge deck, and h is the distance from the channel floor to the underside of the deck (see Fig. 1). They also point out that the drag and lift coefficients significantly deviated from the corresponding values in an unbounded domain. In another paper, Malavasi & Guadagnini (2007) used a laboratory flume to study the interaction between a free surface flow and a rectangular cylinder in the water. They found that the rectangular cylinder created a blockage effect on the water flow, and the Reynolds number and the blockage ratio together affected the hydrodynamic loading on the cylinder. The blockage ratio is defined as the ratio of the frontal area of the bridge to the channel cross-sectional area.

On the other hand, Malavasi & Trabucchi (2008) used a three-dimensional k-ε turbulence model to investigate the proximity effects of a solid wall on the wake flow of a rectangular cylinder (aspect ratio L/D = 3) placed above a solid wall with different gap ratios h/D (h is the distance of the lower side of the cylinder to the wall). Their simulation results showed that the drag and lift coefficients increased as the gap ratio, S/D, decreased.

However, the above studies only covered a narrow range of flow conditions. Whether their results could be applied to other flow conditions (for example, supercritical flow) still needed to be examined. This study used a Large Eddy Simulation (LES) model to investigate the interactions between a free surface flow and fully submerged bridge decks. A series of numerical simulations were carried out to clarify the influences of the Froude number, the blockage ratio and the submergence ratio on the force coefficients of the bridge deck.

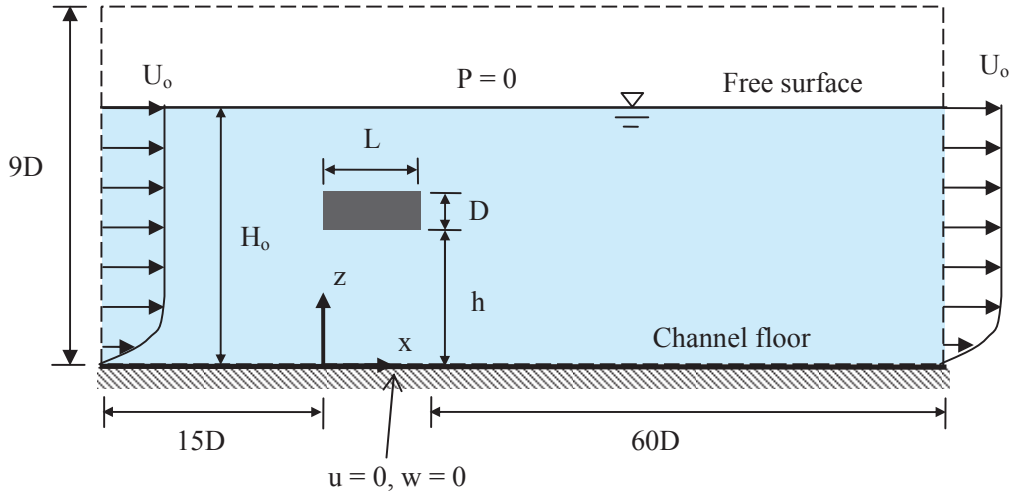

Figure 1. Schematic diagram of a fully submerged rectangular bridge deck.

2 NUMERICAL MODEL

This study used a Large Eddy Simulation (LES) model to simulate the flow field around the bridge deck. The fluid motion was simulated by solving the continuity equation and the Navier-

Stokes equations. The free surface was tracked by the Volume of Fluid (VOF) algorithm. The governing equations can be expressed as:

$$\frac{\partial \bar{u}_i}{\partial x_i} = 0 \tag{4}$$

$$\frac{\partial \overline{\rho u_i}}{\partial t} + \frac{\partial \rho \overline{u_i u_j}}{\partial x_j} = -\frac{\partial \bar{P}}{\partial x_i} + \rho g \delta_{i3} + \frac{\partial}{\partial x_j}\left[\mu_{eff}\left(\frac{\partial \overline{u_i}}{\partial x_j} + \frac{\partial \overline{u_j}}{\partial x_i}\right)\right] \tag{5}$$

where the subscripts i, j = 1, 2 represent the x and z directions, respectively; t is the time, $\bar{u}$ and $\bar{P}$ are the filtered velocity and pressure, ρ is the density of water, g is the gravitational acceleration, and μ_{eff} is the effective viscosity, defined as:

$$\mu_{eff} = \mu + \mu_{SGS} \tag{6}$$

where μ is the dynamic viscosity of water, and μ_{SGS} is the viscosity of sub-grid scale turbulence, defined as:

$$\mu_{SGS} = \rho(C_s \Delta_s)^2 \sqrt{2\bar{S}_{ij}\bar{S}_{ij}} \tag{7}$$

where C_s is the Smagorinsky parameter, S_{ij} is the rate of strain, and Δ_s is the characteristic length of the spatial filter:

$$\Delta_s = 2(\Delta x \Delta z)^{1/2} \tag{8}$$

In this study, the value of the Smagorinsky parameter was set to be $C_s = 0.30$. In addition, the projection method (DeLong, 1997) was used to solve the Poisson Pressure Equation (PPE) and to decouple the velocity and pressure in the Navier-Stokes equations. The water surface was simulated by the Volume of fluid (VOF) method (Hirt & Nichols, 1981).

$$\frac{\partial f_m}{\partial t} + \nabla \cdot (f_m \mathbf{u}) = 0 \tag{9}$$

The value of $f_m = 1$ corresponds to a cell full of water; and $f_m = 0$ represents the cell is full of air. Further details of the numerical model can be found in Wu & Liu (2009).

3 RESULTS AND DISCUSSIONS

In order to demonstrate the accuracy of the numerical model, the present Large Eddy Simulation (LES) model was compared with the experimental results of Malavasi & Guadagnini (2007). A stationary, rectangular cross-sectional bridge deck (thickness D = 0.06 m, length L = 0.18 m, aspect ratio L/D = 3) was placed above the channel floor. The deck was fixed in the channel and parallel to the channel floor. The distance from the channel floor to the underside of the deck was h = 0.14 m (see Fig. 1). The width of the bridge deck was equal to the width of the channel, and the flow direction was parallel to the length of the bridge deck. The bridge pier was not considered in this study. The water depth of undisturbed flow was in the range of $H_o = 0.17 \sim 0.5$ m, upstream velocity $U_o = 0.2$ m/s, the submergence ratio $h^* = (H_o - h)/D = 0.5 \sim 5.0$, the blockage ratio Br = 0.12 ~ 0.35. The Reynolds number $Re = U_o D/\nu = 1.2 \times 10^4$, and the Froude number $Fr = U_o/(gH_o)^{1/2}$ was in the range of Fr = 0.09 ~ 0.15. In order to examine the influence of the flow velocity on the force coefficients of the bridge deck, Malavasi & Guadagnini (2003) defined a deck Froude number as:

$$Fr_D = \frac{U_o}{\sqrt{gD}} \tag{10}$$

where D is the thickness of the bridge deck.

The drag and lift coefficients were computed from the pressure distribution around the cylinder and compared with the experimental results of Malavasi & Guadagnini (2007). As shown in Figure 2, the simulation results of the uniform grid (936 x 110) and the non-uniform grid (496 x 110) both are close to the measured drag and lift coefficients. The biggest difference for the time-averaged drag coefficient was 1.9%. In order to reduce the computing time, the non-uniform grid was used for the rest of the simulation.

Figure 2(a) depicts that the drag coefficient C_D increased as the submergence ratio, h^*, increased in the range of $0 \le h^* < 1.0$. This is because the bridge deck was partially submerged and the frontal area of the deck under the water surface increased as h^* increased. However, the value of C_D decreased as the submergence ratio, h^*, increased when $h^* \ge 1.2$. Malavasi & Guadagnini (2007) explained this trend by asserting that the variations of h^* induced the change in the blockage ratio, and the increasing blockage ratio resulted in the increase of the drag coefficient.

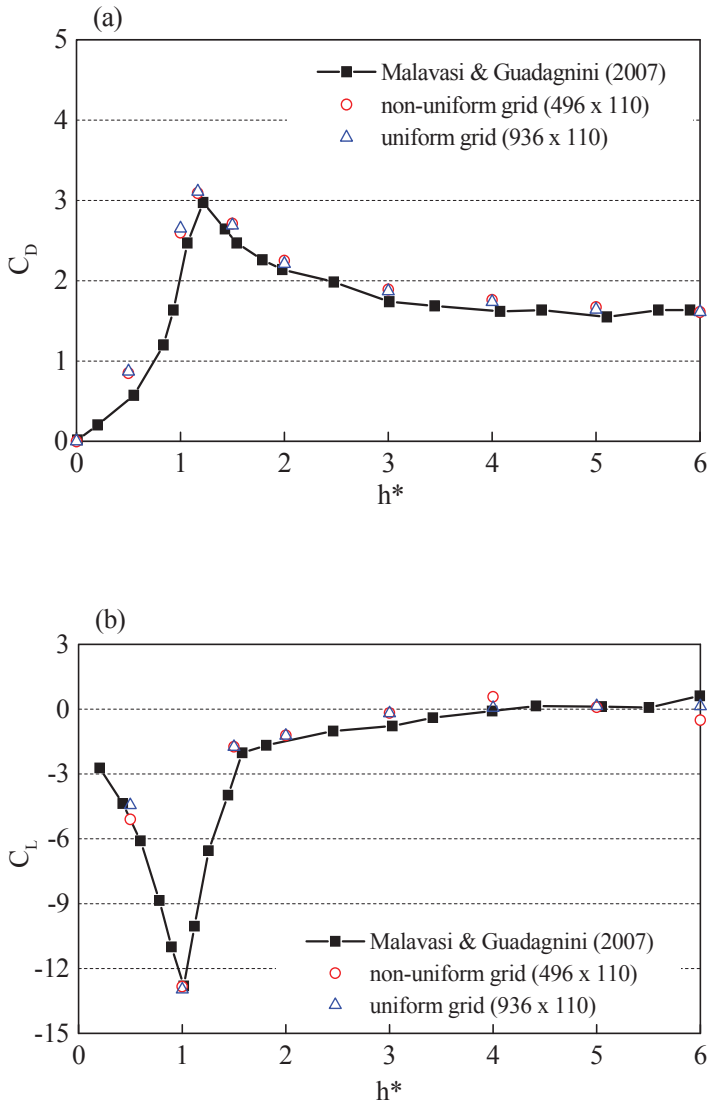

Figure 2. Comparison of model predictions and experimental results of Malavasi & Guadagnini (2007): (a) drag coefficient; (b) lift coefficient.

However, the submergence ratio and the blockage ratio were related to each other in the experimental conditions of Malavasi & Guadagnini (2007). Discriminating the influences of the blockage ratio and the submergence ratio on the drag coefficient can be difficult.

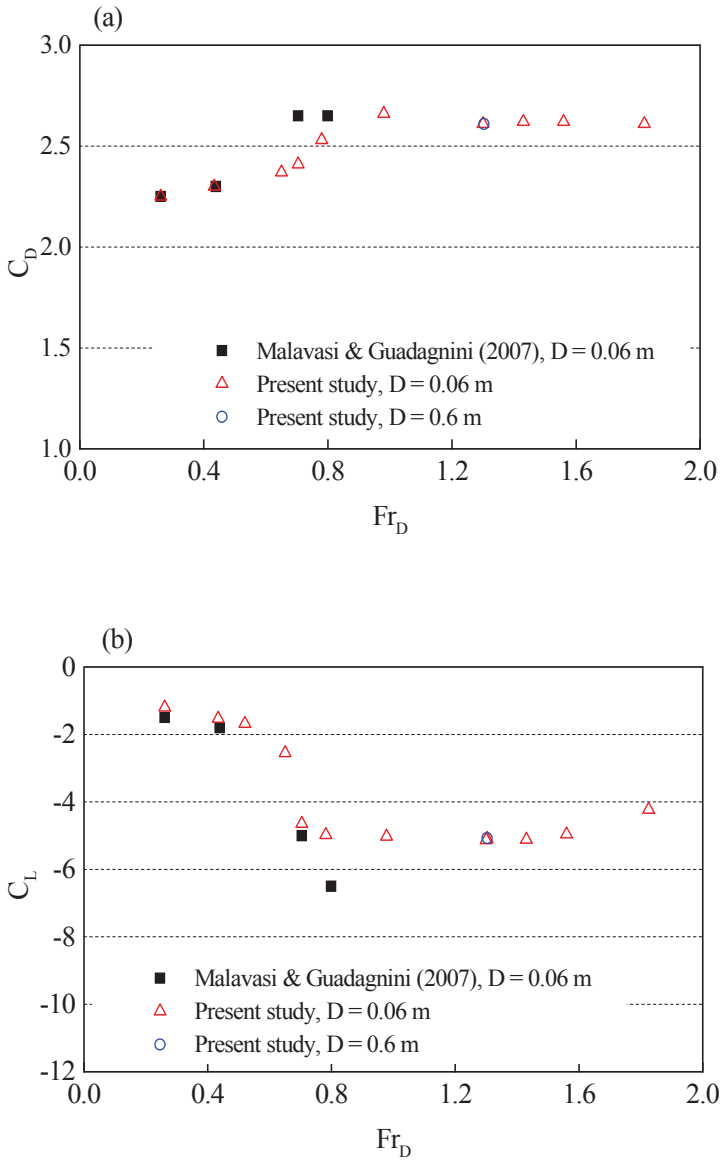

Figure 3. Relationship between force coefficients and deck Froude number for submergence ratio h* = 2.0, and blockage ratio Br = 0.23: (a) drag coefficient; (b) lift coefficient.

On the other hand, Figure 2(b) shows that the lift coefficient, C_L, was negative and decreased as the submergence ratio, h^*, increased in the range of $0 \le h^* \le 1.0$. This is due to the negative pressure (suction) produced by the separation bubble only occurred on the lower side of the deck when $h^* < 1.0$. When the deck was fully submerged ($h^* \ge 1.2$), the lift coefficient, C_L,

increased until it approached zero ($h^* \geq 3.5$). It was easy to understand this phenomenon because the pressure coefficients, C_p, became symmetric on the upper and lower sides when the water surface no longer influenced the separation flow on the upper side of the deck.

The drag and lift coefficients of the present study were plotted against the deck Froude number in Figure 3. The submergence ratio was $h^* = 2.0$, the aspect ratio was L/D = 3, and the blockage ratio was Br = 0.23. The Reynolds number was $Re = 1.2 \times 10^4 \sim 6.54 \times 10^4$, and the Froude number based on water depth H_o, $Fr = U_o/(gH_o)^{1/2}$, was in the range of Fr = 0.13 ~ 0.88. Namely, the channel flows were all sub-critical flows. However, the flow condition covered sub-critical flow to super-critical flow while using the deck Froude number ($Fr_D = 0.26 \sim 1.82$).

Figure 3(a) shows that when $Fr_D < 0.50$, the computed drag coefficient, $C_D = 2.25$, was close to the value $C_D = 2.0$~2.2 suggested by Hamill (1999) for bridge deck design. But the value of C_D increased slightly as the deck Froude number increased, and became a constant $C_D = 2.6$ when $Fr_D > 0.80$. In addition, the lift coefficient suddenly decreased from $C_L = -1.5$ to $C_L = -5.0$ when the deck Froude number was $Fr_D > 0.80$ (see Fig. 3(b)). This implied that there was a flow transition when the deck Froude number increased from 0.50 to 0.80.

The time-averaged water surface curves of different deck Froude numbers are shown in Figure 4. The gray area represents the location of the bridge deck. The location of the water surface was determined by setting the volume fraction $f_m = 0.5$. The water surface was smooth and undisturbed for low Froude number ($Fr_D \leq 0.52$). However, due to the back-water effect, the water surface was levitated in front of the bridge deck and suddenly dropped behind the deck when the Froude number was $Fr_D \geq 0.78$. This was the reason that the drag and lift coefficients went through a transition as the deck Froude number increased. The flow condition transformed from a sub-critical flow to a trans-critical flow as the deck Froude number increased from $Fr_D \leq 0.52$ to $Fr_D \geq 0.78$. The trans-critical flow covered the near-critical flow ($0.8 < Fr_D < 1.0$), critical flow ($Fr_D = 1.0$) and super-critical flow ($Fr_D > 1.0$).

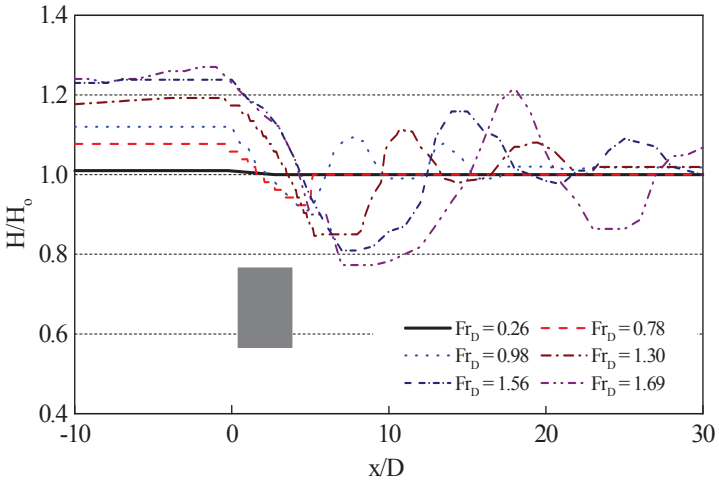

Figure 4. Water surface variations of different deck Froude numbers for h* = 2. The gray area represents the location of the bridge deck, x is the distance from the leading edge of the deck.

It should be noted that, for trans-critical flows, the height of the water surface above the deck and the amplitude of the surface disturbance increased as the deck Froude number increased. The surface disturbance behind the deck gradually decreased as the water flowed downstream. This is similar to the ship wave generated by a moving object near the water surface (Bal, 2008). The increase of the drag coefficient from $C_D = 2.2$ to $C_D = 2.6$, as the flow condition changed from sub-critical flow to trans-critical flow, was due to the wave-induced drag.

Figure 5 compares the distribution of the time-averaged pressure coefficients on the upper and lower sides of the deck for $Fr_D = 0.26$, 0.78 and 1.30, $h^* = 2.0$. The spatial average pressure coefficients were $C_{p3} = -2.01$, 0.66, 0.92 on the upper sides and $C_{p4} = -3.21$, -4.32, -4.17 on the lower sides, respectively. As can be seen in Figure 5, the pressure coefficients C_{p4} on the lower side of the deck were all negative and were close to each other for different Froude numbers. But the pressure coefficients $C_{p3} < 0$ on the upper side of the deck for the sub-critical flow ($Fr_D = 0.26$) and $C_{p3} > 0$ for the trans-critical flows ($Fr_D \geq 0.78$). The positive pressure coefficient, C_{p3}, was caused by the downward flow above the bridge deck. This positive pressure on the upper side together with the negative pressure on the lower side engendered a large downward force on the deck (negative lift coefficient C_L).

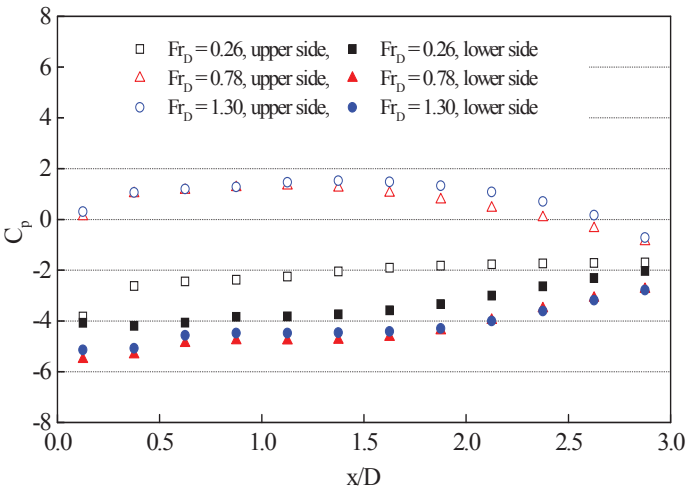

Figure 5. Distribution of time-averaged pressure coefficients on the upper and lower sides of the deck for $Fr_D = 0.26$, 0.78 and 1.30. The submergence ratio h* = 2.

Besides the Froude number effect, the force coefficients were influenced by the blockage ratio. This section focuses on the blockage effect on the force coefficients. The deck thickness D = 0.06 m, length L = 0.18 m (aspect ratio L/D = 3), and the free-stream velocity $U_o = 0.20$ m s^{-1} were kept constant throughout the simulation. The Reynolds number was $Re = 1.20 \times 10^4$, and the deck Froude number was $Fr_D = 0.26$. The variation of the blockage ratio included two different simulation series. The first simulation series kept the distance from the channel floor to the underside of the deck constant (h = 0.14 m), while changing the water depth $H_o = 0.23 \sim 0.50$ m. This was similar to the experimental setup of Malavasi & Guadagnini (2007). The submergence ratio was in the range of $h^* = 1.0 \sim 6.0$, and the blockage ratio was $Br = 0.12 \sim 0.26$. The second

simulation series changed the water depth, H_o and the height above the channel floor, h, while keeping the submergence ratio ($h^* = 2.0$) constant. The blockage ratio was in the range of Br = 0.05 ~ 0.20.

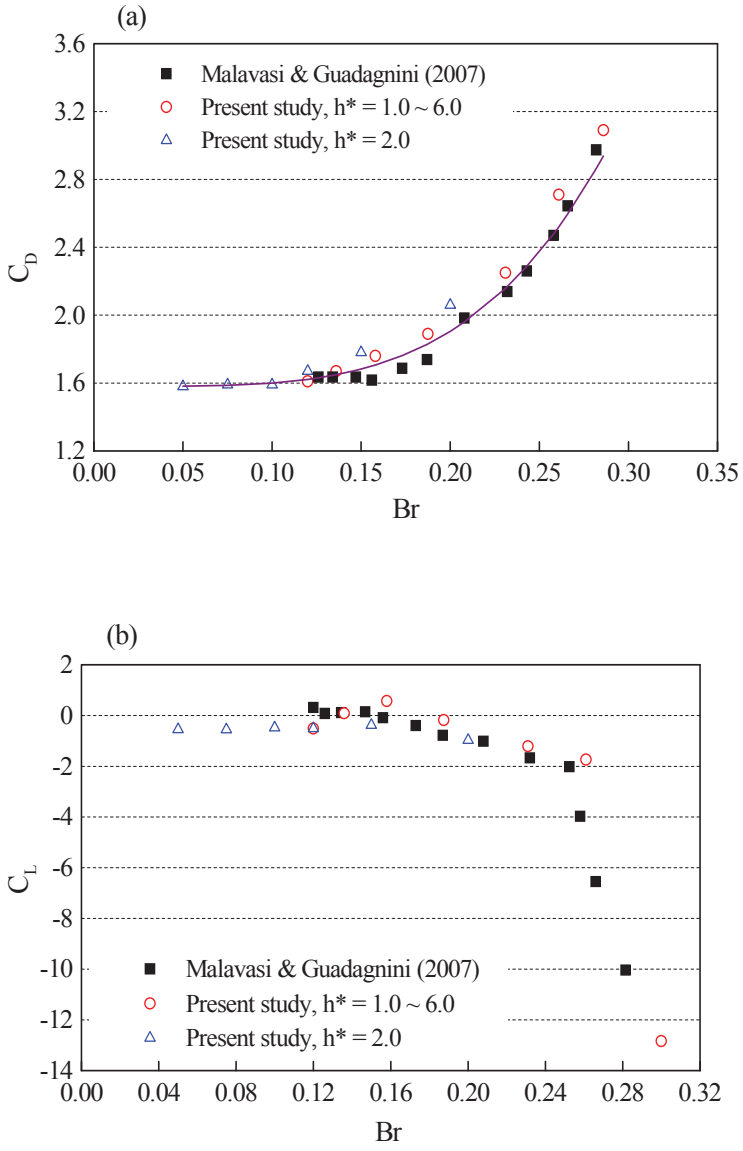

Figure 6. Relationship between force coefficients and blockage ratio for $Fr_D = 0.26$: (a) drag coefficient; (b) lift coefficient. The line is the prediction of Eq. (11).

The force coefficients were plotted against the blockage ratio in Figure 6. The flow condition was sub-critical flow ($Fr_D = 0.26$). The experimental results of Malavasi & Guadagnini (2007) were also plotted in the figure for comparison. Note that in Figure 6(a), the relationship between the drag coefficient and the blockage ratio was independent of the submergence ratio h^* for sub-

critical flow. The drag coefficient was a constant C_D = 1.6 when the blockage ratio was Br < 0.14. When Br > 0.14, the value of C_D increased from 1.6 to 2.8 as the blockage ratio Br increased. This is because the pressure difference between the frontal and rear faces of the deck increased by the blockage effect, and higher pressure drop resulted in a greater drag on the deck. In other words, the drag coefficient C_D = 2.0~2.2 suggested by Hamill (1999) may not be applicable for bridge decks with a large blockage ratio (Br > 0.23) or in trans-critical flows ($Fr_D \geq 0.78$). An empirical equation between the drag coefficient, C_D, and blockage ratio Br can be found by least square regression:

$$\frac{C_D}{C_{Do}} = 1.0 + \alpha \cdot Br^n \tag{11}$$

The parameters α =128.4, n = 4.0 and C_{Do} = 1.58 is the drag coefficient of rectangular cylinders of aspect ratio L/D = 3 in an unbounded domain. The coefficient of determination was R^2 = 0.938. This equation could be used to compute the drag coefficients of fully submerged bridge decks ($h^* > 1$) with a rectangular cross-section in sub-critical flows.

On the other hand, Figure 6(b) shows that the lift coefficient, C_L, decreased as the blockage ratio increased. The lift coefficient was $C_L > -2.0$ when the blockage ratio Br < 0.25. This is because the water surface restricted the development of separation flow on the upper side of the deck, and resulted in the asymmetric pressure distribution on the upper and lower sides of the deck. However, the negative lift coefficient became fairly large ($C_L < -3.0$) when the blockage ratio Br > 0.25. When the blockage ratio Br > 0.25, even in sub-critical flows, the pressure distribution is similar to trans-critical flow shown in Figure 5. The spatial average pressure coefficients, C_{p3}, on the upper side of the deck were positive, together with the negative pressure on the lower side generated a large downward force on the deck.

4 CONCLUSIONS

This study used a Large Eddy Simulation (LES) model and the Volume of fluid (VOF) method to investigate the interactions between the free surface flows and fully submerged bridge decks. The model prediction was verified by comparing it with the experimental data of Malavasi & Guadagnini (2007). The numerical model then was used to calculate the hydrodynamic forces on bridge decks of rectangular cross-section. The results indicated that the drag and lift coefficients were dependent on the deck Froude number, $Fr_D = U_o/(gD)^{1/2}$. The water surface was flat and undisturbed for sub-critical flow ($Fr_D \leq 0.52$). When the deck Froude number was $Fr_D \geq 0.78$, the water surface rose up in front of the submerged deck and dropped behind the deck, created a large surface disturbance.

In addition, the drag coefficient remained a constant C_D = 1.6 when Br < 0.14, and the value of C_D increased as the blockage ratio, Br, increased for sub-critical flows ($Fr_D \leq 0.52$). For trans-critical flows ($Fr_D \geq 0.78$), due to the wave-induced drag, the drag coefficient was larger than that for sub-critical flows with the same blockage ratio. Furthermore, the lift coefficient was a function of the deck Froude number, Fr_D, and the submergence ratio, h^*. This is because the separation shear flow on the upper side of the deck was constrained by the water surface and resulted in an asymmetric pressure distribution on the upper and lower sides of the deck. For trans-critical flows and submergence ratio h^* = 2.0, the downward flow above the deck produced positive pressures on the upper side of the deck and subsequently generated a large negative lift force on the deck.

ABSTRACT: In the paper, by secondary development of commercial computational fluid dynamics software FLUENT, establish two-dimensional bending and torsional fluid-structure interaction numerical model to calculate flutter critical wind speed of Great Belt East Bridge and Tacoma Narrows Bridge.According to time histories of vertical displacements and torsional displacements, we can judge flutter critical wind speed and flutter modality. The numerical results show:when the wind speed is more than 63m/s, Coupled vertical-torsional flutter is found in Great Belt East suspension bridge; When the wind speed is more than 8m/s, Torsional dominated flutter is found in Tacoma Narrow Bridge. Critical wind speed of flutter by numerical simulation is in agreement with wind tunnel test.At the same time, this paper uses numerical wind tunnel technique displays the vortex drift along the beam, reveals the interaction between the main beam and vortex motion is one of the reasons leading to divergent vibration.

KEYWORDS: fluid-structure interaction,divergent vibration,vortices movement bending-torsional coupled flutter,torsional dominated flutter,critical flutter wind speed

1 INTRODUCTION

Flutter is a complex physical phenomenon,It is basically divided into two categories in term of aerodynamic.There is no flow separation phenomenon in streamlined profile object, such as aircraft wings in small angle of attack.When flutter happen at the situation we call it classical flutter.It is first flutter.Second flutter is related with the flow separation and vortex formation. It is likely to occur in the lifting surface in large angle of attack or no streamlined profile building structures.It is called stall flutter.

Bridge flutter is a divergent self-excited vibration, which can potentially result in catastrophic failure of a structure.It is mainly due to vibration of the structure can absorb the energy in the flow air and the energy is greater than energy dissipation of the structural damping in the vibration.There are two types of flutter phenomena in bridge structure: One is bending-torsional coupled flutter another is separated flow flutter. Bending and torsion coupled flutter is generally occurs in the streamlined beam.The majority of bridge deck is non-streamlined. Flow separation phenomenon occur at the corners of the deck where vortex shedding is generated, then single degree of freedom of torsional flutter is likely to occur. It is separated flow flutter.

In the paper,by secondary development of commercial computational fluid dynamics software FLUENT, establish two-dimensional bending and torsional fluid-structure interaction numerical model to calculate flutter critical wind speed of Great Belt East Bridge and Tacoma Narrows Bridge. According to time histories of vertical displacements and torsional displacements, we can judge flutter critical wind speed and flutter modality.It is critical flutter wind speed when the main beam start divergence vibration under a certain wind speed.

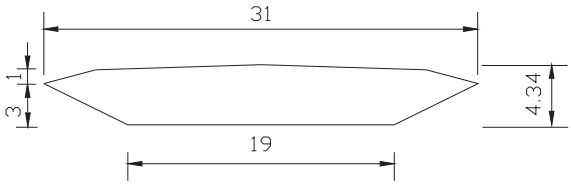
2 NUMERICAL SIMULATION

2.1 Great Belt East Bridge and Tacoma Narrows Bridge

As shown in Figure 1.,Figure 2. and Figure 3., Great Belt East Bridge has a main span of 1624m. The semi-streamlined steel box deck is 31m wide and 4.34m high. Tacoma Narrows Bridge was constructed as a 1660 meter long suspension bridge with a main span of 853 meters, the third longest suspension bridge in the world at that time.The bridge deck was 11.9 meter wide, supported by two 2.45 meter deep plate girders(I-girders).At November morning 7 in 1940,A wind of 16-19m/s was blowing,The segments of the span were heaving periodically up and down in fifth antisymmetric vertical mode as much as 0.9m for about 3 hours, with oscillation frequency of 0.6-0.63Hz.At 10 clock in morning,one middle girder suspender root breaking,suddenly antisymmetric vertical vibration change into the antisymmetric torsional vibration, frequency is 0.23Hz,soon after,change to 0.2Hz, amplitude is bigger and bigger (approximately 8 meters),until the deck began to sway with an amplitude of about 45 degree, suspenders break,bridge deck steel fracture and ruined, falling to the valley[1][2].

Figure 1. Great Belt East Bridge [1]

Figure 2. Tacoma Narrows Bridge[2]



(1) Great Belt East Bridge

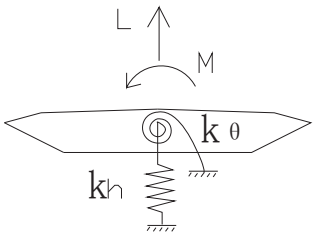
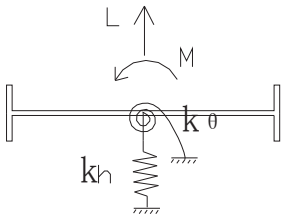
Figure 3. Girder Cross-sections(m)

2.2 Numerical simulation principle

The structure is regarded as mass, spring and damping system.Schematic diagram of numerical simulation is shown in Figure 4.The governing structural equation for the one-degree-of-freedom heaving mode and torsional mode is shown as (1),(2).



(1) Great Belt East Bridge



(2) Tacoma Narrows Bridge

Figure 4. Schematic diagram of numerical simulation

$$m\ddot{y} + c_h\dot{y} + k_h y = F_h \quad (1)$$

$$I_\theta\ddot{\theta} + c_\theta\dot{\theta} + k_\theta\theta = M_\theta \quad (2)$$

Where m is the mass per unit length of the body, I_θ is the mass moment of inertia. k_h is the translational spring stiffness, k_θ is the rotational spring stiffness. c_h and c_θ is the structural damping coefficients. F_h and M_θ is the fluid forces. y denotes the transverse location of the centre of the body and θ denotes the rotational angle of the body around elastic centre.The governing equations of the incompressible flow is the continuity equation and the Navier-Stokes equations as (3),(4).

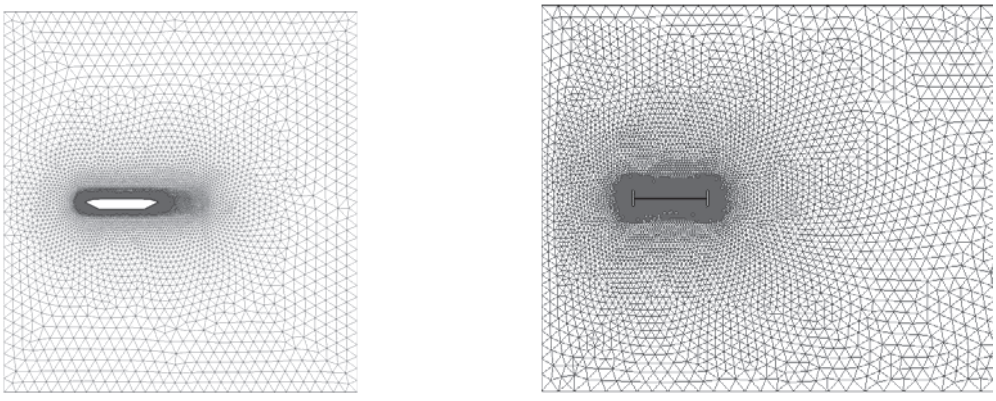
$$\nabla\cdot\vec{V} = 0 \quad (3)$$

$$\frac{\partial\vec{V}}{\partial t} + (\vec{V}\cdot\nabla)\vec{V} = -\frac{1}{\rho}\nabla p + \mu\nabla^2\vec{V} \quad (4)$$

Where ρ is the density of the fluid. $\vec{V}, p, t$ denote the velocity vector,pressure,time respectively[3].

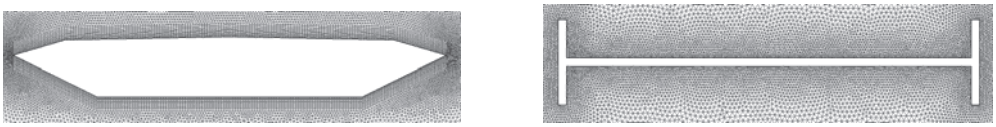
Solve equation (3),(4),obtain pressure and velocity around object,calculate aerodynamic force acting on the object. This can be done by FLUENT. Then extract lift and moment into vibration equation (1) (2) and solve the vibration equation by Newmark method.The velocity is assigned to the object and simulate object move by FLUENT dynamic mesh technique. This can be done by secondary development of FLUENT which program code is embedded to the FLUENT by user defined function(UDF).

2.3 Numerical simulation model



(1) Great Belt East Bridge (2) Tacoma Narrows Bridge

Figure 5. Whole mesh



(1) Great Belt East Bridge (2) Tacoma Narrows Bridge

Figure 6. Local mesh

Computational grid is shown in Figure 5. and Figure 6..The flow runs from the left to the right.The inflow boundary is specified with the inflow velocity. On the right exit boundary,it is specified with free flow.The upper and lower borders is specified with the wall. The no-slip boundary condition is employed on the body surface. Fine grid is created near the body and the grid becomes gradually coarser in the far field. Navier-Stokes equations are solved by using finite volume method,second-order upwind difference form and SMPLEC algorithm. RNG turbulence model is used in Great Belt East Bridge and the LES turbulence model is used in Tacoma Narrows Bridge. Properties of the suspension Bridge is shown in Table 1.

Table 1. Properties of the suspension Bridge [3][4]

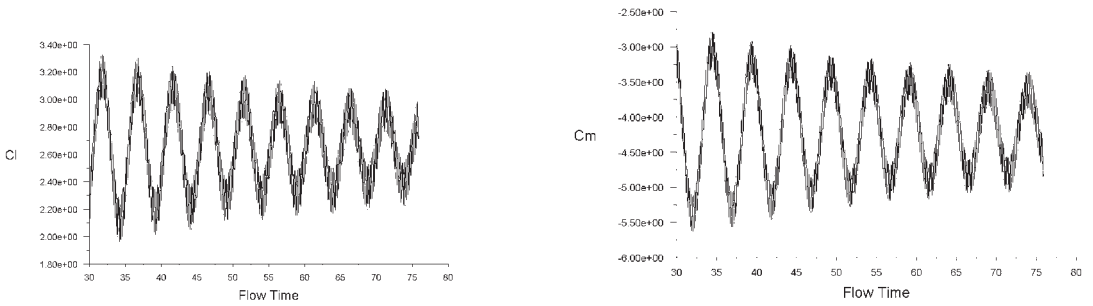
parameters	unit	Great Belt East Bridge	Tacoma Narrows Bridge
Mass per unit length	kg/m	23687	4250
Mass moment of inertia	kgm/m	$2.501x10^6$	177730
Natural vertical frequency	Hz	0.097	0.13
Natural torsional frequency	Hz	0.27	0.2
vertical damping ratio		/	0.005
Torsional damping ratio		/	0.005

The vertical damping ratio and torsional damping ratio of Great Belt East Bridge are $1.59x10^{-3}$ and $3.18x10^{-4}$ respectively in the paper.

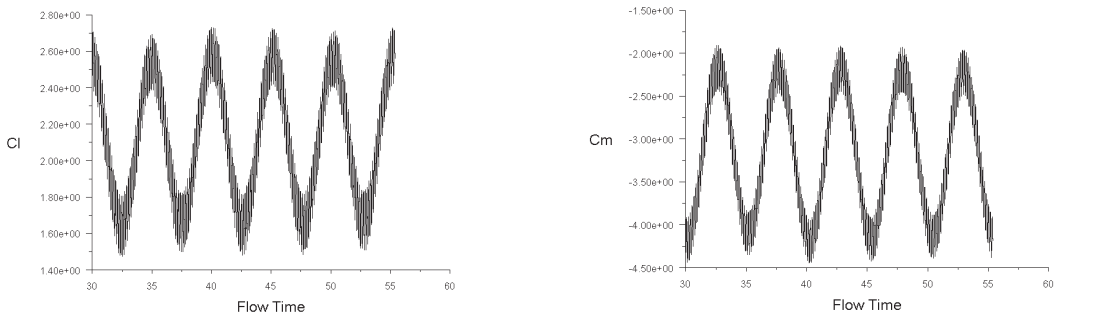
3 NUMERICAL SIMULATION RESULTS

3.1 The Great Belt East Bridge

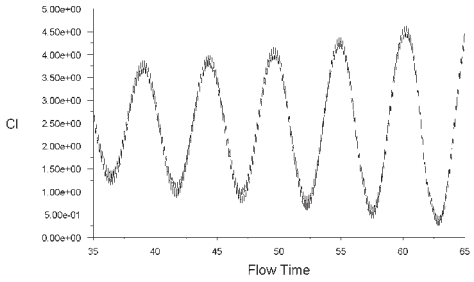
3.1.1.Time histories of Lift coefficient and moment coefficient

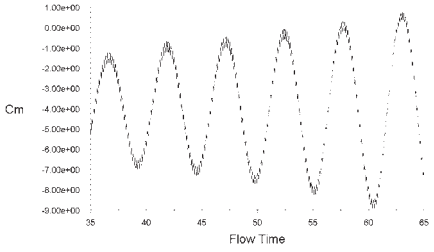


（1）v=60m/s



（2）v=63m/s





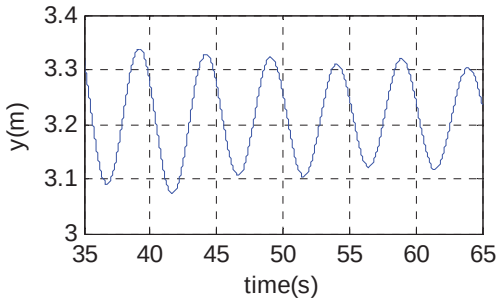
（3） v =65m/s

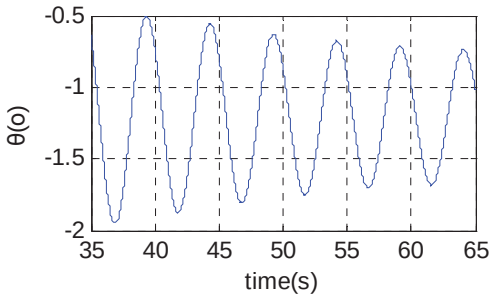
Figure 7. Time histories of Lift coefficient

Figure 8.Time histories of moment coefficient

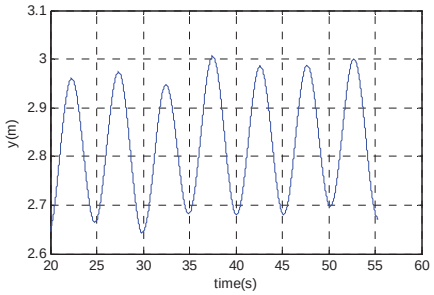
As shown in Figure 7. and Figure 8.,We can see the force acting on the deck at different wind speed.When the wind speed is 60m/s,The force acting on the deck gradually decreased. When the wind speed is 63m/s,The force acting on the deck remain almost same. When the wind speed is 65m/s,The force acting on the deck gradually increased.

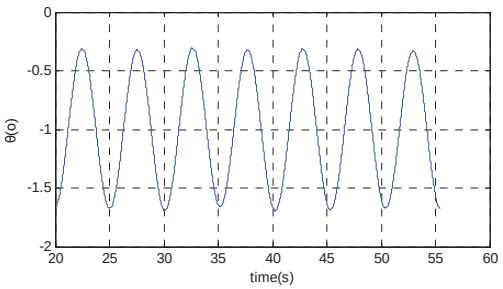
3.1.2 Time histories of displacements



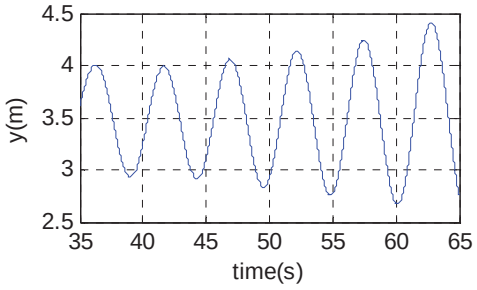


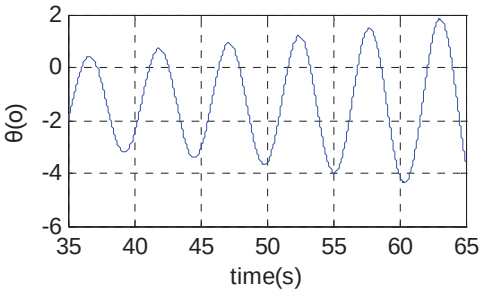
v=60m/s





v=63m/s





v=65m/s

Figure 9.Time histories of vertical displacements

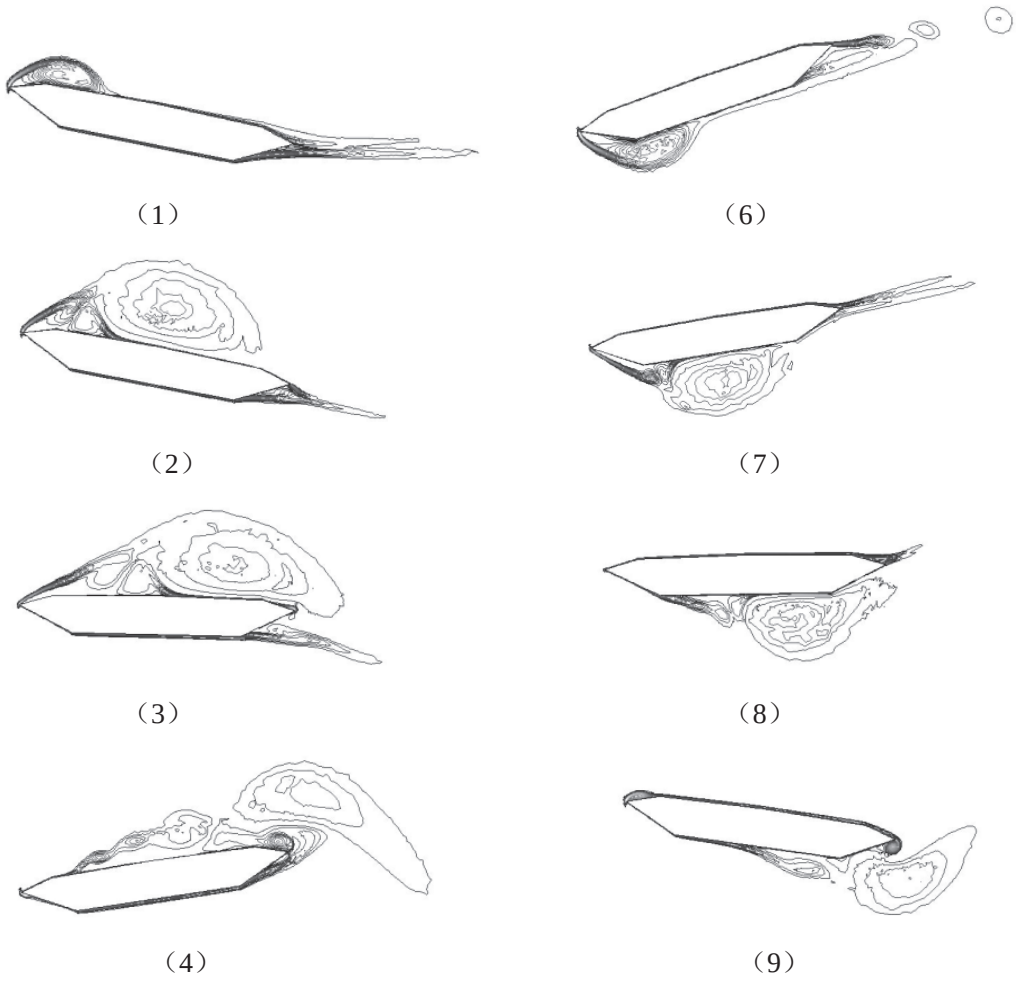
Figure 10.Time histories of torsional displacements

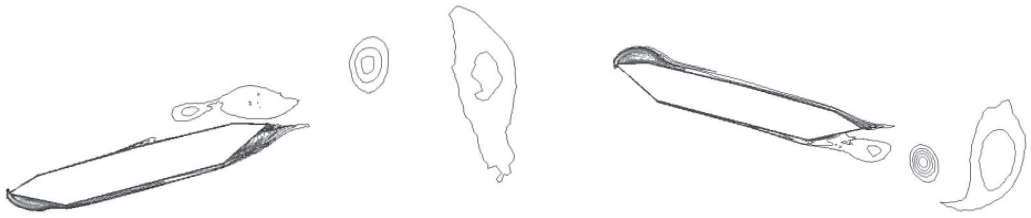
Figure 9.and Figure 10. show the displacements change of deck at different wind speed.When the wind speed is 60m/s , vertical and torsional displacements gradually decreased.When the wind speed is 63m/s ,vertical and torsional displacements remain almost same.When the wind speed is 65m/s, vertical and torsional displacements gradually increased. Divergent coupling vibration between vertical-bending model and torsional mode of deck is found when the wind speed is over 63m/s. Vertical vibration frequency and the torsional vibration frequency are about 0.2Hz,which is between the vertical and torsional natural frequencies. As shown in Table2.,Critical wind speed of flutter by numerical simulation is in agreement with wind tunnel testing.

Table 2. Critical wind speed of flutter[3]

source	critical wind speed of flutter（m/s）
wind tunnel testing (section model)	74
numerical simulation	63—65

3.1.3. Contours of vorticity magnitude at different times





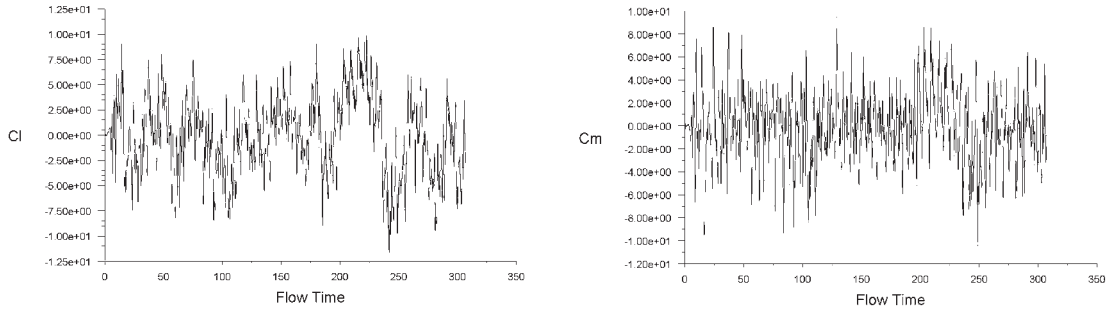
（5） （10）

Figure 11. Contours of vorticity magnitude at different times

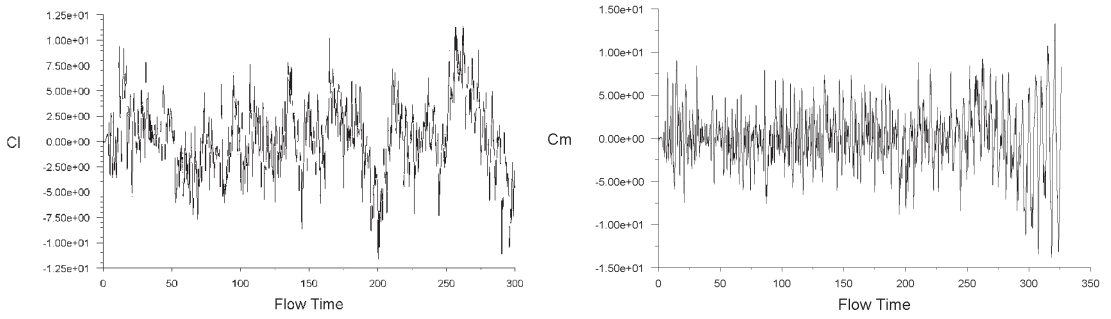
As illustrated in Figure 11., we can see the movement of object is driven by vortex. Rotate clockwise and drift along the lower part of the main beam,main beam rotate counterclockwise,vortex rotate counterclockwise and drift along the upper part of the main beam,main beam clockwise torsion.The interaction between the main beam and vortex motion lead to divergent vibration.

3.2 Tacoma Narrows Bridge

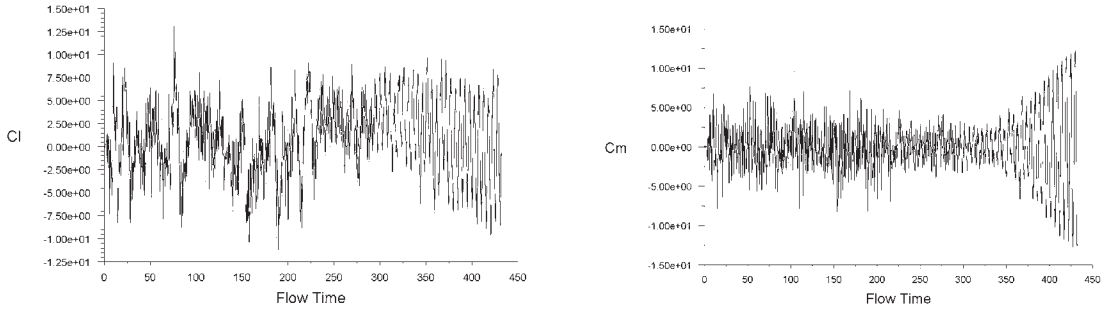
3.2.1 Time histories of Lift coefficient and moment coefficient



（1）v =8m/s



（2） v =10m/s

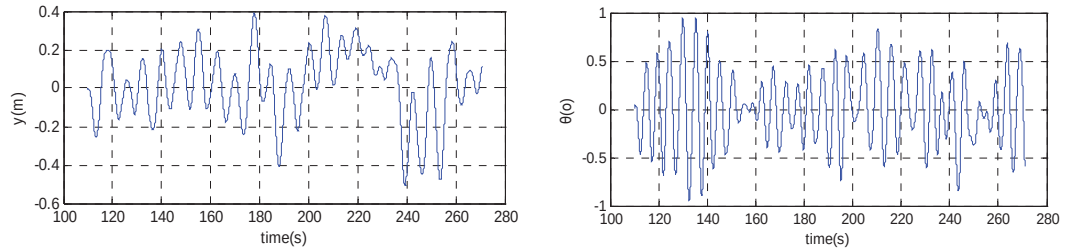


（3）v =12m/s

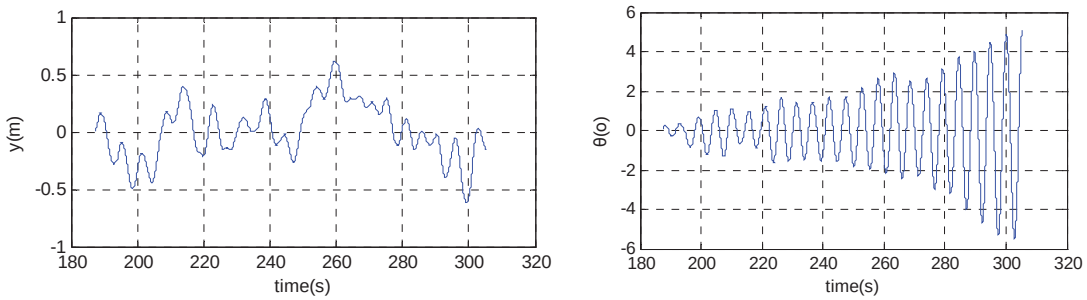
Figure 12. Time histories of Lift coefficient Figure 13.Time histories of moment coefficient

As shown in Figure 12. and Figure 13.,We can see the force acting on the deck at different wind speed.When the wind speed is 8m/s,The force acting on the deck remain almost same.When the wind speed is 10m/s or 12m/s,The force acting on the deck gradually increased.

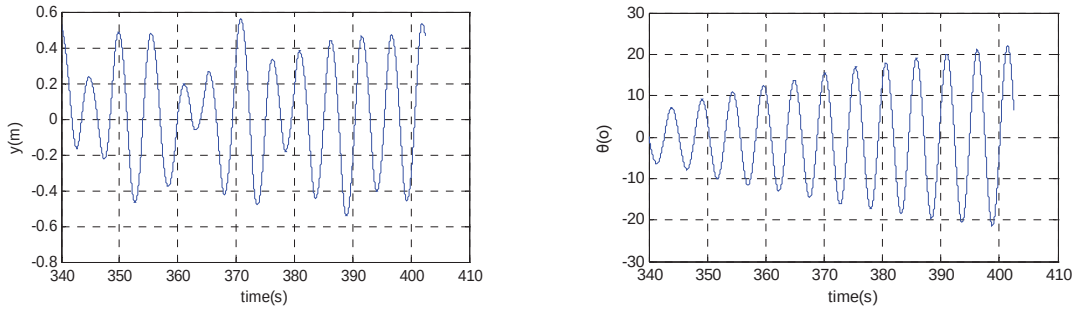
3.2.2 Time histories of displacements



（1） v =8m/s



（2） v =10m/s



（3）v =12m/s

Figure 14.Time histories of vertical displacements Figure 15.Time histories of torsional displacements

Figure 14. and Figure 15. shows the beam displacement under different wind speeds. When the wind speed is 8m/s, vibration is limit, vertical displacement does not exceed 0.4m, torsional angles degree is less than 1 degrees; When the wind speed is 10m/s, The maximum vertical displacement is 0.4m, The maximum torsion angle is above 5 degree and increases with time; When the wind speed is 12m/s, torsional vibration divergence is evident. the oscillation frequency is 0.2Hz, the same as torsional frequency of the structure. As Table 3. shows,Critical wind speed of flutter by numerical simulation is in agreement with wind tunnel test.

Table 3. Critical wind speed of flutter(m/s) [4]

result	Tacoma Narrow Bridge
wind tunnel test	11.5
numerical simulation	8—10

3.2.3. Contours of vorticity magnitude at different times

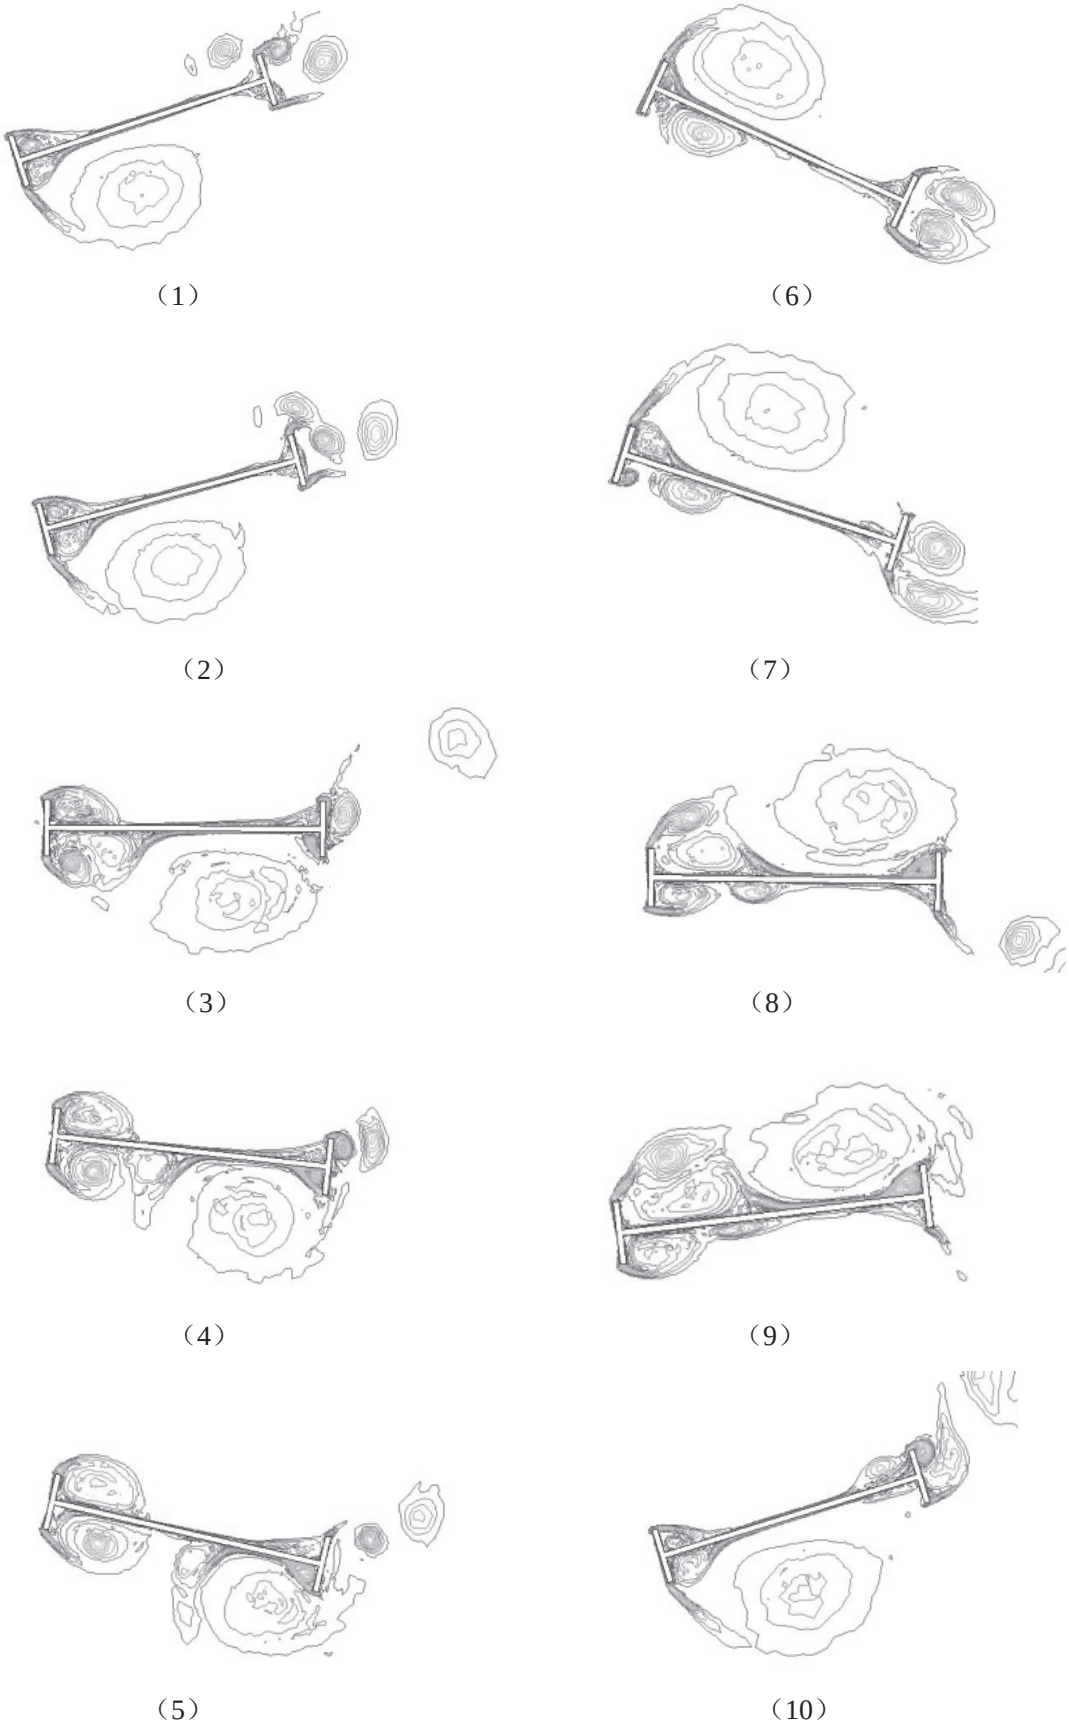


Figure 16. Contours of vorticity magnitude at different times

As illustrated in Figure 16., it is noted that H shaped section movement is drive by vortex. Vortex is generated by upstream end and continuous development, movement, The vortex experienced a complete cycle from developing, moving and ultimately shedding. Actions on structures also completed a cycle of evolution. If we effectively prevent the large-scale vortex formation, twisting instability can be controlled in a certain extent. Tacoma bridge girder design is obvious defect: width span ratio of the stiffening beam is small, torsional rigidity is weak, On both sides there is windtight bluff body longeron, It is easy to cause the aeroelastic instability.So we might increase the cross-sectional size to get sufficient torsional rigidity and adopts a streamline cross section shape and ventilated structure to prevent large vortex formation.

4 CONCLUSION

By numerical simulation analysis can we get the following conclusions:

(1) Critical flutter wind speed by numerical simulation is in agreement with wind tunnel test.

(2) Bending-torsional coupled flutter is found in Great Belt East suspension bridge. Flutter frequency is between the vertical natural frequency and torsional natural frequency of structure. Torsional domined flutter is found in Tacoma Narrow Bridge. Flutter frequency is the same as torsional natural frequency of structure.

(3) The interaction between the main beam and vortex motion is one of the reasons leading to divergent vibration.

ABSTRACT: A direct simulation method for flutter stability of bridge deck was developed based on CFD software Fluent. Flutter stability of two representative sections, rectangular section and streamlined section, was simulated by using this method. The validity of the simulation method was verified by comparison of simulation result and wind tunnel test result.

KEYWORDS: Bridge Deck Flutter Stability Direct Simulation

1 INTRODUCTION

Bridges become more and more flexible with the increase of span. Wind–resistant design of bridge becomes more and more important. Flutter is a kind of divergent vibration style which may occur for long-span flexible bridges. The flutter of bridge decks can be classified into two categories. One is single-degree torsional flutter which may occur for bridge decks with sharp angles. The other is bending-torsional coupled flutter which may occur for bridges with streamlined decks. Flutter may destroy bridge. Therefore, it is very necessary to ensure that the flutter critical wind speed is higher than flutter checking wind speed in design stage of long-span bridges. At present, there are two main simulation methods for flutter stability of bridge deck. One is based on flutter derivatives which are gotten by simulated forced motion of bridge deck. The flutter critical wind speed of bridge deck is calculated by using the flutter derivatives. The other one is direct simulation method. The vibration displacements of bridge deck in different wind speed are simulated. The flutter critical wind speed of bridge deck is gotten by checking vibration displacements. In the past, researches paid more attention to the first simulation method [1-7], while less attention to on direct simulation method [8-9]. The study on direct simulation method is almost based on self-written program which is short of applicability.

In recent years, with rapid development of computer technique, some universal CFD software, such as Fluent, CFX, and so on, were adopted by bridge design organization because of good interface, convenient pre-processor and post-processor, open secondary developing function and so on. It is meaningful to perform direct simulation of flutter stability based on these universal CFD software to evaluate the flutter critical wind speed of the bridge deck in preliminary design stage. In present paper, a direct simulation method for flutter stability of bridge deck was developed based on CFD software Fluent. Flutter stability of two representative sections, rectangular section and streamlined section, was simulated by using this method. The validity of the simulation method was verified by comparison of simulation result and wind tunnel test result.

2. DIRECT SIMULATION METHOD

First of all, the bridge deck is simplified to bending-torsional two degree spring-mass-damping system. The dynamic equation is as follows:

$$m\ddot{h}(t)+c_h\dot{h}(t)+k_h h(t)=L(t) \qquad I\ddot{\alpha}(t)+c_\alpha\dot{\alpha}(t)+k_\alpha\alpha(t)=M(t) \tag{1}$$

where $\ddot{h}(t)$, $\dot{h}(t)$ and $h(t)$ are instantaneous bending acceleration, bending velocity and bending displacement; $\ddot{\alpha}(t)$, $\dot{\alpha}(t)$ and $\alpha(t)$ are instantaneous torsional acceleration, torsional velocity and torsional displacement; $L(t)$ and $M(t)$ are instantaneous lift force and torque on bridge deck.

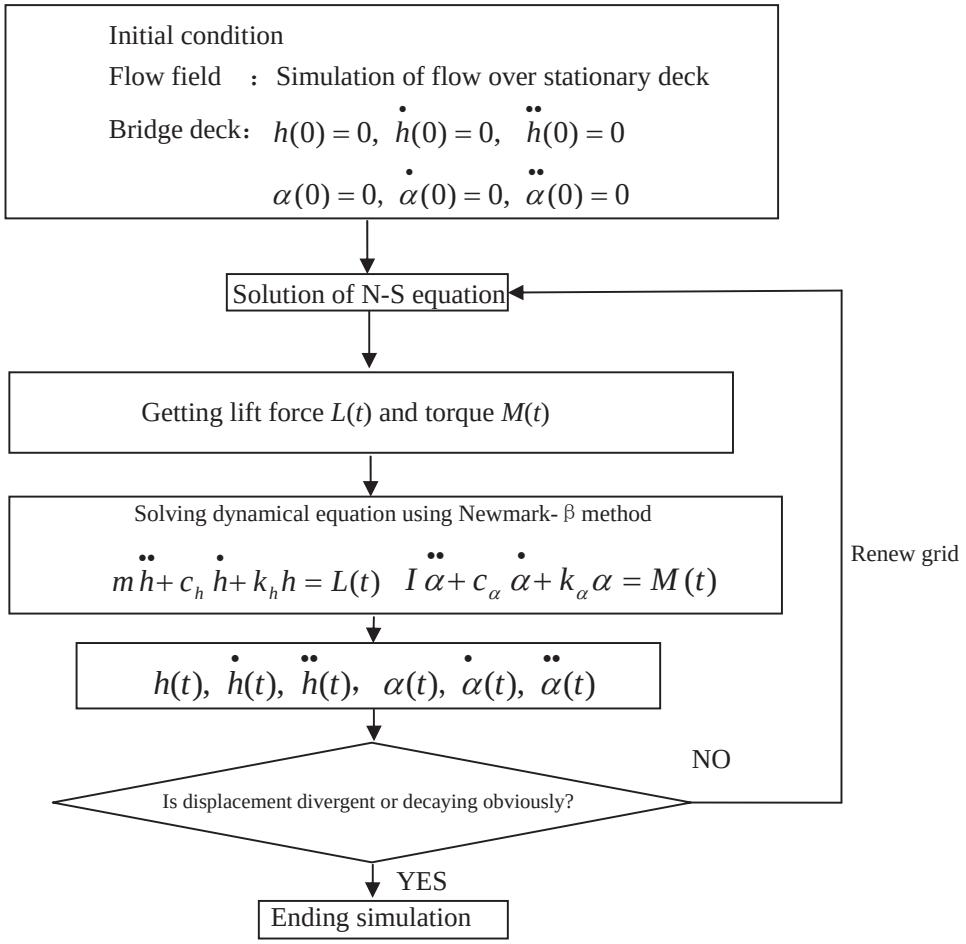

Figure 1 Procedure of direct simulation in every wind speed

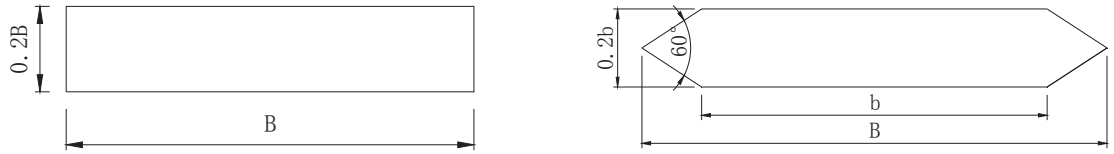
The bridge deck vibration displacements under several wind speeds need to be calculated in direct simulation method. In order to improve efficiency, the flutter critical wind speed can be estimated through Wind–resistant Design Specification for Bridge at first. Then the direct

simulation can be carried out around the estimated wind speed. The procedure of direct simulation in every wind speed is shown in Figure 1. Firstly, flow around static bridge deck is performed. When the flow is stable, the bending degree and torsional degree are unrestricted. Before first calculating time step, the preliminary value of bending acceleration, bending velocity, bending displacement, torsional acceleration, torsional velocity and torsional displacement are set to zero. For every time step, the fluid control equation, Navier-Stocks equation is solved and the lift force and torque on the bridge deck is gotten, then the bending and torsional displacements can be obtained by solving equation (1) using *Newmark-β* method. Simulation in given wind speed ends if the displacement divergent or decaying obviously.

3. SIMULATION MODEL

In present paper, flutter stability of two representative sections, rectangular section and streamlined section, was simulated. The dimensions of these two representative sections are shown in Figure 2. The width and height of rectangular section are 30cm and 6cm. The width and height of streamlined section are 40.392cm and 6cm. The numerical simulation region and boundary condition are shown in Figure 3. The simulation region is two dimensional rectangular region. The distance between inlet and middle point of simulation region is 10times the width of section. The distance between outlet and middle point of simulation region is 20 times the width of section. The distance between top wall and bottom wall is 20 times the width of section The boundary conditions are set as follows: velocity inlet boundary condition for inlet; outflow outlet boundary condition for outlet; free-slip wall boundary condition for top and bottom wall; no-slip wall boundary condition for surface of deck section.



(a) rectangular section (b) streamlined section

Figure 2 Dimension of two representative sections

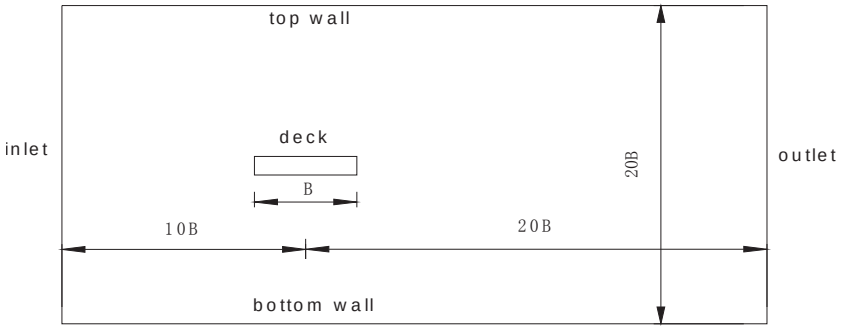


Figure 3 Numerical simulation region and boundary condition

Figure 4 and Figure 5 shows numerical grid of the two sections. Rigid mesh grid is used in inner region. Stationary mesh grid is used in outer region. Between the rigid mesh grid and stationary mesh grid is dynamic mesh grid. The width and height of rigid mesh are about two times and one time the width of section, respectively. Both the width and height of dynamic mesh grid are about six times the width of section. When deck section vibrates, the rigid mesh grid follows the deck section synchronously; the static grid keeps stationary; the shape and dimension of dynamic mesh changes constantly. The number of mesh grid for rectangular section and streamlined section are about 76800 and 62300, respectively. In region which is far away the section, the size of mesh grid is big comparatively. In region which is near the section, the size of mesh grid is small comparatively.

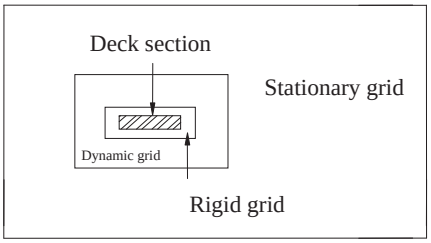

Figure 4 illustration of numerical grid division

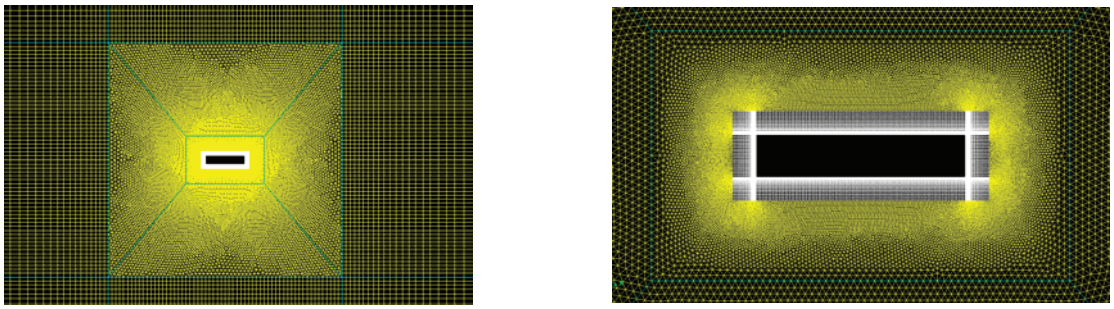
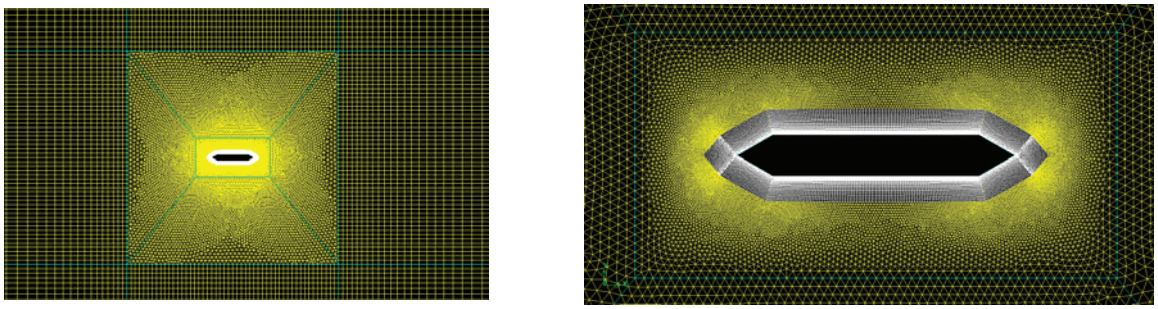


(a) rectangular section

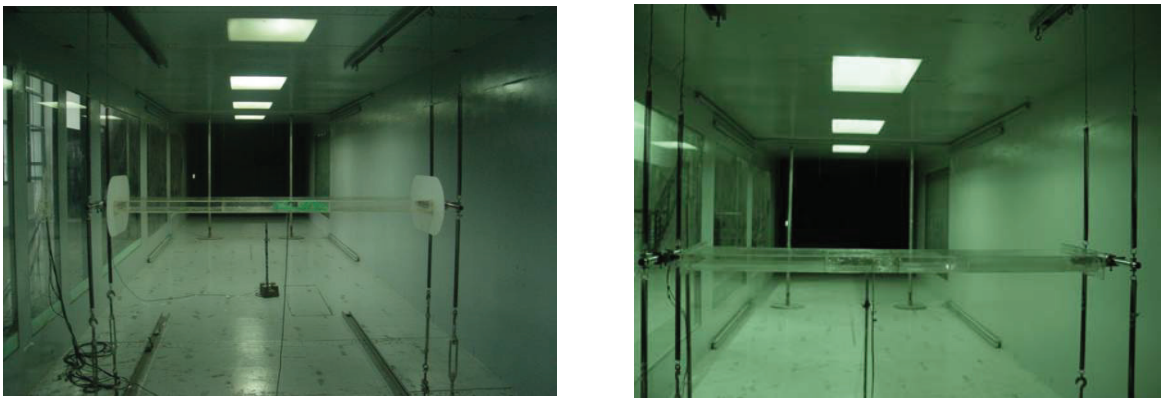


(b) streamlined section

Figure 5 Numerical grid of two representative sections

In order to validate the direct simulation result, wind tunnel tests were performed to measure the flutter stability of these two sections. The photos of wind tunnel tests are shown in Figure 6. The length of sectional model is 1.5 meter. The test parameters, including model mass, mass moment of inertia, bending vibration frequency, torsional vibration frequency and damping ratio, are

listed in Table 1. The direct numerical simulation parameters are in accordance with wind tunnel test parameters. The only difference is that the mass and mass moment of inertia per unit length are used in direct numerical simulation.



(a) rectangular section (b) streamlined section

Figure 6 Photo of wind tunnel test

Table 1 Parameters of wind tunnel test

section type	m(kg)	I(kg m^2)	f_h (Hz)	f_α (Hz)	ξ_h	ξ_α

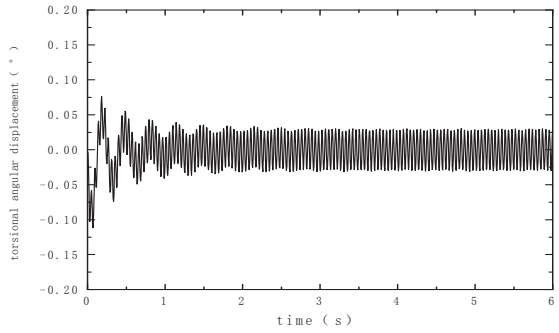
streamlined section	13.38	0.1505	2.54	5.27	0.3%	0.3%

4 SIMULATION RESULT

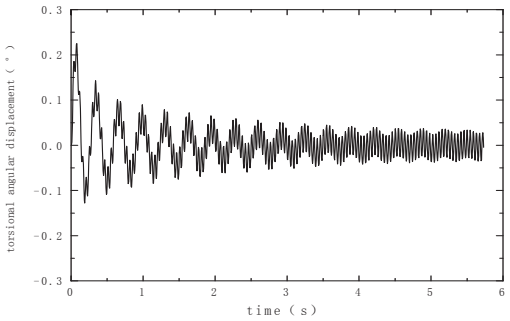
Figure 7 and Figure 8 show curves of torsional angular displacement versus time history of streamlined section and rectangular section, respectively. Figure 9 shows amplitude spectrum of curves of torsional angular displacement versus time history. In these figures, the reduced wind speed is defined as follows:

$$V_r = \frac{U}{f_t B} \tag{2}$$

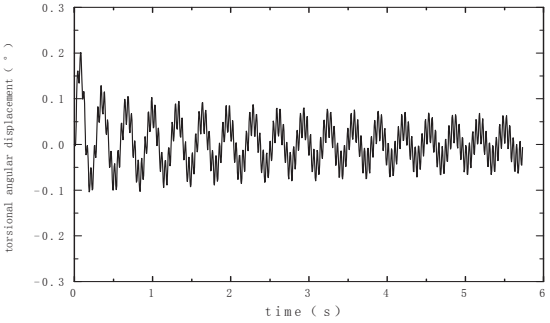
Where U is incoming wind speed, ft is torsional vibration frequency of model, B is width of model.



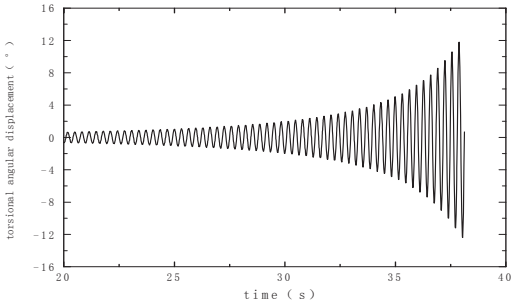
(a) Vr=10.80



(b) Vr=11.27

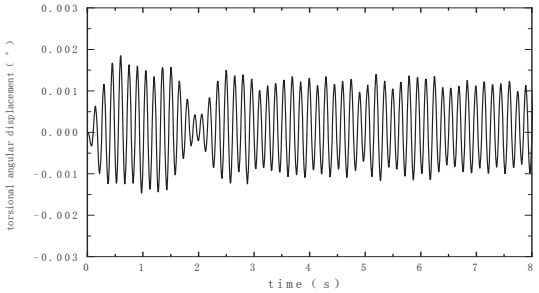


(c) Vr=11.51

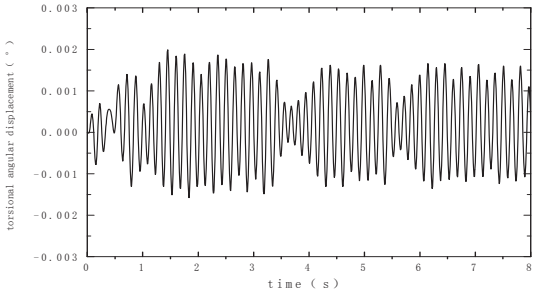


(d) Vr=11.74

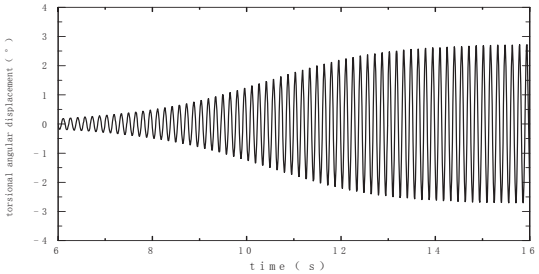
Figure 7 Curves of torsional angular displacement versus time history of streamlined section



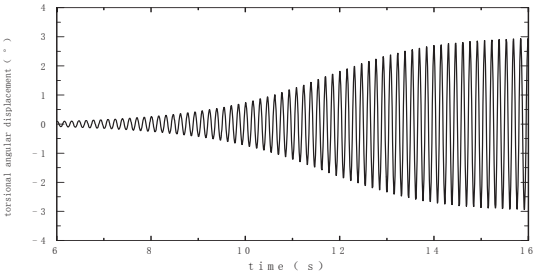
(a) Vr=3.29



(b) Vr=3.77

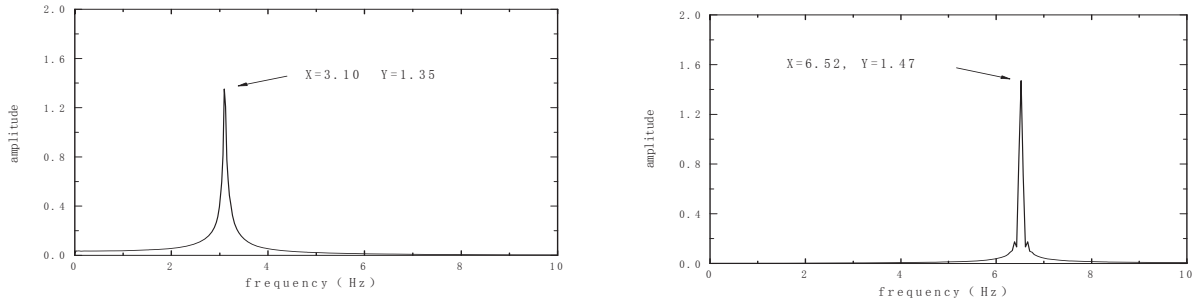


(c) Vr=4.00



(d) Vr=4.24

Figure 8 Curves of torsional angular displacement versus time history of rectangular section



(a) Streamlined section Vr=11.74 (b) rectangular section Vr=4.0

Figure 9 Amplitude spectrum of curves of torsional angular displacement versus time history

From Figure7 and Figure 9(a), it can be seen that: (1) when reduced wind speed is less than11.51, torsional angular displacement of streamlined section is decreasing with increase of time. This illustrates that the total damping of model is positive. (2)When reduced wind speed is less than11.51, with increase of reduced wind speed, torsional angular displacement of streamlined section is decreasing slowly. This suggests that although the total damping of model is positive, the absolute value of total damping becomes small with increase of reduced wind speed. (3)When reduced wind speed reaches to 11.74, torsional angular displacement of streamlined section is increasing with the increase of time. This illustrates that the total damping of model changes from positive to negative. Flutter critical wind speed is around 11.74. (4) When flutter occurs, the torsional vibration frequency is 3.10Hz. This frequency is between natural bending vibration frequency and torsional vibration frequency. This suggests that flutter style for streamlined section is bending-torsional coupled flutter.
